Equations (4) and (6) provide a system of $n + 1$ equations in the $n + 1$ unknowns λ, q_1, $q_2, \ldots, q_n$, and the knowns $I, p_1, p_2, \ldots, p_n$, $x_{11}, x_{12}, \ldots, x_{nm+n}$. Solving these equations provides the maximizing values of λ and of consumption, say, λ^*, q_{1*}, $q_{2*}, \ldots, q_{n*}$. The effect of change in price p_s upon q_{r*} is given by the well-known expression $\partial q_{r*}/\partial p_s = -q_s \cdot \partial q_r/\partial I + S_{sr}$, where S_{sr} = the Slutsky-Hicks-Allen substitution term. Assume the producer of product u makes a small change in x_{uv}, while all other x_{ij}'s, all prices, and income remain constant.[1] By differentiating equations (4) and (6) with respect to x_{uv}, and manipulating, one obtains

$$(9) \quad \partial q_{r*}/\partial x_{uv} = -(1/\lambda^*) \sum_{i=1}^{n} (\partial U_i/\partial x_{uv}) S_{ir},$$

where $U_i = \partial U/\partial q_i$. The change in q_{r*} resulting from a change in composition of product u depends upon the effects of the change in

[1] Product u is a slightly different product after this change from what it was before the change. Before the change, the quantities of characteristics per unit of product u were $x_{u1}, x_{u2}, \ldots, x_{uv-1}, x_{uv}, x_{uv+1}, \ldots, x_{um}$. Afterwards, they are $x_{u1}, x_{u2}, \ldots, x_{uv-1}, x_{uv} + dx_{uv}, x_{uv+1}, \ldots, x_{um}$.

composition upon marginal utilities and upon substitution terms. Thus, the change in demand for product r as x_{ur} changes depends upon product r's complementarity or substitutability with other goods. Hence, the consumer's purchases of product r can vary even though his income and product prices remain constant, provided that producers vary at least one consumption input-output coefficient.

Assume that $\partial U_u/\partial x_{uv} > 0$ but $\partial U_i/\partial x_{uv} = 0$ for $i \neq u$, i.e., increasing the amount of characteristic v in product u increases the marginal utility of product u but leaves other marginal utilities unaffected. Then, from equation (9),

$$(10) \quad \partial q_{r*}/\partial x_{uv} = (-1/\lambda^*)(\partial U_u/\partial x_{uv})S_{ur}.$$

If products u and r are substitutes ($S_{ur} > 0$), increasing the value of x_{uv} reduces the demand for product r. If the two products are complements ($S_{ur} < 0$), increasing x_{uv} increases the demand for product r. Setting $r = u$ in equation (10) yields

$$(11) \quad \partial q_{u*}/\partial x_{uv} = (-1/\lambda^*)(\partial U_u/\partial x_{uv})S_{uu} > 0.$$

Equations (9), (10), and (11) provide the hypothesis stated in theme 2.

Comparison with Lancaster's Analysis

Recently Lancaster used the product characteristics concept in his activity analysis of consumer behavior. He formulated the consumers' utility maximization problem as (p. 21)

$$(12) \quad \max\ U(X) \text{ subject to } P'Q \leq I, \quad BQ = X, X \geq 0, \text{and } Q \geq 0.$$

X is a vector of quantities of characteristics, Q and P are vectors of quantities and prices of products, and B is the consumption technology matrix of input-output coefficients. The ith row of $BQ = X$ can be written as

$$(13) \quad \sum_j b_{ij}q_j = x_{0i},$$

where b_{ij} = the quantity of the ith characteristic in one unit of product j, and q_j and x_{0i} are as defined previously in CGCM. The rules for deriving the dual to this problem are discussed by various writers, among whom are Sengupta and Fox. Applying these rules leads to n dual constraints (one for each product) of the form

$$(14) \quad p_j \geq \sum_i b_{ij}z_i \text{ for } z_i \text{ unrestricted in sign.}$$

This corresponds closely to equation (8), since b_{ij} corresponds to $\partial x_{0i}/\partial q_j$ and z_i corresponds to the marginal implicit price of characteristic i. Lancaster did not derive equation (14) from his general activity analysis model. But he did derive equation (14) from a special expenditure minimizing linear program.

Others who have used the product characteristics concept without, however, developing themes 1 and 2 are Theil and the workers in the hedonic price index area (see Griliches, Adelman and Griliches, Dhrymes). These writers use the utility function equation (3). They are prevented from deriving themes 1 and 2 by their assumption that the magnitudes of the x_{ij}'s and the q_i's are determined by the consumer. The x_{ij}'s are treated here as parameters to the consumer and variables to producers. The consumer can decide how much of product i to buy; he cannot however decide the amount of each characteristic to be contained in or provided by one unit of product i.

Three reviews of Lancaster's model have recently been published (Hendler, Lucas, Ratchford). Lucas questions Lancaster's assumption of a linear consumption technology, equation (13). This criticism does not apply to CGCM; compare equation (13) with equation (1). Hendler discusses limitations arising from Lancaster's assumption that marginal utilities of all characteristics are nonnegative. We do not make this assumption; any $\partial U/\partial x_{0j}$'s in equation (6) may be negative. Both Lucas and Hendler seriously question Lancaster's assumption that utility depends only upon total quantities of characteristics and not upon their distribution among commodities. This criticism does apply to CGCM. Themes 1 and 2 can be derived from a variation of CGCM to which none of these three criticisms apply. Define t_{ij} as the total quantity of characteristic j obtained from total consumption of product i. Then $x_{0j} = \sum_i t_{ij}$. In this variation of CGCM, the arguments of the utility function are the variables x_{0j}'s and the ratios x_{0j}/t_{ij}'s. But since the x_{0j}'s are functions of the t_{ij}'s, the utility function can be expressed simply as a function of the t_{ij}'s. The statement of theme 1 derived from this model is exactly like equation (8) except that t_{ij} replaces x_{0j}. The statement of theme 2 is exactly like equation (9).

Empirical Tests

Equation (8) provides the hypothesis that for each product purchased by the consumer, the

price he pays can be expressed as the sum of the products of marginal yields of characteristics and ratios of marginal utilities. We have called these latter ratios marginal implicit prices. All of the data seen on yields of product characteristics are consistent with the assumption that $\partial x_{0j}/\partial q_i = x_{ij}$ = constant. Assuming this and assuming $\partial E/\partial x_{0j} = E_j$ = constant, equation (8) can be written as

$$(15) \qquad p_i = \sum_j x_{ij}E_j + E_{m+i}.$$

Regressing product prices upon product characteristics (as measured by x_{ij}) provides a test of the hypothesis that p_i is linearly related to the x_{ij}'s. If $\partial E/\partial x_{0j}$ is not believed constant, one might use

$$(16) \qquad p_i = \sum_j x_{ij}\beta_j + \sum_j x_{ij}^2 \beta_{jj},$$

and determine marginal implicit price, say, for characteristic h, as $\partial E/\partial x_{0h} = E_h = \beta_h + \beta_{hh}x_{ih}$. Hedonic price workers generally have used logarithmic equations ($p_i = \pi_j x_{ij}^{\beta_j}$) or semilogarithmic equations ($p_i = \exp(\Sigma x_{ij}\beta_j)$) to relate product prices to product characteristics. Neither of these forms is consistent with equation (8); they cannot be interpreted as relating product price to the sum of the products of marginal yields of characteristics and marginal implicit prices.

Dhrymes applies equation (15) to U.S. automobile prices. He found that a large proportion of the variance in U.S. automobile prices could be explained by a linear combination of automobile length, width, brake horsepower, number of cylinders, number of doors, and presence or absence of automatic transmission and power steering. Cowling and Cubbin found that a large proportion of variance in U.K. automobile prices could be explained by a linear combination of automobile characteristics.

Waugh (1928, 1929) estimated relations between wholesale prices of fresh vegetables and their characteristics. He collected data on wholesale prices and characteristics of individual lots of asparagus, tomatoes, and cucumbers. He regressed the ratio of the price of each lot to the average price of the product on measures of product characteristics and converted the regression coefficients into prices of product characteristics. For example, from his analysis of prices of asparagus, he concluded that (*a*) each additional inch of green color per stalk added 38.45¢ to the price of one dozen standard bunches, (*b*) each additional stalk per bunch reduced price by 4.6¢, and (*c*) each additional percentage variation in size of stalk decreased price by 0.76¢ per dozen standard bunches.[2] For asparagus and tomatoes he used a linear equation, like equation (15). For cucumbers, he used a nonlinear relation, like equation (16).

In these studies, the values of the x_{ij}'s were fairly easily determined, either by inspection or by studying manufacturer's specifications. We performed a more rigorous test of equation (8), more rigorous because the characteristics are not easily identified and measured. The linear form was used to relate annual average retail prices of thirty-one different meat, dairy, and poultry items to amounts of various nutritional elements they provided per pound.

Table 1 lists the thirty-one food items. Their national annual average retail prices per pound for 1969 and 1970 were obtained from U.S. Bureau of Labor Statistics reports. Amounts of sixteen different nutritional elements per pound of each food were obtained from Watt and Merrill. These sixteen elements and their units of measurement are identified in table 2.

Suppose that one's sample contains one observation on each of n products and these products contain m common characteristics, that is, each of the m common characteristics is possessed by two or more of the n products. Then it is not possible to estimate a separate price for each common characteristic and each product's unique characteristic because the number of coefficients to be estimated exceeds the number of observations. The number of observations is n but the number of coefficients is $n + m$, m coefficients for the prices of common characteristics plus n coefficients for the prices of unique characteristics. To handle this degrees-of-freedom problem, we imposed restrictions on the prices of unique characteristics. First, the prices of unique characteristics are assumed to be the same for every product. With the requirement that $E_{m+i} = E_{17}$ for all i, the following equation was estimated:

$$(17) \qquad p_i = \sum_{j=1}^{16} x_{ij}E_j + E_{17} + \epsilon_i \qquad \text{for } i = 1, 2, \ldots, 31.$$

In this form several pairs of the independent variables were highly intercorrelated. After eliminating one variable of each of these pairs

[2] Although equation (8) refers to retail prices and Waugh studied wholesale prices, his results are consistent with theme 1 because wholesale and retail prices are highly positively correlated.

Table 1. Thirty-one Food Items Used in Estimation

Item i
1. Round steak
2. Sirloin steak
3. Porterhouse steak
4. Boneless rump roast
5. Rib roast
6. Chuck roast

18. Canned ham
19. Bologna sausage
20. Salami sausage
21. Liver sausage
22. Frying chicken
23. Chicken breasts
24. Eggs
25. Grocery fresh milk
26. Delivery fresh milk
27. Skim fresh milk
28. Evaporated milk
29. Ice cream
30. American process cheese
31. Butter

and eliminating other variables with small t-ratios, the results in the second and third columns of table 3 are obtained.

Next, the price of uniqueness was assumed to be a function of raw material source and the following equation was estimated:

$$(18) \qquad p_i = \sum_j x_{ij} E_j + E_i + \epsilon_i,$$

where $E_i = E_B$ for food items 1 through 8, beef; $E_i = E_V$ for item 9, veal cutlets; $E_i = E_H$ for items 10 through 15, pork; $E_i = E_L$ for item 16, lamb chops; $E_i = E_{PM}$ for items 17 through 21, processed meats; $E_i = E_P$ for items 22 through 24, poultry products; and $E_i = E_D$ for items 25 through 31, dairy products. Analysis of variance indicated that many of these E_i were not significantly different from each other.

Finally, the products whose prices of uniqueness were not significantly different from each other were grouped together, and the following equation was estimated:

$$(19) \qquad p_i = \sum_j x_{ij} E_j + E_i + \epsilon_i,$$

where $E_i = E_{18}$ for all items except veal cutlets and lamb chops, $E_i = E_{25}$ for veal cutlets, and $E_i = E_{32}$ for lamb chops. These results are presented in table 3. Equation (19) yielded a significantly larger value of R^2 than did equation (17) or (18). All three equations yielded significant values of R^2. Thus, all are consistent with theme 1. Results in table 3 were obtained by pooling data for 1969 and 1970 because results of an F-test for equality of two sets of coefficients did not reject the hypothesis that the coefficients were equal in the two years.

We interpret $\hat{E}_j$ in table 3 as estimated implicit prices paid by consumers in 1969–70 for the nutritional elements identified in the first column. For example, $j = 2$ identifies food energy measured in calories; $\hat{E}_2 = 0.026$ in equation (19) indicates the estimated implicit price of food energy was 0.026¢ per calorie. Suppose there was some cut of beef that was like sirloin except that it contained one hundred more calories of food energy and ten more grams of protein per pound. Equation (19) predicts that the price of this cut of beef would have been 19¢ per pound higher than the price of sirloin in 1969–70: 0.026(100) + 1.666(10) = 19.26.

Dhrymes and Cowling and Cubbin obtained negative coefficients for some automobile characteristics. Waugh obtained negative coefficients for some vegetable characteristics (1928, 1929); as mentioned earlier, he found a negative marginal implicit price of 4.6¢ for number of stalks per bunch. Negative marginal implicit prices are consistent with CGCM

Table 2. Nutritional welements and Their Units of Measurement

Nutritional Element j	Nutritional Element	Unit of Measurement of Nutritional Element (per pound)
1	Water	%

32	—	—	67.270	3.246	¢/lb.
R^2	0.624		0.853		

[a] $\hat{E}_j$ is the estimate of E_j. Equation (19) has fifty degrees of freedom. For fifty degrees of freedom, critical levels of absolute values of t-ratios are 2.678 at 1% level, 2.008 at 5%, 1.658 at 10%, 1.300 at 20%, and 0.681 at 50%.

[b] Dash indicates not estimated.

and with observation. Some product characteristics are undesirable. Adding more of one of these characteristics to a product reduces its value to consumers. We do not know why $\hat{E}_8$ and $\hat{E}_{16}$, the marginal implicit prices for phosphorous and ascorbic acid, are negative. Two hypothetical explanations are (*a*) phosphorous and ascorbic acid impart an unpleasant taste, texture, or odor and (*b*) they are proxies for some characteristic that degrades taste, texture, or odor.

These four statistical studies are the only ones we know of that bear on theme 1. The results of all four are consistent with the theme.

The multiple regression method used in these studies is not the only available method for estimating prices of nutritional elements. The shadow prices in duals of programming models of human diets also provide estimates of implicit prices of nutritional elements (see Smith 1959, 1963 for discussion).

Equation (9) presents the hypothesis that consumer demand for a product is related to the characteristics of the product as well as to prices and income. Four studies have tested this hypothesis; all have confirmed it. In a study of demand for beer, Stone tested and accepted the hypothesis that ". . . if stronger, and to that extent better, beer is obtainable at a given price, then more beer will be drunk" (p. 180). Brems found that the ratio between registrations of new Fords and new Chevrolets was significantly positively related to the ratio of their brake horsepower. The Cowling and Cubbin study of the U.K. automobile market found automobile demand to be related to automobile characteristics. Harrington and Gislason found that retail sales of peaches were affected by peach color, retail sales of apricots were affected by color, defects, and hardness, and retail cherry sales were affected by ripeness of cherries. All four studies are consistent with theme 2.

Summary and Conclusions

The first theme of this paper is that for each product consumed, the price paid for the product equals the sum of the marginal monetary values of the product's characteristics. The marginal monetary value of each characteristic equals the product's marginal yield of the characteristic multiplied by the marginal implicit price of the characteristic. This theme is derived in three different ways: from Lancaster's analysis, in CGCM, whose assumptions are less restrictive than Lancaster's, and in a third model whose assumptions are less restrictive than those of CGCM. Results of all relevant statistical analyses are consistent with the theme. One practical use of this theme is in use of marginal implicit prices to evaluate grading schemes for consumer products. Ladd and Martin used a model similar to

CGCM to evaluate the present U.S. corn grading system.

The second theme of this paper is that consumer demands are affected by characteristics of goods. This theme was derived from CGCM and from another model. Results of statistical studies are consistent with this theme. One practical application of this theme is in product design. If the relation of consumer's purchases to product characteristics is known, a product can be designed to maximize profit by determining how much of each characteristic to put into the product. Dorfman and Steiner analyze the problem of optimal product design for a product having one variable characteristic. Ladd and Martin analyze the problem for a product having several variable characteristics.

CGCM has implications for the definition and measurement of product quality. It leads to the same conclusion that Southworth presented when he wrote, "Webster's first definition of 'quality' makes it synonymous with 'characteristic.' Quality meaning 'superior quality' is a derived or secondary meaning. Quality, then, need not be ordinal—good, better, best. It may only be different" (p. 1385).

Consideration of CGCM leads naturally to the idea that we measure a product's characteristics in order to measure its quality. In doing this we replace the idea of "product quality" by "product qualities" and measure "qualities" by measuring characteristics. This recognizes that it may not be possible to rank two similar products according to their quality. It may be that product A is of higher quality than product B according to one characteristic but of lower quality according to a second characteristic. Then all we can say is that A and B are of different quality.

The Value of Frost Forecasting: A Bayesian Appraisal

A. E. Baquet, A. N. Halter, and Frank S. Conklin

The economic value of frost forecasts is estimated under various assumptions concerning prior information, accuracy of forecasts, and the shape of the orchard operator's utility functions. The frost protection decision process is simulated in the context of Bayesian decision making under uncertainty. The averaged seasonal values estimated per day per acre were \$5.39 for frost forecasts provided by the U.S. Weather Service, \$8.57 for perfect frost forecasts, \$4.73 for profit maximizers, and \$191.39 for completely ignorant decision makers. The methodology used has general application to determination of economic value of information under conditions of uncertainty.

Key words: Bayes, decision making, frost forecasts, information value, risk, uncertainty, weather.

Orchard production is highly vulnerable to weather effects, particularly from frost damage during a six-week period of flowering and bud development. From mid-March to mid-May, nighttime temperatures in Jackson County, Oregon, are likely to fall low enough to cause frost damage in pear orchards. The specific temperatures below which frost damage will occur depend upon several factors, including the development stage of the blossom from which fruit emerges (Washington State University).

Each afternoon during a frost season a temperature forecast is given by a meteorologist employed by the U.S. Weather Service, who lives in Jackson County for a two-month period during the frost season. The forecast is first issued at 4:00 p.m. over local radio and television stations. Temperature and dewpoint prognostications are given, along with a subjective prediction whether or not heater firing will be needed that night.[1] A revised forecast is given later in the evening. A telephone service is provided also, whereby the orchardists may call an unlisted number to receive the latest weather forecast directly from the meteorologist. The orchardists are faced with the decision of whether or not to protect their orchards each night during the frost season. Each orchardist may then use the forecast that has been given, along with his own feelings as to the accuracy of the forecast, any other information available, and his own attitude toward uncertainty in deciding whether or not to protect the orchard. If an orchardist has decided that protection will be needed, then how much protection he uses is determined for the most part by how much the forecasted temperature is below the critical temperature and the type of mechanical protection used by the orchardist. In Jackson County the major protection scheme involves orchard heaters (Bates, Lombard). Heaters will raise the orchard temperature 4° to 5° when approximately thirty-five are used per acre. Thus, if the temperature is forecasted to be 2° below the critical temperature, the orchardist may decide to light only half his heaters.

Although frost protection is but one phase of an orchard management process, the decisions made relative to it have a direct and significant economic effect on orchard production since, if the crop is lost to frost, the decisions pertinent to orchard operation for the rest of the season may have limited or no effect on current year production. Thus, fore-

Conklin is an associate professor of agricultural and resource economics at Oregon State University, Corvallis.

Oregon Agricultural Experiment Station Technical Paper No. 4197.

[1] Dewpoint influences the specific value of the critical temperature. Dewpoint is the temperature level below which moisture held in suspension in the air condenses in the form of dew or frost. When the dewpoint is above 32°, the moisture condenses to form dew and provides some protection against frost. Because there is no unanimity among orchardists as to the role the dewpoint plays in determining the specific value of the critical temperature, it was not included in this study.

cast information appears to have considerable economic value to orchardists. The funding of the forecasting services provided by the U.S. Weather Service is a continuing problem for this agency. The economic value of this information can have much to do with the level of funding, yet little effort has been expended on determining this value (Byerlee, Lave, Thompson). It is the intent of this paper to provide estimates of the economic value of frost forecast information under various assumptions concerning prior information, accuracy of the forecasts, and the shape of operator's utility functions. This paper views the frost protection decision process in the context of Bayesian decision making under uncertainty (Baquet, Byerlee, Byerlee and Anderson, Dillon, Halter and Dean).

Model for Evaluating Frost Forecast Information

A diagram of the simulation model used in evaluating frost forecast information is shown in figure 1. There are three major components shown in the diagram to be discussed in turn. These are the nightly frost protection decision, the simulated nightly weather conditions, and the accounting that determines the value of the frost forecast for that night.

Nightly Frost Protection Decision

The frost protection decision covers the center of the diagram from the monetary payoff table to the frost protection level. The payoff table shows the possible monetary gains from various frost protection actions (number of heaters lighted) for each possible state of nature (θ_k, where $k = 1, \ldots, 16$ temperatures from 21° to 35° and over). The payoff values are developed from expected values of the crop and harvest savings. The expected values of the crop are determined by the expected price and yield as well as the bud loss.

A utility function estimated for the individual orchardist is used to convert the dollar payoff table to the utility payoff table. This table is then multiplied by the posterior probabilities, $P(\theta_k|Z_j)$, to give the utility of actions given the forecast (Z_j, where $j = 1, \ldots, 16$). From this posterior utility table, the optimal action for each forecast is obtained, this action being the one with the highest utility for that forecast. The optimization is carried out using Bernoulli's principle to obtain the optimal action A^{**}_{ij}, or Bayes's strategy (Baquet, Bernoulli, Dillon):

$$(1) \qquad U(A^{**}_{ij}) = \max_i \ U(A_i|Z_j) = \max_i \ [\sum_k U(a_k)P(\theta_k|Z_j)],$$

where $U(A^{**}_{ij})$ = the utility value of the optimal action for each forecast (Z_j), A_i = the set of alternative actions, $i = 1, \ldots, m$, Z_j = the set of forecasts, $U(a_k)$ = the utility of the dollar payoff from an action for each state of nature k, and $P(\theta_k|Z_j)$ = the posterior probability of a state θ_k and a forecast Z_j, $k = 1, \ldots, 16$, and $j = 1, \ldots, 16$. After the forecast is given, the optimal action for that forecast from the Bayes strategy defines the level of frost protection to be followed, which together with the simulated temperature determines the bud loss for that night and so on.

Actual Nightly Temperature

Simulated temperatures for a particular night are determined by a random process described by the posterior distribution $P(\theta_k|Z_j)$; that is, a temperature is drawn at random from a probability distribution of the states of nature (θ_k) given for each forecast (Z_j).

Value of Frost Forecast

The third component of the diagram is the determination of the value of the forecast. In utility terms, this is the difference between the expected utility of the optimal action if one did not have the forecast and the expected utility of the optimal action with the forecast. While one can obtain this utility value $U(Z_j)$ for a forecast after it is given, of greater interest here is the $U(Z_j)$ value for the entire set of forecasts or in other words the value of the service itself for the entire frost season. In general, the $U(Z_j)$ is still the difference between the utility of the set of optimal actions given the forecasts, but the analysis is carried out before the forecast is given. Using available literature, let us develop this concept further (Baquet, Byerlee, Dillon, Halter and Dean, Harvey).

Suppose a choice has to be made between a set of actions, $A_1, A_2, \ldots, A_m$, where the ith action (A_i) has a set of uncertain consequences, $[a_k]$. Which a_k occurs depends on the state of nature that occurs. The states of na-

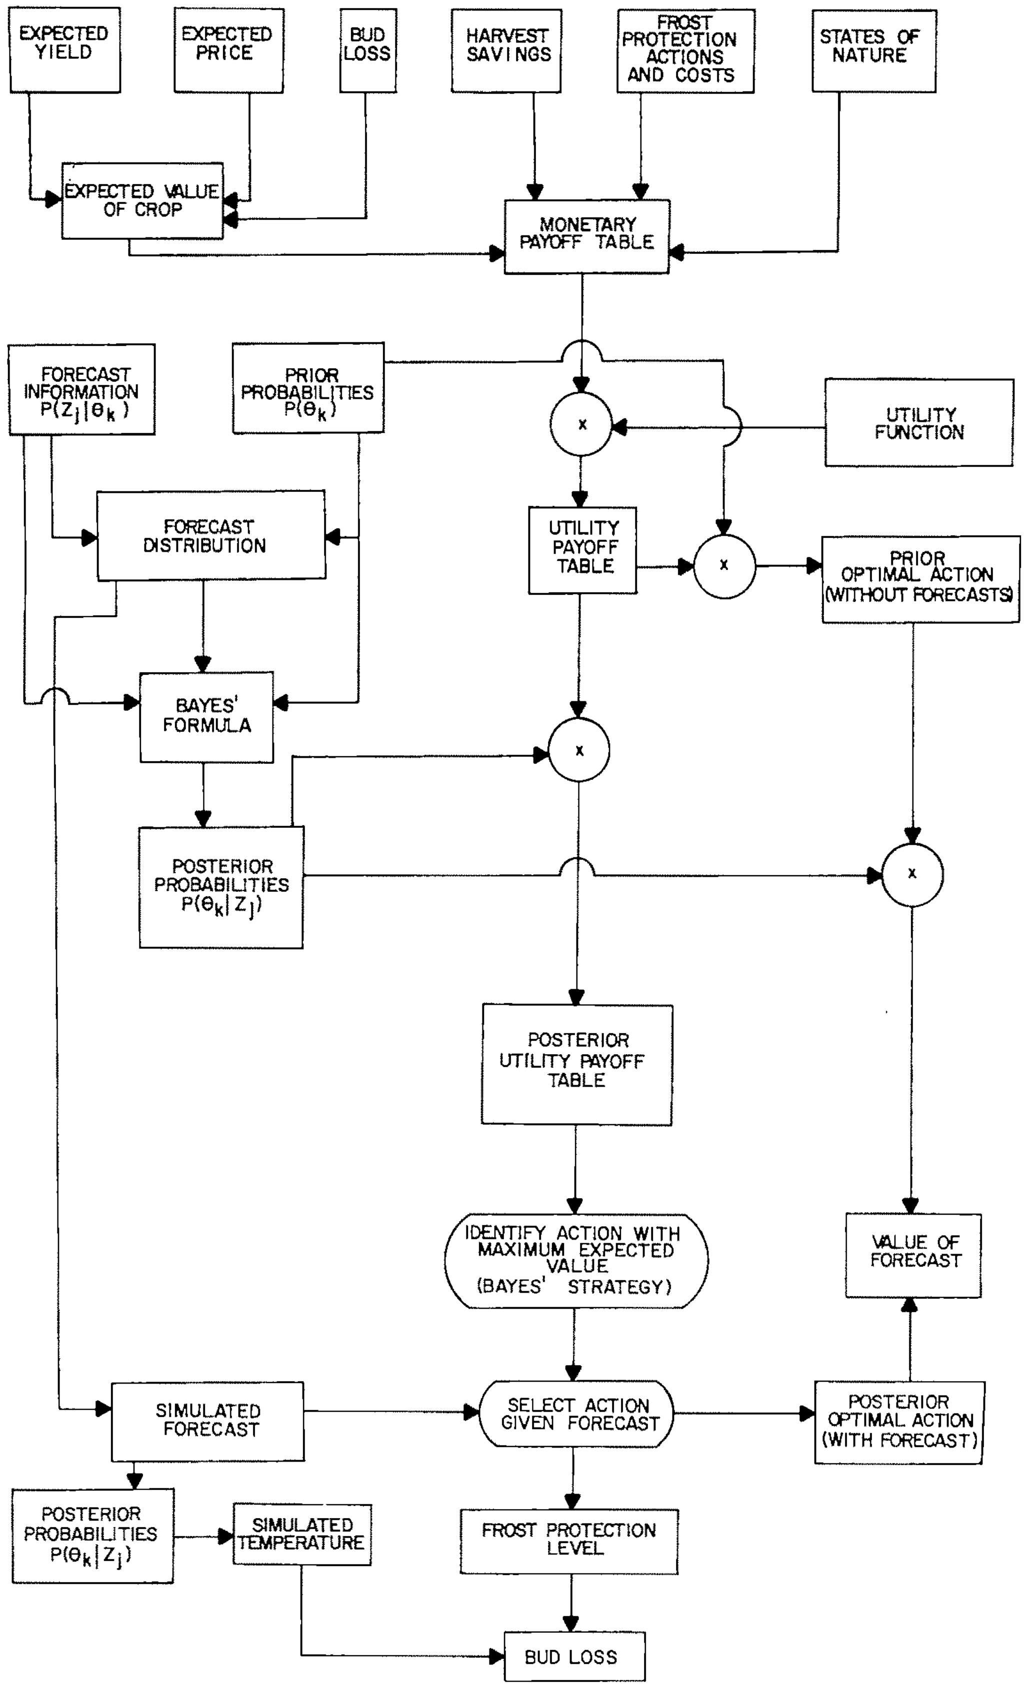

Figure 1. Flow diagram of simulation model used in the valuation of frost forecast information

ture follow the probability distribution $P(\theta_k)$. Thus, the uncertain consequences also follow the probability distribution $P(\theta_k)$. The consequence of a_k of A_i is a random variable, and a particular consequence a_k has a utility $U(a_k)$. In the case given here, the set of consequences $[a_k]$ are specified as gains or returns from the orchard's expected production potential.[2]

The expected utility of the ith action is

$$(2) \qquad U(A_i) = \sum_k U(a_k)P(\theta_k),$$

and the optimal action A^*_i is the one with the highest utility. The decision procedure, then, is to choose the action that has the maximum utility. This can be represented mathematically as

$$(3) \qquad U(A^*_i) = \max_i \ U(A_i) = \max_i \ [\sum_k U(a_k)P(\theta_k)].$$

A^*_i is the prior optimal action (without forecast) in figure 1.

Assume that a particular piece of information (Z_j) relative to the occurrence of state of nature (θ_k) is available to the decision maker at a cost of C. Given that the decision maker has knowledge about the conditional distribution of Z_j relative to $\theta_k(P(Z_j|\theta_k))$, Bayes's formula allows for revision of the prior probability distribution of $\theta_k(P(\theta_k))$ to obtain the posterior probability distribution $P(\theta_k|Z_j)$:

$$(4) \qquad P(\theta_k|Z_j) = \frac{P(\theta_k)P(Z_j|\theta_k)}{P(Z_j)},$$

where $P(Z_j) = \sum_k P(\theta_k)P(Z_j|\theta_k)$. This sequence of calculations is shown in the left upper center portion of figure 1. This posterior probability distribution was used in finding the Bayes strategy in the decision sequence described above.

We let A^{**}_{ij} ($i = 1, 2, \ldots, m$ actions, and $j = 1, 2, \ldots, n$ states) represent the optimal action for the jth forecast (Z_j). The Bayes strategy may be specified by the n-element vector:

$$(5) \quad \{A^{**}_{ij}\} = (A^{**}_{i1}, A^{**}_{i2}, \ldots, A^{**}_{ij}, \ldots, A^{**}_{in}).$$

The probability that each of these actions will be followed is the probability that the forecast Z_j will be given, i.e., $P(Z_j)$. The utility of the Bayes strategy $(U(\{A^{**}_{ij}\}))$ can be calculated as

$$(6) \qquad U(\{A^{**}_{ij}\}) = \sum_j U(A^{**}_{ij})P(Z_j).$$

The value of the set of forecasts in utility terms is

$$(7) \qquad U(\{Z_j\}) = U(\{A^{**}_{ij}\}) - U(A^*_i),$$

that is, the utility of the Bayes strategy minus the utility of the prior optimal act. Written into its component expressions and in terms of money, the utility value of the set of forecasts is given by

$$(8) \quad U(\{Z_j\}) = \sum_j [\sum_k U(a^{**}_k - C)P(\theta_k|Z_j) - \sum_k U(a^*_k)P(\theta_k|Z_j)]P(Z_j),$$

where a^{**}_k = the monetary outcome of the Bayes action, a^*_k = the monetary outcome of the optimal prior action, and C = the monetary cost of the information.

The term in square brackets is the utility value of a particular forecast. The utility value of a possible prediction set $\{Z_j\}$ is equal to the weighted average of the posterior value of the particular predictions, the weighting scheme being $P(Z_j)$. Thus, if

$$(9) \qquad U(\{Z_j\}) = \sum_j U(Z_j)P(Z_j)$$

is positive, the information is worth having. However, this is of little practical use, since decision makers or public agencies cannot transfer utility values in transactions with others. Thus, it is necessary to determine the monetary value of the set of forecasts.

The monetary value of the forecast is the maximum amount of money the decision maker could give up and remain as well off with the forecast as he would have been with just his prior information. In other words, the monetary value is determined by the dollar amount that, when subtracted from each cell of the dollar payoff table and converted to utility, yields the same expected utility as the optimal prior act.

The maximum amount that should be paid

---

[2] Initially, we thought the payoff table should be in terms of dollar values of crop losses. This was based on the notion that before the frost season orchards have the potential for a full crop and then during the frost season some of this potential is lost. We were initially going to use the disutility of these losses. However, orchardists indicated that in regard to frost protection they do not think in terms of what is lost but rather in terms of what is saved, implying that there is only an expected production potential at the beginning of the frost season but that the actual potential develops during this period and whatever portion is saved by frost protection is a gain. Frost protection is viewed as a means for generating a high production potential by the end of the frost season.

by the decision maker is given by the value of C in equation (8) that makes $U(\{Z_j\}) = 0$. When $U(\{Z_j\})$ is equal to 0, the decision maker is as well off with just his prior information as he is with the additional information.

Empirical Data Used in the Application of the Simulation Model

The simulation model of figure 1 requires three types of data to make it operational. These are probability distributions, utility functions, and the monetary payoff tables. The model has been programmed for computer calculation and, given the data, the computer program provides the value of the frost forecasts for the total season and on a per-acre-per-day basis. The expected yields and prices and the utility functions used for this study came from orchardists in the Jackson County pear-growing area of Oregon. The probability distributions were derived from historical weather records for the U.S. Weather Service (U.S. Dep. of Commerce).

Probability Distributions

Temperatures have been recorded at selected unheated orchards during the frost season since 1957. Forecast data for an "average orchard" have also been recorded since 1957. The average orchard was selected for its ability to exhibit temperatures that are similar to the temperatures in the majority of the orchards in the county. Based on historical and current orchard temperature data from the average orchard site, the owner or manager of an orchard is expected to extrapolate the forecasted temperature from the average orchard to the expected temperature in their orchards.

Both the forecasted and recorded temperatures for the average orchard have been used in this study to determine the prior probability distribution $P(\theta_k)$ and the conditional probability distribution $P(Z_j|\theta_k)$ from the sixteen years of data available (Courson and Navarro). The conditional probabilities are given in table 1. There were 925 days covered by the records, of which 420 have recorded temperatures. On the remaining days, both the forecasted and actual temperatures were over 35°. Each cell in table 1 was determined by dividing the number of times a given forecast (Z_j) occurred by the number of times a specific state of nature (θ_k) occurred during the sixteen years of frost season data.

The ability of the forecaster to predict a temperature condition is independent of the absolute value of the actual temperature; thus, the $P(Z_j|\theta_k)$ values of table 1 are not dependent on the week or the month of the frost season when the prediction is made. Consequently, all temperature observations made during each frost season since 1957 are included in

[a] ND represents "No Danger"; all temperatures above 35° are in this category.

deriving the conditional probability values in table 1, irrespective of when they occurred during a particular season.

In table 1 the actual temperatures are the independent variables and the forecasted temperatures are the dependent variables. Thus, the table should be read from top to bottom within a particular column. The blanks within the table indicate that this particular forecast temperature/actual temperature combination never occurred. For example, the (Z_3, θ_2) cell is blank. This means that the actual temperature of 35° was never forecasted incorrectly as 34°.[3]

The probabilities of low nighttime temperatures occurring ($P(\theta_k)$) from the historical records are contained in table 2. Lower temperatures are more probable in March than in May of any given year; thus, these probabilities do depend on the period when they are recorded. To take the seasonal effect into account, it was necessary to divide the frost season into four two-week intervals. This is not to say that individual orchardists do not have other prior information available at the time the frost protection decision is made. The implication is that the historical temperature probabilities provide the minimum level of information available without any nighttime forecasts.

[a] The frost season in Jackson County starts when the earliest pear variety exhibits bud swelling, one of the stages of bud development. Based on the nine years of available data, the average date for this appears to be March 14. The season ends in May after no freezing temperatures are recorded. The average ending date is May 13.

Utility Functions

The second type of data needed for the model are individual orchardists' utility or risk preference functions. With the cooperation of the Jackson County Extension Agents, it was determined that there are approximately 11,500 acres of pear orchards and about 100 pear orchardists in Jackson County. Approximately 90%, or 10,350 acres, are protected by some means. The protected acreage was further subdivided into the portion protected by orchard heaters and the portion protected by some other device. This resulted in a final acreage figure of 9,800 acres heated by orchard heaters and controlled by thirty-six commerical orchardists, leaving 550 acres protected by some other method.[4]

Of the thirty-six commercial orchardists, twenty-six were interviewed to obtain information concerning their orchard operation. Utility functions were derived by the now well known Ramsey method for eight of the twenty-six orchardists interviewed (Baquet; Byerlee; Davidson, Suppes, and Siegel; Dillon; Halter and Dean; Lin, Dean, and Moore; Mosteller and Nogee; Officer and Halter; Ramsey). These eight orchardists (22% of the producers) controlled 5,060 acres, 52% of the heater-protected acres of pears in the county.

Polynomial equations were fitted by ordinary least squares to the data points obtained; the fitted utility functions showed five orchardists with cubic equations and three with quadratic equations. Each orchardist exhibited risk aversity to some degree in the relevant income ranges. Risk aversity depends upon the sign of b in a quadratic utility function of the form $U(x) = x + bx^2$ (Dillon, Pratt). For higher order polynomials, risk aversity may change as the level of expected income changes. Orchardists 3, 5, and 7 had values less than 0, indicating risk aversity. For the remaining orchardists, risk aversity depends upon the level of expected income. From $75,000 to about $500,000, orchardist 6 exhibited risk aversity. This is in contrast to the range from $500,000 to $550,000, where he exhibited risk preference. (For details, see Baquet; Conklin, Halter, and Baquet.)

[3] For use in the simulation model, the distributions in tables 1 and 2 were smoothed to include missing data points (Schlaifer).

[4] A commercial orchardist is defined to be an orchardist who derives his primary source of income from his orchard operation. County agents estimated that twenty-five acres of orchards would be needed to fit this classification.

Monetary Payoff Tables

The third basic input for the model is the payoff table. This table represents the returns for all possible combinations of the states of nature and the actions. Three relevant actions for orchardists in Jackson County are: a_1 = light no heaters, a_2 = light one-half of the total heaters available, and a_3 = light all the heaters available. The states of nature are the possible temperatures that may occur. These correspond to the temperature from 21° to 35°, with all temperatures above 35° being combined into one state of nature. The payoff table is a 3 × 16 array, each element of which must have a dollar value associated with it.

Each cell of the array $(A_i, \theta_k))$ is calculated for each night from the equation (a_i, θ_k) = (expected gross return per acre for the remaining crop − the expected value of crop loss − the cost of protection + the expected harvest savings) × (the number of acres under the orchardist's management).

The expected gross returns per acre for the current crop are determined as the expected price times the expected yield. The expected prices and yields used in the model were based on "normal" year prices and yields obtained in the survey of orchardists.

The expected value of the crop loss is the value of the possible crop loss on a particular night if no frost protection is provided. The amount of crop loss on a given night is a function of the bud loss, and the bud loss in turn is a function of the stage of development and the temperature. The critical temperatures for 10% and 90% kill for pear buds in eight development stages are given in table 3. To provide the entire range of percentage kills from 0 to 100%, a linear interpolation between the 10% and 90% was made. The two points were plotted, a straight line was drawn between them, and approximations were derived from this relationship.

The relationship between bud loss and crop loss is critical in the determination of dollar losses from frost damage in pear orchards. Personal discussion with orchardists indicated that a normal crop can be obtained with as much as a 50% bud loss. A linear crop loss/bud loss relationship was assumed for bud losses greater than 50%, i.e., the equation was crop loss = 2 (bud loss) − 100, for bud loss ≥ 50. The dollar value of the crop loss is determined as the percentage crop loss times the expected gross return per acre.

Table 3. Critical Temperatures for Pear Buds by Development Stages

Bud Development Stage[a]	1	2	3	4	5	6	7	8
Average temperature for 10% kill	15	20	24	25	26	27	28	28
Average temperature for 90% kill	0	6	15	19	22	23	24	24

Source: Washington State University.

[a] The eight development stages are: (*a*) scales separating, (*b*) blossom buds exposed, (*c*) tight cluster, (*d*) first white, (*e*) full white, (*f*) first bloom, (*g*) full bloom, and (*h*) post bloom.

The cost of heating varies between orchardists as well as between the types of heating methods used. The survey data indicated that full protection costs vary from $22 per acre per night to $75 per acre per night, based on five hours average use per night. Action 1 (no protection) has a zero protection cost associated with it. Based on interviews with orchardists, it has been established that action 3, full protection, will increase orchard temperatures 5°, while action 2, half protection, will raise temperatures 3°. These two temperature effects were incorporated in the model to modify bud loss percentages.

If an orchardist loses some or all of his crop during the frost season, he does not incur some of the harvest costs that occur later in the growing season. Based on the survey results it was determined that for an 84% crop loss harvesting expenses would not be reduced but that for crop losses greater than 84% harvesting expenses would be less than 100%. If the crop loss was 100%, there would be no harvesting expenses. These two points were used to develop a linear relationship between crop loss and harvest cost reductions. The value of the harvest cost reduction is determined as a percentage of total estimated harvest expenses. These expenses were determined for each orchardist. The input data for determining the payoff table is summarized for each orchardist in table 4.

Survey results indicate that spraying and pruning expenses must be incurred, even though the current year's crop has been frozen out. The trees still need to be protected from insects and diseases to assure production potential in subsequent years. These costs are viewed as affecting future rather than current year production and so were not included in the payoff table.

Results from Model Application for Eight Orchardists in Jackson County, Oregon

The computer program makes all of the necessary calculations given the input data described above according to the sequence given in figure 1. In order to provide some insight into the contribution of various factors to the value of the frost forecasts, a number of different runs were made with the simulation model, utilizing various assumptions. These assumptions were: (*a*) the orchardist maximized his expected utility and had no prior information at the time of the nightly forecast, i.e., $P(\theta)$ was assumed to be uniform, (*b*) the orchardist maximized his expected utility and used the historical prior probability distribution of table 2, (*c*) the orchardist maximized his expected monetary value and used the historical prior probability distribution, and (*d*) the orchardist maximized his expected utility, used the historical prior probability distribution, and had perfect forecast information, i.e., there are only 1's in the diagonal of table 1.

For each assumption and for each orchardist, fifteen runs of the simulation model were made representing fifteen different random seasons (Conklin, Halter, and Baquet). The value of the forecast information from each run was added and then divided by (*a*) the number of acres, (*b*) the number of days in the season, and (*c*) 15, to provide an average seasonal per-day-per-acre value for each orchardist, as is shown in table 5. Each column of table 5 corresponds to one of the four assumptions made, in their respective order. The rows represent the eight orchardists except the last row, which is the average across the eight orchardists.

The value of $5.39 per day per acre (column 2) represents an upper bound on the value of

Table 5. Value of Frost Forecasts per Day per Acre

Operator Number	No Prior Information and Utility Maximization	Historical Prior Information and Utility Maximization	Historical Prior Information and Profit Maximization	Historical Prior Information, Perfect Forecasts, and Utility Maximization
	$			
1	89.09	2.02	3.05	5.07
2	228.17	5.37	4.27	7.32
3	254.10	8.66	5.92	10.72
4	268.68	4.89	6.71	10.82
5	217.43	4.98	3.97	6.65
6	49.42	0.74	1.50	3.26
7	178.30	11.21	5.74	14.24
8	254.94	5.27	6.66	10.51
Average	191.39	5.39	4.73	8.57

the frost forecasts provided by the U.S. Weather Service, assuming the orchardists used the historical prior information and only the frost forecasts issued by the agency.

The value of $8.57 per day per acre (column 4) represents the value of perfect forecasts, assuming the orchardists used the historical prior information. The difference of $3.18 per day per acre ($8.57 – $5.39) represents the maximum amount that could be expended on improving the U.S. Weather Service frost forecasting services and keep the users of the forecasts at the same level of utility as they would be without the forecast information. These are only the benefits of perfect forecasts and do not imply that the U.S. Weather Service could, or should, provide perfect forecasts for that expenditure.

The value of $4.73 (column 3) per day per acre represents the upper bound on the value of frost forecasts, assuming that the orchardists had linear utility functions or that they maximized expected monetary values. The difference of $0.66 ($5.39 – $4.73) represents the contribution of risk aversity to the value of the forecast information.

The value of $191.39 (column 1) per day per acre represents the value of the frost forecasts if one were completely ignorant of the historical prior probability distribution and used the principle of insufficient reason to justify using a uniform prior distribution. The difference of $186.00 per day per acre ($191.39 – $5.39) represents the value of the historical prior probability distribution in making frost protection decisions in this situation. It is apparent that in a sixty-day frost season the accumulated value of the forecasts, if one were paying for them, would soon exceed the value of the crop (see table 4). Clearly, no orchardist would pay such amounts for the forecast information. Equally clear is the fact that no orchardist is that ignorant of the prior historical probability distributions. If he were, he is no longer in the pear production business. The importance of the prior information in determining the value of the forecasts should also be apparent. Thus, the economic value assigned to frost forecasts is conditional upon the prior information that one has at the time the frost information is used. The values given in column 2 of table 5 are our "best" estimates of the value of frost forecasts in Jackson County, Oregon, provided that one knows only the historical prior probabilities on any night of the frost season.

Conclusions

Springtime frosts in Jackson County can have serious effects upon the bud development of pear orchards. In order to reduce the crop loss resulting from spring frosts, most orchardists in Jackson County employ some type of protection measure. This paper has used a simulation model of the Bayesian decision process to derive dollar values for frost forecasts provided by the U.S. Weather Service.

The value of the forecast derived here is specific to the eight orchardists and their environmental conditions, and extrapolation to all orchardists in Jackson County cannot be made without assumptions regarding the risk philosophies and other input data of the unsampled orchardists. While we conclude that the frost forecast service is of considerable value to the eight orchardists sampled, general recommendations as to appropriate frost protection strategies for all orchardists cannot be made and the value of the forecast for the entire county cannot be determined. However, the methodology used and the decision framework illustrated has general application to other problems wherein the economic value of information is to be evaluated under conditions of uncertainty.

The value of the frost forecast was confined to the within-year period of a sixty-day frost season. Further analysis would be necessary to evaluate the effect from annual cultural practices including pruning, thinning, and insect and disease control, which influence future or between-year orchard production. Modification of the payoff matrix would achieve this purpose.

Crop Yields: Random, Cyclical, or Bunchy?

Clifton B. Luttrell and R. Alton Gilbert

This paper investigates whether changes in weather have random effects on crop yields. The data are yield series of several crops for the United States, individual major producing states, and major producing areas. Statistical tests show little evidence of nonrandomness in these series. There is almost no evidence of cycles or bunchiness prior to 1932, none for national average yields or the weighted average for major producing areas. Since 1932 there is some evidence of autocorrelation; however, this appears to reflect the uneven application rate of high yielding inputs, such as fertilizer and hybrid seed.

Key words: autocorrelation, cycles, bunchiness, nonparametric, nonrandomness, randomness, skewness.

With the decline in the nation's stocks of farm products since 1972 and the possibility of smaller government holdings of such products through price-support operations in future years, greater attention is being focused on the short-run food supply situation. Year-to-year fluctuations of crop production are receiving special consideration since, with low reserves, a few successive years of relatively low yields could cause a sharp reduction in the quantity of food available and sharp increases in food costs.

It is generally agreed that weather is a major factor influencing annual variations in crop yields and production. However, there is great disagreement on the pattern of annual weather variations and its influence on yields. Some analysts contend that weather has a nonrandom impact on yields. One type of nonrandomness postulated is cyclical weather patterns that allegedly generate yield cycles of approximately the same number of years with a series of good weather and high yield years followed by a series of poor weather and low yield years. Others have postulated a tendency for several years of yields above trend to be followed by several years of yields below trend. Such a pattern is called bunchiness, a type of nonrandomness with less regularity than periodic cycles.

An analysis of crop-yield patterns is important for determining national food and agricultural policies. One objective of such policies is to prevent large reductions in food consumption as a result of large reductions in supply of farm products. If there are periodic yield cycles, reductions in consumption could be avoided in years of low yields by accumulating reserves in years of high yields. If crop yields display bunchiness but no regular cyclical pattern, an appropriate policy might be to accumulate large stocks of reserves during years of above trend yields and hold them until yields fall substantially below trend. On the other hand, if yields are essentially random, a smaller quantity of reserves would be sufficient to maintain stable consumption.

This article tests the validity of nonrandom yield theories for several major crops in the United States using average yield data for several states and for the nation. The data were selected to test for periodic movements or bunchiness in yields over large enough areas to affect national crop production. The question of periodic movements or bunchiness in yields at specific locations is not considered in this study.

Weather Cycle Views

Belief in weather cycles dates back to the Old Testament days when Joseph interpreted Pharoah's dream to the effect that seven years of good crops would be followed by seven

Clifton B. Luttrell is an assistant vice president and R. Alton Gilbert is an economist at the Federal Reserve Bank of St. Louis, Missouri.

years of poor crops and famine. Weather cycle theories were outlined in a systematic manner by W. Stanley Jevons and his son H. S. Jevons in the 1870s and early 1900s, respectively. They postulated that sunspots behaved in a cyclical manner and in turn transmitted their cyclical influences to weather, crop yields, and the business community (H. Jevons; W. Jevons, pp. 194–205). In the 1920s Henry L. Moore, an American economist, traced the origin of business cycles from periodic movements of celestial bodies to weather and crop yields. He reported cycles of eight years' duration (pp. 101–2).

In recent years less emphasis has been placed on the impact of weather and crop cycles on general business conditions. Nevertheless, belief in such cycles has remained widespread. In 1942 Fulmer reported a tendency for large crops of cotton, apples, and wheat to occur every six years as a result of sunspots (pp. 385–405). Another study presents evidence of regularly recurring cycles in cotton yields and bunchiness in grain sorghum yields from 1916 to 1955 in the High Plains of Texas (Lin, Hildreth, and Tefertiller, p. 596). In an analysis of corn yields in Illinois, Indiana, Iowa, Missouri, and Ohio, Thompson reported cyclical weather patterns that caused below average yields during the decades of the teens, thirties, and fifties of the current century and above average yields in the alternate decades (pp. 454–56).

In contrast to the above proponents of weather and crop yield cycles or bunchiness, other analysts have found the impact of weather on crop yields to be random. Foote and Bean could find no evidence of nonrandomness in U.S. corn yields (p. 30). In a study of cotton, corn, and oat yields in Mississippi, Day found little evidence of bunchiness (pp. 713–19).

Nature of the Data

The data for this study are the U.S. Department of Agriculture series on average yields per acre harvested for various crops in the United States as a whole, yields for various states, and weighted average yields for selected groups of states.[1] The series for the United States begin in 1866. The series for some of the states begin in 1866 and others begin several years later (USDA, all references).

The data are analyzed to determine whether year-to-year changes in weather have random effects on crop yields. Several factors in addition to weather are assumed to have influenced yields, especially since the 1920s. These additional factors include variations in soil fertility due to changes in the location of production areas, improved seed, machinery, weed and disease controls, increased use of chemical fertilizer, and government acreage-control programs that removed the less fertile areas from crop production during the 1950s and 1960s. These nonweather influences are assumed to largely affect yield trends with year-to-year yield patterns dominated by changes in weather. Evidence cited in a following section indicates that in recent decades nonweather influences may have also caused several shifts in yield trends, and therefore the statistical test must be interpreted with allowance for this possibility.

The appropriate data for studying yield bunchiness depends upon the objective of the study. In studies by Day and by Lin, Hildreth, and Tefertiller, the motivating issue appears to be the effects of changes in weather on yields of individual farms. The data used in those studies were derived from agricultural experiment station records. Therefore, those studies investigate the degree of bunchiness in yields at individual locations. In contrast, the objective of this study is to determine whether there is bunchiness or a cyclical pattern in total U.S. production of various crops.

For the purpose of this study it is not sufficient to examine just average U.S. yields of various crops. The crop-yield series have been affected by an important development that it not likely to be repeated—the opening of major new territories in the western states for cultivation since the series began in the 1860s. As more land was brought under cultivation, average yields were affected by the fertility of the new lands relative to the fertility of the land already under cultivation. Major producing states are identified for each crop, and the crop-yield series for a number of these individual states are included to deal with the possible biases due to the additional acreage

[1] The grains selected for analysis—wheat, corn, rye, barley, and oats—are the only major grains produced in this nation for which data are available on yields since 1866. Data on yields by state are available since 1866 for all of these grains except oats. Cotton was selected as a major nongrain crop. Individual states included in the analysis have been major producing states in recent years.

brought into production. Crop yields for major producing areas are calculated from the acreage and production data for the individual states. Such series are less likely to be affected by changes in the land under cultivation than average yields for the United States.

The crop-yield series for each of the major producing states are also analyzed for bunchiness since such analysis can provide information about the potential for bunchiness in total U.S. production. To illustrate such potential, suppose that bunchiness is observed for a crop in each of the major producing states, but no evidence of bunchiness was found for the states combined because when some states have been in phases of low yields other states have been in phases of high yields. If in future years the phases of high and low yields for the major producing states were to coincide, bunchiness for the major producing states combined and possibly for the nation would result. On the other hand, if there is no evidence of bunchiness in individual states, less potential exists for bunchiness in major producing states combined or for the nation.

Empirical Results

The statistical tests are for a type of nonrandomness or "bunchiness" in the yield series that occurs when a deviation from trend in one year tends to be followed by a deviation from trend in the same direction the next year. Under this general definition, periods of exceptionally good and bad crop years would not necessarily follow regular patterns in terms of number of consecutive years that yields are either above or below trend. A cyclical pattern in crop yields at periodic intervals is one type of bunchiness; a tendency for such periodic cycles would be indicated by the following statistical tests.

Tables 1 and 2 present three tests for bunchiness.[2] For purposes of these tests, the series are divided into two time periods, the first from the beginning of each series until 1932 (table 1) and the second from 1933 to 1974 (table 2). The series are divided at 1932 because of a change in trend growth of yields at about that time as shown in figures 1, 2, 3, and 4. A sharp change in trend would tend to bias some of the statistical tests for bunchiness.

Nature of the Empirical Tests

The first test for bunchiness is based upon regression analysis. Natural logs of crop yields are regressed against time to estimate a trend line. The test for bunchiness in this regression analysis is a test for first-order positive autocorrelation using the Durbin-Watson statistic.

The Durbin-Watson statistic is not used in the studies of bunchiness mentioned in the previous section because of the authors' concern about nonnormality of yields, particularly skewness. Statistical inference based upon the Durbin-Watson statistic is valid only if the distribution of observations approximates a normal distribution. A test for skewness is presented in the first columns of tables 1 and 2. (For a discussion of the test for skewness and significance levels of the test statistic, see Snedecor and Cochrane, p. 86 and table A3.) The Durbin-Watson statistic is reported in the fifth columns for only those series that are not significantly skewed at the 5% level.

Nonparametric tests of randomness in crop yields need not be limited by the assumption of normally distributed observations. The test statistics reported in the sixth columns of tables 1 and 2 are those used in the Wallis-Moore runs test for phase lengths, a nonparametric test for randomness (Wallis and Moore). This test statistic is based upon the frequency with which first differences of a series change sign. One type of nonrandomness indicated by this test statistic is a series of first differences that change sign from positive to negative and back to positive more frequently than would be expected for a random series. The other type of nonrandomness would be adjacent first differences that change sign less frequently than expected for a random series. The second type of nonrandomness is called bunchiness in this study.

The Wallis-Moore runs test would not be sensitive to certain types of bunchiness in yields. Suppose a pattern of yields is such that they lie below trend for a few years, with annual deviations from trend being random, and then yields change to lie above trend for a few years, with annual deviations from trend again being random. Increases in yields would not necessarily be followed by further increases or declines by further declines.

[2] Tests based upon cotton yields are not presented for table 1 because of the limited number of observations on these yields in the time period covered by the table. Data on yields of oats in individual states are not available for a sufficient number of years to be included in this analysis.

[a] Weighted average of yields in the states listed below. Observations for these series are limited to the fewest observations for any of the individual states listed under each crop.
[b] Does not indicate bunchiness but more phases of length one than would be expected for a random series.

The statistics reported in the seventh column of tables 1 and 2 are used in a nonparametric test of this alternative pattern of bunchiness. A trend in yields is calculated as a nine-year moving average centered on each year for which trend is calculated. In this test a run is a sequence of years during which yields were either below or above trend. The test statistic is based upon the number of runs in a series (Draper and Smith, pp. 95–97). This test would show evidence of bunchiness only if the test statistic is negative, indicating that the actual number of runs is less than the expected number.

Test Results, 1866–1932

The discussion of test results concentrates first on data for the period from the beginning of the series until 1932 (table 1). During this period yields are assumed to have reflected primarily the influences of weather and the natural fertility of the land on which crops were grown.

The test results show evidence of skewness in some of the yield series of corn and barley during this period. The skewness is in the negative direction for both crops, indicating that for those series there were upper limits on crop yields near which observed yields tended to fall, but occasionally there were very low yields.

The Durbin-Watson test provides little evidence of positive autocorrelation in crop yields in the period 1866–1932. There is significant evidence of positive autocorrelation for only the following series: wheat in Colorado and Nebraska and rye in the United States and South Dakota.

The Durbin-Watson statistics for rye yields

Note: * = significant at the 5% level, ** = significant at the 1% level, and U = uncertain.
[a] Weighted average of states listed below.
[b] Symbols for levels of statistical significance are not given for these t-values, since all are significant at the 1% level.

are significant because of a break in the trend around 1910. The trend was positive from the beginning of each series to around 1910 and negative from around 1910 until the early 1930s.[3] The fit of the trend line is improved by regressing the natural log of rye yields for the nation on time and time squared. With the trend reestimated in this way, the Durbin-Watson statistic is 2.219, thus showing no evidence of positive autocorrelation.[4] Therefore, allowing for a nonlinear trend in the log of rye yields, there is no evidence of bunchiness in those yields for the years 1866–1932.

Of the twenty-six crop-yield series in table 1, three have values for the Wallis-Moore runs test statistic that indicate significant nonrandomness. This test statistic is significant at the 5% level for wheat yields in Kansas, Nebraska, and North Dakota. However, as indi-

[3] Yield data by county support the conclusion of a negative trend in yields from 1909 to 1934. County-yield data are available for the agricultural census years, three of which are 1909, 1919, and 1934. For the sixty-four counties in North and South Dakota combined for which rye yields were recorded in 1909, 1919, and 1934, all but twelve had lower yields in 1919 than in 1909 and lower yields in 1934 than in 1919. Yields in all of those twelve counties were lower in the very dry year of 1934 than in 1909.

[4] The form of this regression equation is as follows (with t-statistics below regression coefficients):

$$\ln Y = 2.3115 + \underset{(6.785)}{0.01277}\, T - \underset{(-5.927)}{0.0002}\, T^2, \quad R^2 = 0.436,$$

with Y defined as rye yields and T as time.

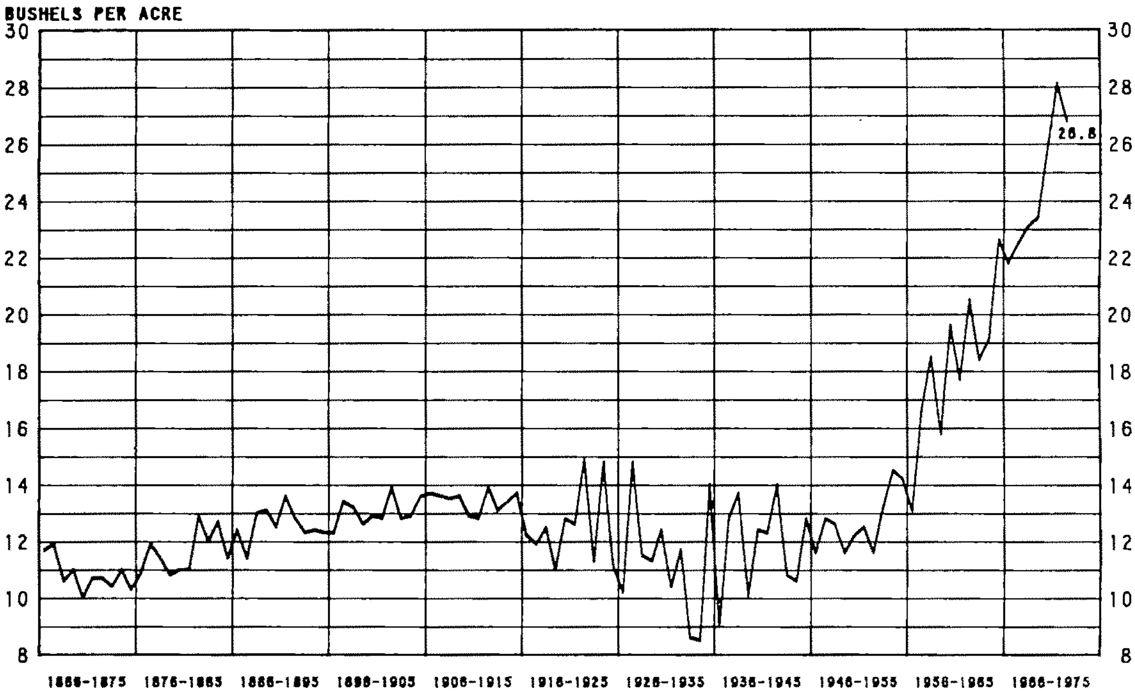

Figure 1. Rye yields per acre harvested in the United States, 1866–1972

cated in table 3, the statistic for wheat yields in Kansas, 1866–1932, is significant only because first differences change signs more frequently than expected, the opposite of bunchiness. This test indicates the greatest degree of bunchiness is in wheat yields in Nebraska. The bunchiness of wheat yields in North Dakota is characterized by changes in yields in the same direction for two years in a row more often than would be expected if the

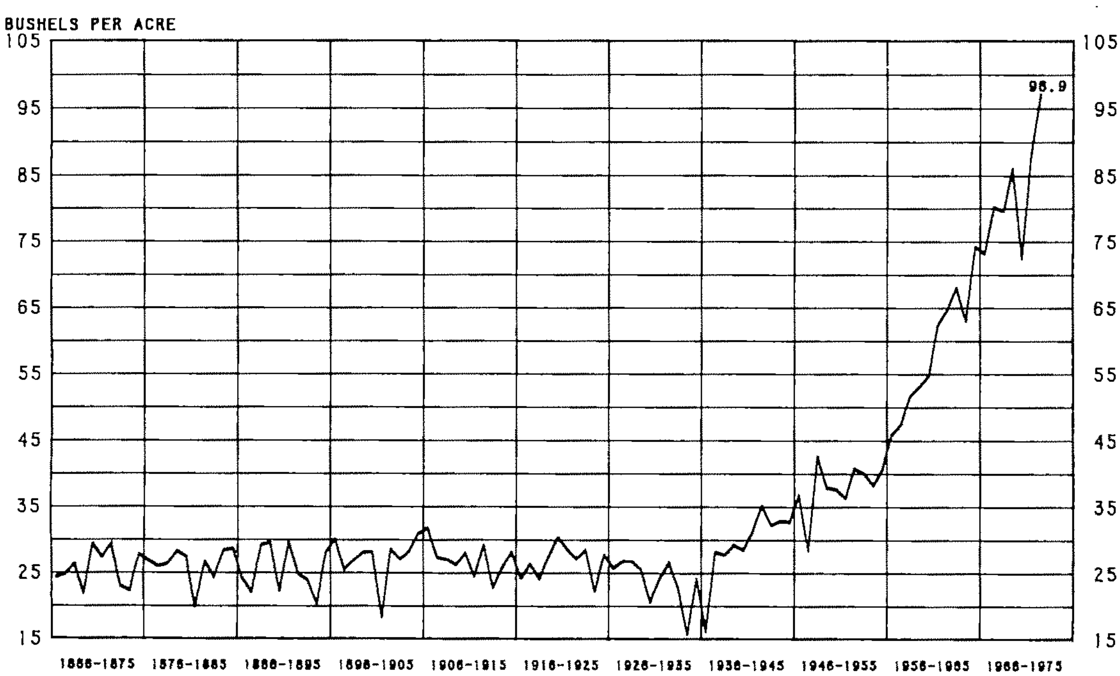

Figure 2. Corn yields per acre harvested in the United States, 1866–1972

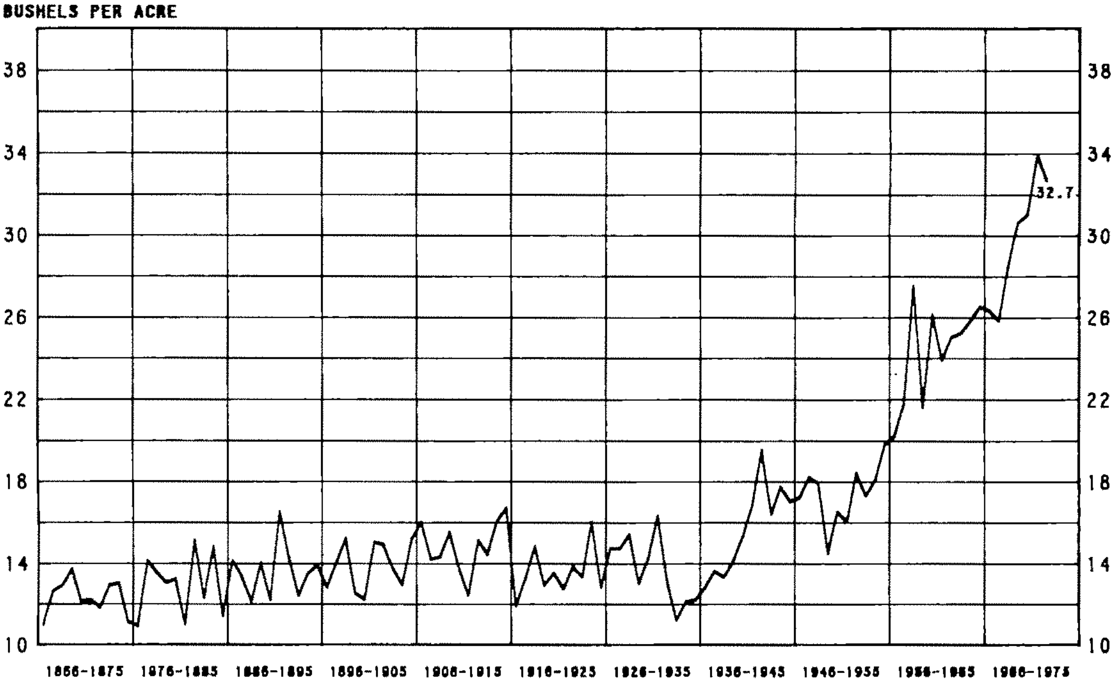

Figure 3. Wheat yields per acre harvested in the United States, 1866–1972

series was actually random. Overall, however, this test on yield data for this period shows little evidence of bunchiness.

Statistics for the runs test with the moving average trend are in the last column of table 1. Since only negative values of this statistic indicate bunchiness, a one-tailed test is conducted. This test of twenty-six crop-yield series shows evidence of bunchiness only for wheat in Nebraska. All of the other series in table 1 have positive values for this statistic, indicating more runs than expected.

Kansas wheat, 1866–1932	8.948	39	25.833	11	11.183	1	3.983
Nebraska wheat, 1866–1932	13.680	9	24.583	14	10.633	7	3.783
North Dakota wheat, 1879–1932	7.088	16	19.583	15	8.433	1	2.983

Note: The terms in this table are calculated by counting phases of various lengths in the yield series. A phase is a sequence of first differences of like sign. For instance, if two adjacent first differences have the same sign (either positive or negative), that is counted as a phase of length 2. The following are definitions of terms in this table. u_1 = number of phases of length 1, U_1 = expected number of phases of length 1 in random sample, u_2 = number of phases of length 2, U_2 = expected number of phases of length 2 in random sample, $u_{>2}$ = number of phases of length greater than 2, and $U_{>2}$ = expected number of phases of length greater than 2 in random sample.

In sum, little evidence of bunchiness is found in the crop-yield series for the years 1866–1932. No evidence of bunchiness is found in yields of corn, barley, and oats either at the national or state levels. Some evidence of bunchiness in yields of wheat is found in two states but none is found for average yields nationally or for the weighted average of the major producing states.

Test Results, 1933–1974

The results of tests for bunchiness for this period are presented in table 2. The Wallis-Moore runs test and the runs test with the nine-year moving average trend show no evidence of bunchiness. However, thirteen of the twenty-five series for which Durbin-Watson statistics are presented show evidence of positive autocorrelation, which lends weight to the hypothesis of bunchiness.

Crop yields, which had remained relatively stable since records were begun in the 1860s, have risen dramatically since the early 1930s as shown in figures 1, 2, 3, and 4. Corn yields, which averaged 24 bushels per acre during the decade of the 1930s, rose to 86.5 bushels per acre in the years 1972–74. Average wheat and cotton yields more than doubled, and the index of average overall crop yields has doubled since the 1930s (USDA 1973).

Rising crop yields since the 1930s largely reflect the increasing application to land of man-made productivity factors. Biological science, through more viable seed; chemistry, through lower cost fertilizer; engineering, through more efficient machinery and equipment; and agronomy, through improved crop rotations, soil management, planting, cultivating, and harvesting practices have all contributed to the crop productivity gains.

Identifying the years in which these man-made yield-increasing factors began to have significant impacts on crop yields is somewhat arbitrary. However, since substantial yield increases had begun in the late 1930s and relatively stable yields preceded the 1930s, the breaking point was arbitrarily chosen at the close of 1932.

Uneven Rates in Changes in Yields, 1930s to 1970s

Evidence of positive first-order autocorrelation in yields cited earlier can be interpreted as either indications of bunchiness in yields or increases in the trend of yields at uneven rates over the period from the 1930s to the 1970s. This section surveys evidence of changes in factors that affected yields at uneven rates during that period, supporting the conclusion of shifts in the trend growth rate of yields rather than bunchiness. In other words, evidence in this section indicates that the trend of yields is misspecified by regressing the natural log of yields on time during the period from the 1930s to the 1970s.

Griliches found evidence of the application of new technology to corn production at uneven rates since the early 1930s (1957, pp. 501–5). In another study he found that fertilizer use was inversely related to its real costs, that such costs declined sharply in the early 1940s, and that most of the response to the decline in cost took place within five years (1958). Shaw found that technological changes increased corn yields in Iowa in two steps over the 1929–60 period, the first when hybrid seed corn came into use from about 1935 to 1940 and the second beginning in about 1954 (p. 226). However, results in table 2 show no evidence of bunchiness in corn yields.

On the other hand, average wheat yields have shown some tendency to bunchiness on the basis of the Durbin-Watson statistic. Wheat yields were generally above the trend line from 1940 to 1948 and below it from 1949 to 1956. In part the higher yields in the 1940–48 period may be attributed to more favorable weather conditions during this period, but weather was not the only factor involved. Other factors include the adoption of a number of new varieties of seed, increased summer fallowing, and rising fertilizer use in the Eastern states. A number of new higher yielding hybrids were released for commercial use during this period.

While any evaluation of the factors causing the variation from trend in wheat yields during these periods is difficult, the rapid development of new high yielding varieties and their later susceptibility to disease may have been an important factor. The gains in yields obtained from the adoption of new varieties were often canceled by the development of new strains of rust that attacked the variety. During the 1949–56 period heavy attacks of black stem rust occurred. The attacks were especially severe on the durum and hard spring wheat that are grown extensively in North and South Dakota, two of the three states in which the Durbin-Watson statistics indicate positive autocorrelation. Yields per harvested acre of durum in the nation declined from an average of 15.2 bushels in 1940–48 to 11.3 bushels in 1949–56. By 1956 rust-resistant varieties had been developed and average yields rose.

In addition to the rust problem, changes in the location of production within the states, the beginning of fertilizer usage, and improved machinery that contributed to more timely seeding and harvesting in the 1940s may have contributed to positive autocorrelation in wheat yields.

Positive autocorrelation is also observed in cotton yields since 1933 on the basis of the Durbin-Watson statistic. Numerous factors including better weed and insect controls, increased use of fertilizer, and improved tillage practices contributed to that tendency.

Major changes in production patterns in the cotton belt states as a result of government acreage-control programs in the 1950s and 1960s also had an impact on yields. The acreage removed from production was probably less fertile than those acres remaining in production. During the period 1949–53, prior to the sharp decline in cotton acreage resulting from the government programs, average cotton yields were below trend (figure 4). However, yields were above trend from 1954 to 1966 when acreage declined rapidly. From the average of the first period centered in 1951 to the average of the second period centered in 1960, the acres planted in cotton declined at a 5.7% annual rate and average yields rose at a 5.2% annual rate. In contrast, from 1930–32 to 1970–72 the acres planted in cotton declined at a 2.8% annual rate and yields rose at a 2.4% rate.

Probabilities of Low Crop Yields

An important consideration in formulating a national grain reserve policy is the probability of several consecutive years of bad crops. The evidence presented above indicates no cyclical or bunchy patterns in crop yields (when adjusted for shifts in trends) over large enough areas to affect national production. Therefore, deviations of crop yields from trend are considered to be random, and probabilities of consecutive years of low yields are estimated accordingly. Two definitions of a bad crop year are used in table 4—yields 5% or 10% below trend. The past variability of yields in each series is used to estimate the probabilities of yields 5% and 10% below trend for one year, two years, and three years in a row. To illustrate the use of table 4, the variability of wheat yields in the United States for the years 1937–68 indicates that the probability of wheat yields being 5% or more below trend in any one year is about 22%, for two years in a row, 4.5%, and for three consecutive years, just over 1%.

The numbers below each probability figure in table 4 indicate the frequency with which various percentage deviations from trend occurred. For instance, during the years 1937–68, wheat yields in the United States were 5% or more below trend in seven out of thirty-two years, or in about 22% of those years. These frequencies of actual occurrence of bad crops provide a check on the randomness and symmetry of the crop-yield series. If the frequencies were to diverge greatly from the probabilities calculated using the normal distribution, the yield data would tend to be nonrandom, skewed, or both. The frequencies are fairly close to the probabilities, especially the probabilities of a bad crop in any one year.

[a] Trend is a nine-year moving average centered on each year for which trend is calculated.
[b] Yield series in this analysis are not skewed according to the tests in tables 1 and 2.
[c] The deviations of yields from trend are calculated as percentage deviations from trend. SD is the standard deviation of those percentage deviations from trend.
[d] If percentage deviations of crop yields from trend are distributed approximately as a normal distribution, the probability of crop yields being 5% or more below trend can be estimated by dividing 5 by SD and finding the probability that corresponds to that quotient in a table of the normal distribution. The same sort of analysis applies to the probabilities of yields 10% or more below trend.
[e] This frequency indicates that in the fifty-nine years of 1870 through 1928 national wheat yields were 5% or more below trend for two years in a row on four occasions. This frequency is expressed as a ratio by dividing 4 by 58, since there were only fifty-eight possible combinations of two years in a row.

Conclusion

An analysis of average yields for a number of major crops in the nation and in leading producing states provides little evidence that yields are either cyclical or bunchy as a result of weather. There is almost no evidence of bunchiness in the period 1866–1932 when there was little influence of new inputs on yields. There is some evidence of positive autocorrelation in yields since 1933. However, such results appear to reflect the uneven rate of applications of high yield producing inputs rather than a nonrandom influence of weather. Evidence indicates that utilization of such inputs as fertilizer, hybrid seed, etc., has been bunchy, having been determined by new discoveries, the dissemination of such knowledge, and changes in relative prices.

No attempt was made to analyze yield patterns in areas smaller than states. If periodic yield patterns exist at individual locations or in small areas, they are apparently offset by yield patterns elsewhere or have an insignificant

impact on average yields for major producing areas and the nation.

National Farm Capital Accounts

Richard W. Simunek

Farm capital flows and finance accounts are quantified to the extent possible using national economic accounting procedures applied to existing farm sector data. Outmoded concepts and data gaps preventing accurate monitoring of economic performance are identified. Current accounting definitions cause substantial capital formation to be recorded as asset valuations. Measures of book value capital consumption allowances, net real estate transfers, and saving in the capital finance account reveal that internal capital financing is important for its magnitude and certainty. The national farm capital accounts improve income and production analysis.

Key words: balance sheet, capital finance, capital flows, economic accounting.

The purpose of this article is to illustrate and discuss the extension of the farm sector accounting system by the addition of change in balance sheet, capital flows, and capital finance accounts. Opening and closing balance sheets are linked by capital flows and asset revaluations. The capital flows account delineates the forms in which capital is accumulated, and the capital finance account monitors its manner of internal and external financing. Methodology employed to construct the national farm capital accounts involves well-recognized national economic accounting concepts (United Nations) quantified to the extent possible with existing farm-sector data. Contrasts between present and proposed accounting rules are drawn and data deficiencies are noted. The national farm capital accounts are presented on the product basis for the farming sector; that is, all nonfarm capital and financial flows and stocks are excluded.

Background

It has been stated that structural and technological changes over time have rendered the theoretical concepts of the farm-sector data system obsolete. As a result, "predictive analysis built upon these concepts performs less well despite great efforts at statistical manipulation of data, refinement of technique, and elaborate economic modeling" (AAEA Committee on Economic Statistics, p. 868). Use of national economic accounting concepts and procedures will help alleviate this situation. This is not to imply that other accounting systems are incorrect or inferior. Each accounting system is designed for a specific purpose. Measurement of the value of production (table 1) is the main purpose of national economic accounting because production of goods and services allows consumption and net capital accumulation (Simunek 1975). In the capital flows and finance accounts, the primary concern is the measurement of net capital accumulation and saving, that is, production not consumed (Simunek 1974).

Development of national economic accounts made possible quantitative economic analysis in the framework illustrated by table 2 and, in turn, increased interest in national economic accounting concepts and the data collection efforts required to support and extend such a system. National economic accounts facilitate economic analysis by identifying the nature of accounting relationships that must hold true; for example, saving must equal net capital formation. Measuring component flows facilitates analysis of functional relationships between, for instance, consumption and disposable income, wages and profits, and capital formation and consumption. Facilitating economic analysis is one facet of national economic accounting; facilitating data

Richard W. Simunek is an agricultural economist with the National Economic Analysis Division, Economic Research Service, U.S. Department of Agriculture.

The views expressed are those of the author and do not necessarily represent those of the U.S. Department of Agriculture. Estimates in this article are not official USDA estimates but are presented to illustrate an accounting procedure. Initial development of the national farm capital accounts began in discussions with Eldon Weeks and Carson Evans, agricultural economists in the Sector Performance Measures Program of the Economic Research Service. Without their insight and guidance, it would not have been possible for this paper to have been written. Lillie Jones assisted with data development. My appreciation is extended to all. Final observations and conclusions and therefore errors are mine.

gathering is the other. National economic accounting concepts and procedures force coordination and systemization of basic economic statistics and assist in locating statistical gaps and weaknesses within and between economic accounts and sectors. A useful discipline is provided by the fact that debits must equal credits and sector accounts must sum to the national accounts.

In recent years, attention has been drawn to the limitations of the data system for the food and fiber system as a whole, as opposed to emphasizing those of individual data series or accounts within the system. Issues have been identified and/or suggestions offered requiring expanding the present farm-sector data system or developing an alternative accounting system that represents extensions of existing performance measure series. Weeks (1971, 1972), Weeks et al., Carlin and Smith, and Carlin and Handy examined farm accounts for measuring the value of farm production using the establishment and product concepts of industry. In reference to capital stocks and flows, Weeks observed that nonmeasurement of farm supplies in the inventory account, own-account (nonpurchased) capital formation,

and certain livestock and perennial crop assets distort income and product flows.

Items treated as fixed capital assets in the total net farm income concept (table 3) for which gross capital expenditures and capital consumption allowances are estimated include dwellings, service structures, land improvements, automobiles, motortrucks, tractors, and other machinery and equipment.[1] Estimates of capital consumption allowances are based on current replacement cost, the amount necessary at current prices to replace buildings and equipment used up during the year.[2] Under the present accounting practices, own-account capital formed and used up is not recorded in gross capital expenditures and capital consumption allowances. In addition, orchards, vineyards, animals used for wool and hair, breeding livestock, and dairy cattle are not considered fixed assets under the total net farm income concept. Expenditures for these assets are treated as current expenses. Cash receipts for culled dairy and breeding livestock are recorded as current income. Time and identity imbalances are thus created in the current account.

Valuation of own-account capital stocks is conceptually included in the balance sheet, although production efforts associated with own-account capital formation are excluded from the present measures of capital flows. All assets in the balance sheet, whether purchased or formed on own-account, are valued at their full replacement cost. Market value of own-account assets is reflected in land prices and livestock and crop inventories. Measures of motor vehicle and machinery flows and stocks include only purchased capital under present accounting definitions.

Change in Balance Sheet Account

Legitimate questions can be raised about the present treatment of certain capital items in the farm income accounts, especially as they are eventually measured in the change in balance sheet account. The procedure followed below is to establish the change in balance sheet account (table 4) as the difference between beginning and ending balance sheets and to explain balance sheet changes by capital flows (table 5). Column 3 shows the total balance sheet value change between two accounting dates. Columns 4 through 9 show the amounts of change accruing to balance sheet components as a result of transactions and asset valuations. The change in balance sheet account readily demonstrates that any nonmeasurement of net capital formation in the capital flows account leads to its being recorded as asset valuations in the balance sheet account. This result supports very strongly adding the output of capital formed on own-account to current measures of farm capital formation.

Capital Flows Account

All entries in the capital flows account are economic activities registered in the farm income accounts except net real estate transfers to nonfarm sectors. Thus, by monitoring the capital accumulation process, the capital flows account monitors the direct effects of farm income on the balance sheet. Gross capital formation in the capital flows account consists

[1] Land improvements are not depreciated in the farm expense accounts.

[2] Market value capital consumption allowances will be greater than book value capital consumption allowances during periods of rising prices, especially for longer-lived assets. For example, market value capital consumption allowances for machinery and equipment equal 89% of their gross capital expenditures in 1974, while market value capital consumption allowances for dwellings equal 310% of their gross capital expenditures.

Table 3. Total Net Farm Income of Farm Operators, 1974

Debit	$ Million	Credit	$ Million
Farm production expenses	73,405	Gross farm income	101,112

of increases in inventory and gross additions to fixed assets.[3] Gross capital disappearance consists of capital consumption allowances and assets transferred out of the farming sector. Inventory change is a component of gross farm income and capital consumption allowances are included in total farm expenses. Asset transfers normally consist of trade-ins and the salvage value of scrapped assets, in addition to capital transfers. However, asset transfers in the farm capital flows account consist of only net real estate transfers, because gross capital expenditures on machinery and motor vehicles are estimated on a net purchase basis (net of trade-in value) in the farm income accounts.

Sales and purchases of real estate within the farming sector represent only a transfer of ownership and not a change in the magnitude of capital available for the production of crops and livestock. It is therefore inappropriate to include purchases of real estate as gross capital expenditures in the capital flows account based on national economic accounting procedures except to the extent that net acquisition of real estate from nonfarm sectors is positive in value. The net decline in acres in farms reported in *Number of Farms and Land in Farms* is valued by the average value per acre sold to nonagricultural uses reported in *Farm Real Estate Market Developments* to estimate net real estate transfers to nonfarm sectors (USDA 1975b, c).[4]

Subtracting all transfers of real estate to nonfarm sectors from all acquisitions of real estate from nonfarm sectors equals net real estate transfers under national economic accounting concepts. An estimate of net real estate transfers under these circumstances can be positive or negative in value, although acres in farming remain constant from one year to the next. For example, assume 1,000 acres in the farm sector valued at $500 per acre

[3] Inventory change derived for total net farm income is consistent with the main purpose of national economic accounting, which is the measurement of current production exclusive of capital gains or losses; that is, no current production "stands behind" capital gains. Net inventory change in the total net farm income concept reflects only physical change as the quantity change in inventory stock is valued at the calendar year average price. An inventory valuation adjustment is made to nonfarm business profit to eliminate inventory profit or loss from the Internal Revenue Service data used to estimate nonfarm income and product. No valuation adjustment is necessary for farm inventories because of the estimation procedures used but, as a matter of interest, the farm crop inventory valuation adjustment for 1974 would equal $3,569 million ($1,484 million minus −$2,085 million) if the IRS data were used and all farmers reported inventory change using the accrual method of accounting (see table 4).

[4] Acres in the farming sector are published annually beginning with 1950. The prices per acre of land sold for nonfarm uses and for all uses are available beginning in 1972 and 1967, respectively. Prior to 1972 the price per acre of land sold for nonfarm uses is estimated.

are transferred to nonfarm sectors and 1,000 acres in nonfarm sectors valued at $300 per acre are transferred into the farm sector. Net real estate transferred for the farm sector equals $200,000, although the change in acres equals 0. It is probably safe to assume acquisitions of real estate from nonfarm sectors are minimal for recent years and that the estimate of net real estate transfers provides a close approximation of the true value.

Defining Capital Stock

Inputs used up during a period of account are classified as intermediate products consumed, and inputs yielding benefits into the future are classified as capital assets under national economic accounting concepts. Breeding stock, draft animals, dairy cattle, and animals raised for wool are classified as capital assets, as recommended by the United Nations. Livestock considered to be fixed assets by the United Nations enter into capital flows under present concepts but as a change in inventory stocks. Inclusion of the production of these livestock in the capital flows account as fixed capital formation would transfer appropriate current farm production expenses into gross capital expenditures, and livestock depreciation would increase capital consumption allowances. To gain a feel for the magnitudes involved, a recent study revealed that the farm operators' total 1973 net income is lowered 21% by redefining dairy and breeding cattle from current to capital account (Dyer).

Other items not presently accounted for either as assets or inventory stocks that could be classified as capital assets include bearing trees, vines, and other perennial crops. Because perennial crops are land related, expenditures on their establishment, maintenance, and improvement included in current farm expenses are accounted for as real estate valuation gains in the balance sheet. This blurs identification and measurement of cause and effect relationships among production, investment, and saving.

Own-Account Capital Formation

Gross capital expenditures for buildings in the farm income accounts rely on data that include purchases of the entire building plus installation. They also include purchases of building inputs such as nails, lumber, roofing material, and cement. Purchases of the latter type indicate own-account capital formation through proprietors' labor, but due to the method of data collection no estimate of own-account capital formation can be made. Gross capital expenditures on land improvements are analogous to buildings and on machinery and motor vehicles are limited to purchased capital only. The problem of appropriately identifying certain perennial crop and livestock capital assets involves a change in definition. However, the total net farm income accounting format, with its major emphasis on marketplace transactions, offers no solution to the latter problem; that is, capital valuation increases will always be overstated to the extent of own-account capital formation.

The income and product account is illustrated as an accounting alternative for measuring own-account capital formation through the example of a farmer who constructed a dairy barn in 1970 after receiving a private contractor's bid of $85,000 (Machan). Using lumber

sawed from the operator's own woods and purchased secondhand materials, the dairy barn was built for $23,000.[5] The dairy farmer estimated that the cost would have been over $100,000 if a private contractor had built it in 1973. To maintain consistency between the 1970 capital flows account and the balance sheet, gross capital formation on the dairy barn should be valued at its current market value of $85,000 rather than at the $23,000 input cost. Replacement cost capital consumption charges should be calculated on the $85,000 market value of own-account capital, and a capital gain of over $15,000 should be recorded from 1970 to 1973. However, under the present cash concept used in estimating total net farm income, gross capital expenditures equal $23,000, and a capital gain of $77,000 is registered in the balance sheet from 1970 to 1973. A shift from own-account capital formation to purchased capital in this example would cause capital formation to increase $62,000 ($85,000 minus $23,000) as measured under the present accounting concepts, although the real magnitude of capital formation has remained constant. Clearly the imputed market value of own-account capital formation will always be measured either as asset valuation gains in the balance sheet, as is done under present accounting concepts, or as gross capital formation in the capital flows account under a new economic accounting scheme.

Farm Supplies

Inputs to current production are accounted for at the time of purchase under current accounting concepts and not necessarily at the time of actual use as required for production analysis under national economic accounting procedures. Purchases of farm supplies are appropriately recorded in current farm expenses, but changes in stocks of farm supplies are not included in net farm inventory change. This distorts income and product flows, and recent events have placed increasing importance on Weeks' initial observation. The 1974 balance sheet of the farming sector indicates that farmers timed their purchases of intermediate products to reduce their income taxes. The $0.9 billion increase in the farmers' liquid financial assets during 1973 did not match the record $1.2 billion rise during 1972, although farm income increased a record 84%. "The moderate gain in farmers' liquid financial assets during 1973 was somewhat less than might be expected in view of their record high net farm income" (Evans et al. 1974, p. 13). Among the explanations offered for this result was "with the high farm income of 1973, probably a larger number of farmers paid cash for certain items such as fertilizer and fuel before the beginning of 1974 for tax purposes."

[5] This example is not unusual. Popular farm magazines contain numerous examples of own-account capital formation in regular do-it-yourself or homemade features attesting to the importance of this type of economic activity.

Capital Finance Account

Agricultural finance research is too heavily oriented toward microeconomics, and significant gaps exist concerning knowledge of the relationship between national economic policy and capital formation in agriculture, asserts Brake. "Economic theory provides the basis for delineating hypotheses to be tested and specifying the relationships to be measured. In many cases gaps in our knowledge of agricultural finance issues stem directly from gaps in the underlying economic theory" (p. 1056). I agree wholeheartedly and would also suggest that past financial research has been limited by lack of a national accounting framework for farm capital financing. To increase the knowledge of the farm capital financing process, Simunek and Evans estimated a capital finance account based on national economic accounting concepts. The results are reproduced in table 6 and figures 1 and 2.

There are difficulties in monitoring farm capital accumulation and finance with both the flow of funds as computed by the Federal Reserve System and the sources and uses of cash funds statement for the farm sector (Penson, Lins, and Irwin; Smith). Flow-of-funds accounting by the Federal Reserve System includes gross capital expenditures, farm inventory change, and financial asset change as farm capital accumulation. Capital consumption allowances at replacement cost value and total farm debt increase are questionably included as capital finance. This has resulted in the illusion of continual net cash disinvestment in the farming sector since 1955 (Simunek and Evans).

Capital accumulation in the farm capital finance account equals gross capital formation plus net acquisition of financial assets. Inter-

[g] Total net farm income of farm operators based on book value capital consumption allowances plus net rent paid to nonoperator landlords.

nal capital financing consists of capital consumption allowances, net real estate transfers, and saving. Capital borrowing is the net increase in total farm debt to acquire motor vehicles and equipment, construct buildings, and make major repairs and improvements to land and buildings. It is the only source of external financing and is estimated.[6]

Capital consumption allowances equal depreciation plus accidental capital damage. They are the replacement cost capital and consumption allowances as reported in *Farm Income Statistics* converted to book values based on the 1969 book value farm balance sheet and the depreciation rates used for estimating total net farm income (Evans et al. 1971, USDA 1975a). The 1969 balance sheet is the only available national benchmark measuring farm assets at their book value. The difference between the book value and the replacement value capital consumption allowances in table 6—the depreciation valuation adjustment—is a residual. Farm financial analysts currently derive cash flow from income as cash receipts minus cash expenses and, while perhaps adequate for financial purposes, this procedure sidesteps the issue of depreciation valuation and the residual estimate of saving.

National income technicians desire replacement cost capital consumption allowances in the capital flows account for interindustry comparisons and calculating rates of return. In no way do capital consumption allowances inflated for price increases accurately record internal funds available for capital financing. In the first place, the incentive to increase capital formation is affected through reduction in income tax obligations by changes in investment and depreciation tax laws as related to book value depreciation. Second, the relationship between capital formation and capital borrowing is dependent upon book value depreciation. The depreciation valuation adjustment of $28,611 million from 1960 to 1974 in table 6 is 124% of capital borrowing, supporting the observation that external cash flow requirements are influenced by book value capital consumption allow-

[6] A detailed explanation of the procedures and data sources used to estimate capital borrowing is contained in Simunek and Evans.

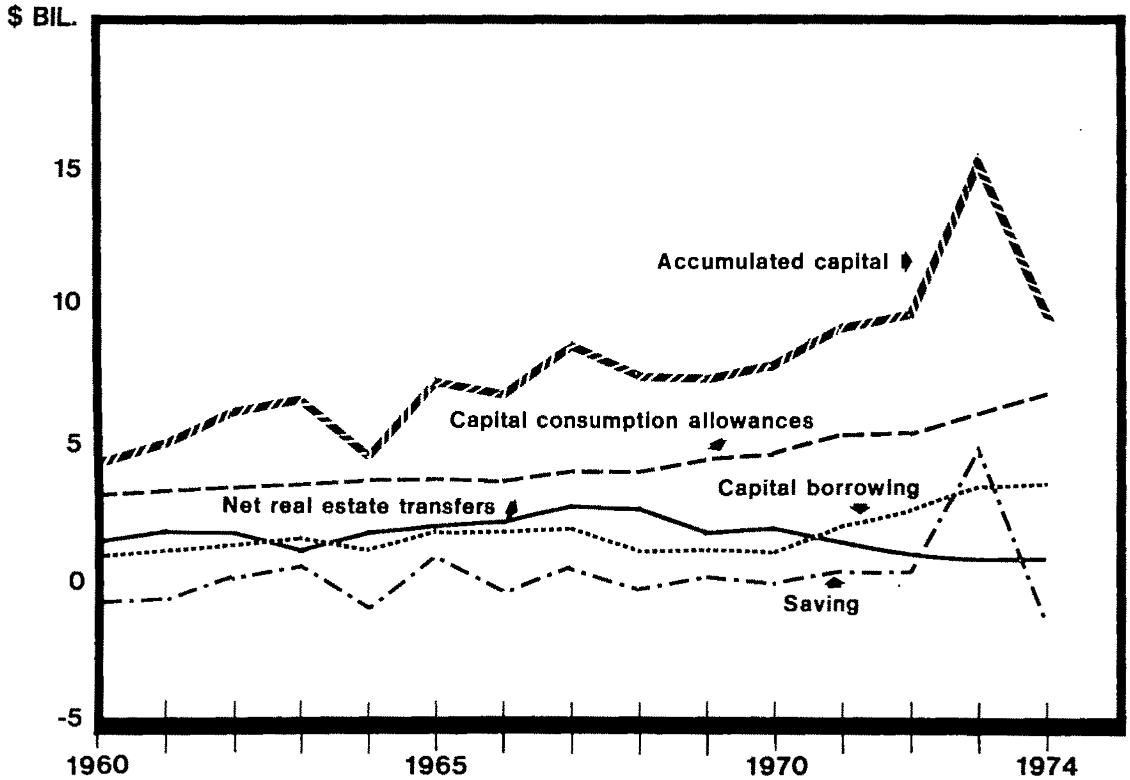

Figure 1. Farm capital finance

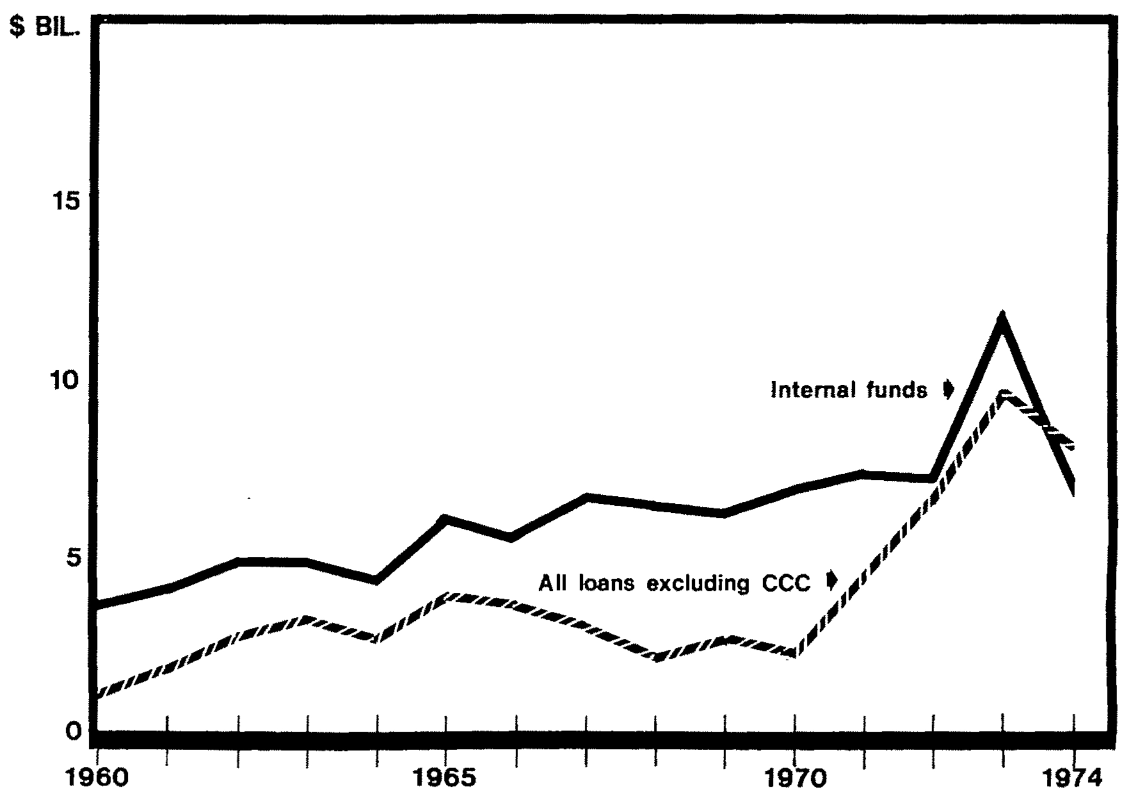

Figure 2. Annual net flow of farm funds

ances. Finally, capital gains or losses are not ignored in the capital finance account but are properly recorded in the assets transferred series as trade-ins, scrapped assets, and assets transferred. For instance, acres of land transferred to nonfarm sectors are valued at their current market value and not at their book value.

Saving is derived as a residual by subtracting capital consumption allowances at book value, net real estate transfers, and capital borrowing from accumulated capital. It is the amount of current production not consumed, while dissaving is the amount of capital stock consumed.

Farm capital accumulation totaled $116.7 billion from 1960 through 1974 or 204% of net farm borrowing for all purposes (including Commodity Credit Corporation [CCC] loans). Internal capital finance explains how farm proprietors were able to carry such a heavy financial burden. Internally generated funds dominate farm capital financing from 1960 through 1974, accounting for 80% of total capital finance, and exceed net farm borrowing for all purposes.

Internal capital financing is important not only because of its magnitude but also because it is a fund source not immediately subject to disruptions in the national money markets. Net farm borrowing excluding CCC loans decreased from $3,622 million in 1966 to $3,105 million in 1967, but internally generated funds increased from $5,455 to $7,182 million, causing a total cash fund increase of $1,210 million. A similar effect occurred from 1969 to 1970, although total funds increased only $144 million. Both periods were times of tight credit (Evans et al. 1971). Apparently, the existence of large amounts of internal funds from book value capital consumption allowances and net real estate transfers plus the potential contribution of saving provides a substantial and assured capital financing base for farm capital acquisition.

Book value capital consumption allowances display a gradual increase in value that is expected since their flow is determined primarily by existing capital stocks on hand, and the influence of annual changes of capital expenditures on depreciation flows is therefore lessened. Net real estate transfers contribute significantly to capital finance and may help to explain the existing paradox of low farm saving versus high farm productivity. Low saving generally indicates low or decreasing productivity for nonfarm sectors. Transfers of farm land to nonfarm sectors represent an exchange of labor-intensive capital for labor-saving capital and at the same time lighten the burden of farm saving.

Farm saving divided by farming income equals a farm saving rate of less than 1.3% from 1960 to 1974. Other factors contributing to low saving are the current definitions of fixed capital assets and gross capital formation. Nonmeasurement of own-account capital formation has a two-fold effect on lowering the estimate of farm saving. First, lack of an estimate of own-account capital formation at the moment of appearance decreases saving by a like amount. Second, that portion of own-account capital not retained in the farming sector is included in asset transfers at full market value.

Farm saving does not equal the total saving required of the economy for farm capital formation. Capital borrowing in the farm capital finance account equals saving by nonfarm sectors and is recorded as saving in nonfarm capital finance accounts. Saving must equal net capital formation for the economy in the national economic accounting framework. For the farming sector, net capital formation in the capital flows account plus financial asset change equals farm saving plus capital borrowing and the depreciation valuation adjustment.

Net real estate transferred in the farm capital finance account is recorded as gross capital formation in nonfarm capital finance accounts. Financial asset change, net real estate transfers, and capital borrowing equal 0 for the nation's capital finance account, assuming no foreign transactions. Saving for the economy can be derived by summing saving in all sector capital finance accounts.

New research areas and priorities are established by the capital finance account. For example, the estimate of saving permits identification of consumption behavior of the farm sector via the consumption function. Because of the importance of internal financing, future farm financial research needs to include investment allowances, depreciation analysis, capital transfers, and saving behavior in conjunction with past farm financial research devoted primarily to interest rates and credit availability. In addition, the role of own-account capital formation as affected by changes in income or capital borrowing needs exploration. Does an increase in income or credit availability cause an increase in total

capital formation or a shift from own-account capital formation to purchased capital?

Summary and Implications

Facilitation of economic analysis and systematization of basic economic statistics are two overall advantages for adopting national economic accounting concepts and procedures for farm sector data and extending such a system to the entire food and fiber system. Economic analysis is facilitated by identifying functional relationships and accounting identities.

Data gaps and weaknesses are readily identified. Adoption of national economic accounting procedures for the farming sector would impose heavy data collection requirements on the U.S. Department of Agriculture for certain items. In other areas, adoption of national economic accounting concepts would not involve any conceptual difficulties other than adjustments to an overall objective. For example, definitions of capital borrowing are not consistent among the Farm Credit Administration, the Federal Reserve System (Melichar), and the Census of Agriculture (U.S. Dep. of Commerce). Also, capital borrowing is not defined consistently with capital formation in the capital flows account.

As stated previously, the national farm capital accounts are quantified to the extent possible with existing farm sector data with the objective of illustrating and discussing accounting concepts and identifying data deficiencies. Empirical results in this article should be viewed and used with discretion. Future efforts will be devoted to improvement of data sources and estimation procedures.

Much capital formation is not presently recorded in the capital flows account but is included in current income and expenses and as asset valuation gains in the balance sheet. A complete accounting of gross farm capital formation cannot be achieved by redefining items considered fixed assets from current account to the capital account. Own-account capital formation will always be recorded as asset valuation gains under the present accounting procedures.

Internal capital finance is important due to its magnitude and its certainty as an available source of funds. Measurement of saving permits identification of farm consumption and saving behavior.

National economic accounting concepts were applied to existing farm data series to develop change in balance sheet, capital flows, and capital finance accounts. In doing so, outmoded concepts and data gaps preventing accurate monitoring of economic performance are identified. Adoption of suggested asset definitional changes and measurement of own-account capital formation will greatly improve the national farm capital accounts for income and production analysis.

Notes

Some Alternatives to Linear Unbiased Estimation and Traditional Pretest Procedures

George Judge

In economics the most widely used statistical technique is based on the linear statistical model and least squares and maximum likelihood concepts. These tools are supported by a body of theory that dates back well over a century to Gauss and Legendre and includes the powerful and beautiful Gauss-Markoff theorem, which says in effect that, out of the class of linear unbiased estimators, least squares is the "best" (minimum variance, minimum mean square error) estimator. The linear unbiased restrictions that are necessary to achieve the Gauss-Markoff result appear to be generally accepted in econometric analysis. However, for the economic researcher who is interested in parameter estimation or prediction appropriate for choice or decision purposes, the property of unbiasedness, which yields an estimator that is right on the average, may have limited usefulness. In addition the best unbiased statistical property only holds if the statistical model is correctly specified, and in economics the sampling process by which the data are generated is seldom known.

Consequently, the purpose of this expository note is to point out that over a range of criteria for evaluating estimators, distributional assumptions, and conditions normally fulfilled in practice, simple estimators exist that are uniformly and nontrivially superior over the parameter space to the least squares and pretest estimators used by most applied researchers in economics.

A Comparison of Traditional and Nontraditional Estimators

As a basis for presenting and contrasting the estimators, let us for expository purposes assume the data are generated by the orthonormal linear statistical model

(1) $$y = X\beta + e,$$

where y = a $T \times 1$ vector of sample observations, X = a $T \times K$ design matrix with $X'X = I_K$,[1] β = a $K \times 1$ vector of unknown parameters, and e = a $T \times 1$ normally and identically distributed vector of random variables with mean 0 and covariance matrix $\sigma^2 I_T$. The traditional least squares, maximum likelihood estimator of β for the orthonormal statistical model is

(2) $$b = (X'X)^{-1}X'y = X'y,$$

where b among linear unbiased estimators has for all β a minimum variance, either component by component or for any linear combination.

The first hint of difficulty for those using this estimator came in 1956 when Stein showed that under a squared error loss measure,[2] $\rho(b, \beta) = E_\beta[(b - \beta)'(b - \beta)]/\sigma^2 = K$, the least squares estimator was inadmissible, i.e., there exists another estimator, say, $\hat{\beta}$, where $\rho(\hat{\beta}, \beta) \leq \rho(b, \beta) = K$ for all β and $\rho(\hat{\beta}, \beta) < \rho(b, \beta) = K$ for some β. In other words, under the standard measure of performance there is a "better" estimator.

In 1960 James and Stein exhibited an estimator that under squared error loss and number of parameters $K \geq 3$ had a risk equal to or less than the least squares estimator for each point in the parameter space. The simple estimator they proposed and showed to have smaller total squared error loss for all β is

(3) $$\delta(b) = (1 - ((K-2)/(T-K+2))((T-K)\hat{\sigma}^2/b'b))b,$$

where b is defined in equation (2) and $\hat{\sigma}^2$ = the unbiased least squares estimator of σ^2. All elements of equation (3) are contained in the output of the usual regression computer program. If we have hypotheses concerning the K unknown parameters, say, β_o, then the estimator may be written in the more general form

(4) $$\begin{aligned}\delta_o(b) &= [1 - ((K-2)/T-K+2)((T-K)\hat{\sigma}^2/(b-\beta_o)(b-\beta_o))](b-\beta_o) + \beta_o \\ &= [1 - ((T-K)(K-2)/K(T-K+2))/F](b-\beta_o) + \beta_o \\ &= [1 - c^*/F](b-\beta_o) + \beta_o.\end{aligned}$$

George Judge is a professor of economics and agricultural economics at the University of Illinois, Urbana-Champaign.

[1] This assumption is made for expository convenience. If the general case, where $X'X$ is a positive-definite matrix, is assumed as Bock, Yancey, and Judge have shown, the conclusions remain and only the conditions change.

[2] Since for a random sample of observations $(y_1, y_2, \ldots, y_t)$ there may be several estimators to choose from, there is a need to introduce a loss function $L(\hat{\beta}, \beta)$ that will reflect the loss or disutility incurred by choosing a particular estimate when β is the true parameter vector. Since the observations y are random, the loss function will also be random. We can then define the risk function $\rho(\hat{\beta}, \beta)$ as the expected value of the loss function. An ideal choice of estimator is one that minimizes the risk for every possible value of the β vector parameter space. However, minimum expected loss estimators for all elements of the parameter space rarely if ever exist except in trivial problems.

The following equation is distributed as an F-random variable with K and $T - K$ degrees of freedom and noncentrality parameter $(\beta - \beta_o)'(\beta - \beta_o)/2\sigma^2$:

$$(5) \qquad F = (b - \beta_o)'(b - \beta_o)/K\hat{\sigma}^2 .$$

When $\beta = 0$ or $(\beta - \beta_o) = 0$, the risk of the James and Stein estimator is $[K - ((T - K)/(T - K + 2))(K - 2)]$ and increases to K, the maximum likelihood risk, as $\beta'\beta$ or hypothesis error $(\beta - \beta_o)'(\beta - \beta_o)$ approaches infinity. At the origin the gain from using the Stein rule, equation (3), may be substantial, depending on T and K, and the gain is positive over a large part of the parameter space.

The moral of the Stein-rule result is that if choice is restricted to linear unbiased estimators the relative risk losses that accrue may be great. By using the Stein rule one can never do worse than the least squares rule, and there is a considerable range of the parameter space where one wins. Thus, simple rules, which result in nonlinear and biased estimators, can improve the sampling performance of the estimators when three or more parameters are involved. It has often been asked in a decision context why so much stress is placed on unbiased sampling theory estimators, which are correct on the average. Results from such rules as the Stein rule make the question all the more embarrassingly difficult to answer.

Traditional and Nontraditional Pretest Estimators

When there is uncertainty about the statistical model and thus restrictions or hypotheses to impose, a traditional way to proceed is by statistical hypothesis testing based on the data at hand, followed by estimation. The econometric literature abounds with exact and approximate tests for identifying sins of omission and comission relative to a variety of false linear models. Thus, for example, use is made of the test statistic F given in equation (5) to test the hypothesis $H_o: \beta = \beta_o$ against $H_a: \beta \neq \beta_o$. H_o is rejected if $F = (b - \beta_o)'(b - \beta_o)/K\hat{\sigma}^2$, which is distributed as a central F-distribution with K and $T - K$ degrees of freedom, is greater than some critical value c determined by the level of the test α. Another example is the stochastic assumption of zero-order autocorrelation where the Durbin-Watson test for autocorrelation is made. On the basis of this test, one goes with the original model or estimates the autocorrelation coefficient and transforms the statistical model. While this two-stage estimation rule is used in much applied work, the econometric literature is strangely silent as to the statistical consequences of making use of the formal and informal pretest or sequential estimation procedures. As recent work by Bock, Yancey, and Judge and others has shown, under criteria commonly accepted for defining "good" estimators, the traditional pretest estimator performs badly (larger squared error loss relative to the least squares estimator) over a large part of the parameter space.

However, worse is to follow—not only does the pretest estimator perform badly relative to the least squares estimator but it turns out that Sclove, Morris, and Radhakrishnan have exhibited an estimator that is uniformly superior to the pretest estimator over the whole range of the parameter space; that is, there exists another estimator that has a squared error loss that is equal to or less than the pretest estimator for all α and for all comparable α levels of significance and corresponding critical values c of the F-test statistic. Furthermore, for some critical values c, the Sclove, Morris, and Radhakrishnan estimator is uniformly superior to both the pretest and least squares estimators over the whole range of the parameter space.

The Sclove, Morris, and Radhakrishnan estimator is from the family of Stein-rule estimators and in fact results when the James and Stein estimator equation (4) is modified in the following way:

$$(6) \quad \delta_{01}(b) = I_{[c,\infty)}(F)(1 - c^*/F)(b - \beta_o) + \beta_o,$$

where $c^* = (T - K)(K - 2)K^{-1}(T - K + 2)^{-1}$ and $I_{(\cdot)}(F)$ = an indicator function that is 1 if F falls in the interval $(\cdot)$ and 0 otherwise. This means the original Stein-rule estimator equation (4) is modified by the rule that $\delta_{01}(b) = \beta_o$ if $F < c$. The Sclove modified Stein-rule estimator equation (6) demonstrates the inadmissibility of the traditional pretest estimators. Monte-Carlo sampling experiments by Yancey and Judge suggest that the losses from using the pretest estimator instead of the modified Stein rule are over a large part of the parameter space nontrivial in nature.

Concluding Remarks

In general, in both econometric theory and practice, sampling theory estimators for the linear statistical model are restricted to the linear unbiased class. For the researcher, however, who is interested in parameter estimation or prediction appropriate for choice or decision purposes, the statistical property of unbiasedness that yields an estimator that is right on the average may have limited usefulness. On the other hand, if one is willing to lay down the cross of unbiasedness and consider nonlinear biased estimators under squared error loss, the family of Stein-rule estimators introduced in the late 1950s dominate (i.e., uniformly superior over the parameter space) the least squares and maximum likelihood estimators under conditions normally found in practice. As Efron and Morris have noted, the Stein-rule estimators can be recommended on the basis of simplicity, generalizability, efficiency, and robustness (over distributional assumptions and performance

criteria). In spite of these qualities, there is little or no mention of these estimators in the econometric literature and applications of the Stein-rule procedures in economics have only started to be explored. Perhaps the time is ripe for applying one of the family of Stein-rule estimators as we work with our false linear statistical models.

Guided Analysis: An Experiment in Educational Technique

Timothy M. Hammonds

Everyone who takes a serious interest in undergraduate teaching is capable of reciting a list of comparatively recent innovations in educational technique. The terms individualized instruction, computer-assisted study, self-learning center, and self-contained learning module (to name a few) have been added to most of our vocabularies, if not to our actual teaching repertoire. Yet no single innovation has emerged as clearly superior to the others or to the conventional lecture format.

After attending numerous seminars on these techniques, the author has drawn two conclusions. First, variety is essential. This means that no single innovation is likely to sweep all others aside. Second, by concentrating on the method of delivery, it is possible to break material into units so small that students lose the power to integrate its concepts.

A new educational technique known as guided analysis is now evolving, which is consistent with both of the observations just cited. It promotes variety of delivery in the educational program, and it places heavy emphasis on concept integration. If one accepts Maslow's hierarchy of needs, then the highest level of intellectual activity is to become an independent decision maker.[1] This suggests that much of the advantage to be gained through higher education is in the ability to face a new problem area, to bring acquired knowledge to bear on unfamiliar ground, and to reach a workable decision by evaluating a variety of alternative solutions. This process is something more than the sum of individual building blocks of knowledge.

One of the major difficulties facing educators is that the transition from skill acquisition to problem solving in an unstructured environment is not a simple one. In an on-the-job environment, problems are often so ill defined that merely recognizing the real nature of the problem takes considerable skill. Guided analysis is designed specifically to bridge the gap between skill acquisition and unstructured decision making.

The objective of this paper is to describe the technique itself and to discuss its application in an experimental program at Oregon State University.[2]

Guided Analysis

The technique was developed at West Virginia University by Wales and Stager for an undergraduate engineering curriculum. Their name for the technique was "guided design," since engineering design situations were the focus. The term "guided analysis" is a corruption by this author in adapting the technique to economic analysis.

The technique itself is most appropriately thought of as a process that serves as a bridge between programmed learning (with some modifications) and the case study method. Case study techniques are useful in higher education. However, the philosophy of guided analysis is that successful performance in open-ended case study situations is a useful goal in undergraduate education but not a useful starting point. The stated goal of this technique is to enable the student to function effectively in the analysis of open-ended case studies that attempt to duplicate on-the-job situations. Instead of thrusting the student directly into this setting with little or no preparation, the process gradually "weans" students from structured problem analysis at a controlled rate. This is a direct rejection of the concept that students develop an adequate decision-making framework from the information delivered in their individual course without additional guidance.

Initially, the technique carefully leads students through an integration of preselected concepts and provides a detailed modeling of the decision-making process expected of a professional in their field. Subsequent problems maintain the emphasis on coursework integration, but the degree of specific guidance diminishes until a case study problem in its traditional sense can be handled. The initial problems of guided analysis make use of the programmed-learning concept with two modifications: the type of problem dealt with and the size of the mental leap between each question in the programmed sequence. In traditional programmed learning, the focus is specific skill acquisition, and a series of very specific problem assignments is utilized. In guided analysis, a series of questions and feedbacks gradually exposes a complex problem setting that the student must eventually grasp as a whole. In traditional programmed learning, the

---

Timothy M. Hammonds is an associate professor of agricultural economics at Oregon State University, Corvallis.

[1] Maslow's seventh need is self-actualization: the need to be an independent, adaptive, creative decision maker.

[2] The educational and psychological literature leading to the development of guided analysis will not be reviewed here. Interested readers are referred to Wales and Stager, Feb. 1972 and March 1972, and Bailie and Wales, 1975.

size of the mental leap required from question to question is small and remains small throughout the program. In guided analysis, the mental leap between questions begins small but gradually enlarges as each problem progresses. Toward the end of these initial problems, the student is required to make the mental leap of pulling together his individual pieces of information and analytic results to attack the problem as a whole.

A prime objective of guided analysis is to increase student tolerance of ambiguity. Ambiguity is an inherent component of most professional problem situations. Students not previously exposed to unstructured open-ended problems exhibit a tendency to view the attendant ambiguity as threatening (Budner). Guided analysis gradually moves the student from specific problem assignments to increasingly ambiguous settings as a method of easing the transition to a professional career.

In summary, guided analysis is a process for taking students from specific to open-ended problem settings at a controlled pace. A series of problems is used with the initial problems structured as modified programmed learning and the final problems structured as case studies. The initial problems provide specific guidance with the amount of guidance decreasing with each successive problem. During this process, stress is placed on integration of previous coursework, development of a professional decision-making framework, and increasing tolerance for ambiguity.

During the winter and spring quarters of 1975, this author conducted an experiment in guided analysis at Oregon State University. The winter quarter experiment consisted of a special project utilizing only guided analysis as a technique. The spring quarter experiment integrated guided analysis into the managerial economics class that was a regular part of the curriculum drawing agricultural economics seniors and first-year graduate students as the primary audience. Prior to the winter quarter of 1975, the project was outlined to the sophomore class and volunteers were solicited for a three-credit-hour class. Ground rules included a requirement of prior completion of a mathematics sequence covering calculus and linear programming. Acceptable courses were mentioned by number but with no mention of the specific skills that would be required. Three acceptable volunteers were enrolled and told that they would function as a problem-solving team. Word of the project spread, and an acceptable three-man team from the junior class also volunteered. They were told that class meetings would not be scheduled but that the teams were free to hold group meetings among themselves and to schedule instructor conferences either individually or by teams whenever they felt the need. They were also told that the problem would require periodic reports, some oral and some written.

The spring quarter project consisted of the same problem exercise as part of a managerial economics course taught entirely on a self-learning center basis. Each individual carried out the spring quarter exercise independently; no teams were used.

No further instructions were given prior to the project except for a general information sheet listing the following objectives: at the end of this course you should have (*a*) improved your ability to look at reasonably complex situations, similar to these you might actually face on the job, and to identify the fundamental problem that must be dealt with, (*b*) improved your ability to integrate material from your various undergraduate courses in practical problem settings, and (*c*) improved your ability to communicate your problem solutions in a form acceptable to business management.

The first portion of the project consisted of a seventeen-page handout entitled "An Introduction to the Process of Decision Making." The handout proceeds in programmed-learning fashion to introduce the steps necessary to reach a decision in any problem setting. It therefore provides a skeleton for problem identification, analysis, and action implementation that may be used throughout the course. The handout takes less than an hour to complete and requires no written response. It was originally developed by Wales and Stager (1974) for their engineering program and was used with their permission.

The project itself, the first problem of a guided analysis sequence, consisted of twelve written instructions and twelve written feedbacks. The technique of guided analysis is to present a series of handouts each giving problem information, followed by an instruction requiring the preparation of either a written or an oral report for the instructor. The instructions and feedbacks used in the experiment were developed by this author.

The philosophy of guided analysis is to place students in a setting that they might actually face as a professional in their chosen career. This strategy breeds personal involvement and provides an incentive for completing the assignment. An effort is made to create a specific need for learning or using a technique before the technique itself is introduced. The first handout appears below.

Conrad Assembly Company

Allan White is a junior in the Department of Agricultural Economics at Oregon State University. He is working for the Conrad Assembly Company during the summer and has been assigned to its comptroller, Mr. Stuart.

Mr. Stuart explains that at a monthly planning session of company executives in June, various members of the executive committee expressed dissatisfaction with the company's profit performance as reported in the six-month income statement just prepared. Conrad manufactures and sells combines.

Instruction CAC-1

Allan has lunch with Mr. Stuart his first day on the job. During lunch, Stuart suggests that an appropriate

summer project would be to look at company operations and suggests ways for improving profitability. What type of response should Allan make if he is interested in pursuing the project?

Each team member must write down the suggestions which Allan might make at this luncheon. Turn the suggestions in and obtain the first feedback.

Each response is greeted with a feedback in written form. The feedbacks present an acceptable solution to the previous instruction, additional problem information, and a new instruction. This provides the student with guidance as soon as he turns in his assignment. It has the advantage of instant feedback, as in programmed learning, while the material is still fresh in the student's mind. It has the disadvantage of requiring the instructor to anticipate the response. This can be handled in several ways. First, many of the simple instructions have obvious responses that may be anticipated without difficulty. Second, the intent of many instructions will be merely to channel the students' thinking, and therefore the feedback need not anticipate the response perfectly. Third, oral conferences may be scheduled before the feedback is given. These conferences provide the instructor with an opportunity to deal with an unanticipated response and to prepare the student for the written feedback that will follow.

The ability to provide proper anticipation without being overly heavy handed in instructional directions to students is an acquired skill. This author familiarized himself with the available literature and then attended a two-day workshop given by Wales and Stager. During the workshop, actual course materials under preparation were reviewed and criticized by Wales and Stager. After this initial exposure, the course materials were completed during the fall and pretested on the winter quarter students. A prime objective of the pretest was to detect unanticipated lines of inquiry and to insert additional or modified feedbacks to deal with those approaches. A guided analysis project probably would not prove successful without adequate pretesting.

Of course, it is impossible to anticipate every response. Guided analysis is designed to stimulate independence and creativity. There are two procedures that may be used to smooth any problems caused by a line of student reasoning not covered in the prepared feedbacks. Since the instructor monitors each response as it is turned in, there is opportunity to schedule a special conference to explore differences of opinion. The first alternative is to reconcile an unanticipated direction of response and to move the student back into the prepared sequence. If the student has initiated a line of inquiry that an instructor feels is worth pursuing, a second alternative is to allow the students to receive an oral series of feedbacks for that portion of their work.

The technique used for the first Conrad Assembly Company feedback was merely to channel student thinking into the decision-making process. The actual feedback is presented below.

Feedback CAC-1

If Allan forgot the proper way to begin the solution of an open-ended problem, he and Mr. Stuart might have discussed broad basic solutions. For example, they might have suggested: (1) expanding the sales force to generate more volume, (2) changing the pricing strategy for the company, (3) diversifying into new product lines, (4) closing down unprofitable operations.

Instruction CAC-2

Fortunately, Allan remembers that the proper first step is to define the problem and to state the basic objective. If you were in his position, what objectives would you have specified for his summer project?

Each group member must write down his objective and turn it in before the next feedback is obtained.

As the problem unfolds, the information provided with each feedback becomes more complex, and the analysis required becomes more difficult. This particular problem requires the students to recognize the difference between full cost accounting and contribution to overhead, to discover the need for linear programming in their analysis and utilize this technique in its graphic form, to discover the nature of opportunity cost associated with capacity for constraints, and to employ simple differentiation for input mix selection. Both teams during winter and all fifteen members of the spring class finished the project within a normal ten-week quarter, proceeding at their own pace.[3]

Evaluation

Student feedback on this project was uniformly enthusiastic. All students rated the course very good to excellent on organization, very good to excellent on learning emphasis, and good to excellent on overall rating of the course.[4] Written comments stressed appreciation of a course that emphasized independent thinking versus memorization and integration of coursework versus narrow focus.

However, one should not accept the evaluations from a single course as an adequate indicator of the worth of a new technique. Newness itself can easily bias student attitudes and therefore test results. A more comprehensive set of data collected at West Virginia University is available for a more meaningful analysis.

The concept of guided analysis (guided design)

[3] The nature of all twelve instructions and feedbacks is too complex to report here. The entire project covers twenty-six pages and is available from the author.

[4] A six-point rating scale was used with choices of very poor, poor, fair, good, very good, and excellent. Class size was not large enough to warrant dividing the students into an experimental group and a control group with a comparison of the resultant test scores.

was first applied on a broad scale in 1971 when the chemical engineering department at West Virginia University used it to develop an introductory freshman course, a two-credit course each semester for sophomores, a six-credit course each semester for juniors, and a ten-credit course block each semester for seniors. The first class to progress through this system graduated in May of 1974. The grade point averages of the last two classes who were exposed to guided analysis and of two previous classes who were not are presented in table 1. Four other engineering departments not on this program are included for comparison.

The only classes with a significant positive deviation (5% level of significance) from the college average G.P.A. (grade-point average) were the 1974 and 1975 chemical engineering classes exposed to guided analysis. The difference between 1972–73 and 1974–75 was not accounted for by better entering students. Bailie and Wales (1975) report no appreciable change in entering the students' high school G.P.A., Math A.C.T. (American College Test) scores, or composite A.C.T. scores.

An earlier effort measured the impact of guided analysis (guided design) on selected student personality variables. The results are reported in Tseng and Wales. Their test compared differences between pretest and posttest scores for a group of students in a guided analysis course and a group in a traditional lecture-laboratory program (three semester hours each). Results indicated a significant improvement for the guided analysis group over the control group in increased tolerance for ambiguity and increased internal orientation with regard to locus of control.

Tolerance for ambiguity was discussed earlier in this paper. Locus of control is an expectancy variable indicating whether an individual generally feels that the events of his life are under his own personal control or beyond his own influence (see Rotter for a more complete discussion). An external orientation suggests individuals with an expectation that events are unrelated to their own behaviors. An internal orientation suggests individuals with an expectation that events are under their own control. By encouraging an internal orientation, guided analysis develops a personality trait generally felt to be desirable for a professional (Tseng and Wales).

Table 1. Deviations from the Average College G.P.A. for Selected Departments, West Virginia University, 1972–75

	Graduation Year

Now for some personal observations on the technique. First, this approach overcomes a weakness in the case study method. In case study analysis, it is easy to focus primarily on the appropriate solutions to each problem. In guided design, a great deal of attention is focused on the method of arriving at those solutions. Students are provided with an opportunity to walk through the method of problem attack expected of a professional in their field.

Second, students are required to recognize the need for a technique previously learned and to use that technique in an applied problem setting. It is one thing to learn linear programming and then to be presented immediately with an exercise demanding its use. It is quite another thing to approach a problem having no advance knowledge of the techniques needed and to recognize the contribution possible from a linear programming approach. Reenforcement of techniques previously learned is essential. A lesson that should be coming through to educators everywhere is that the rate of decay for knowledge not frequently used is astonishingly rapid. Guided analysis provides the instructor with an opportunity to demonstrate the practical importance of various techniques by letting students discover these techniques outside of the normal classroom setting.

Third, students are required to integrate material from several previous courses, mathematics, accounting, and economics, for this particular problem. Based on comments from the winter and spring quarter students, the opportunity for coursework integration should begin early, probably during the sophomore year. Students easily lose sight of the overall direction of curriculum because their view is focused intensely on one piece at a time. The lament "when do we get a chance to put all this together?" has been heard, no doubt, by every advisor at one time or another.

If the reader agrees that one of the fundamental objectives of higher education is to create independent decision makers, then guided analysis holds great promise. The technique helps to prepare the student for a professional work environment and to develop enthusiasm and perspective for the individual skill techniques learned in the many undergraduate courses. It therefore may be used to provide a strengthened sense of direction in the instructional program.

The available evidence is strong enough to suggest that agricultural economists take time to familiarize themselves with the literature on this technique and to consider its use in their own programs.

An Integrated Approach to Farm Management Education

Kenneth M. Menz and John W. Longworth

Farm management lies well to the vocational end of the theoretical-vocational spectrum of tertiary courses in agricultural economics. Students and potential employers generally expect courses in farm management to contain some exposure to realistic management situations. However, as French has emphasized, it is "relevance" rather than exposure to the real world per se that is required. Furthermore, the application of farm management procedures and methods of pseudo real world situations may achieve relevance at the cost of education. If farm management instruction is to improve the "allocative ability" (Huffman, p. 96) of the students who participate in these courses, then the emphasis must be on concepts rather than on the mechanical use of tools (Boehlje, Eidman, and Walker, p. 196).

The aim of this paper is to describe an approach to teaching farm management that emphasizes self-discovery and relevance. Our technique takes maximum advantage of the motivation and involvement created by a complex, computerized management simulation known as the Central Tablelands Farm Management Game (CTFMG).[1] Our purpose is to show by example how a computer simulation exercise can be integrated with other traditional and nontraditional teaching techniques in an effort to achieve specific educational goals. "Effective teaching requires a flexible instructor who employs multiple teaching techniques which then create an environment where learning takes place both inside and outside the classroom" (Kendrick, p. 766).

By basing the course on a realistic management simulation, we aim to create a classroom environment in which the student learns to recognize management problems and then actually "reaches out for" analytical procedures to help meet the challenges posed by these problems. We view all components of the course as tools for assisting decision making, and we try to introduce each new tool at the time when it will have a maximum impact upon the student. Such timing is based upon consideration of student need (for the management tool) and upon the student's level of prior knowledge. Each tool is evaluated by students in an instructor-led group discussion after the initial usage and then periodically throughout the course in the light of new knowledge that may alter opinions. "Teaching and learning are frequently confused in higher education. . . . One can observe in any classroom that teaching can proceed in the absence of learning" (Kropp, p. 757). Our approach aims to place the emphasis on learning. This is facilitated by relatively small classes (less than thirty-five) and a generous course weighting in the curriculum. The only prerequisite for entry is a one semester microeconomics course. The percentage of students who will ultimately assume a managerial role is not known, but it is unlikely to exceed 20%. On the other hand, a very high percentage of recent graduates are employed in extension-research positions.

The Simulation Exercise in Action

The use of farm management games for instructional purposes is not new. Longworth (1970) presents a history of the gaming concept. The large number of games now available and their diversity presents a real challenge for an instructor who is considering adoption of this teaching technology. However, insufficient attention has been paid to exploring alternative ways in which games can be used for specific purposes (e.g., for learning how to use and critically evaluate farm management decision procedures). We outline below how the CTFMG represents the focus of our course in farm management. Perhaps our experience will encourage others to renew the search for a game suitable for their own purposes and to realize the enormous potential of such games.

Instruction in Planning Methods

Very early in the course each student is presented with a copy of the participants' manual for the CTFMG (Longworth 1973b). This booklet contains a complete description of their farm, the phys-

Kenneth M. Menz is a lecturer and John W. Longworth is a reader in the Department of Agriculture, University of Queensland, Australia.

The authors are grateful to Mike Hayward and Jim Gaffney for their contributions to farm management education at the University of Queensland.

[1] A slightly out-of-date description of the game including flowcharts and ALGOL 60 computer programs may be found in Longworth (1969a). The programs have since been revised and rewritten in FORTRAN IV. Operating manuals are available (Longworth 1973a, b). The CTFMG is the most widely used computerized farm management game in Australia (Lindner). Tanner reports a detailed survey of student reactions to playing this (and other) games.

ical and economic environment, the resource restraints, and the institutional limitations. It also indicates how the manager is to record his decisions. The enterprises from which each manager must choose include various types of pastures, oats, wheat, potatoes, and livestock (beef cattle, wool, and meat sheep).

Apart from the need to create long-term development and survival strategies, detailed decisions of the following type are required: (*a*) which pasture species to grow, what seeding and fertilizer rates to use; (*b*) what cultural and cropping operations are required and when; (*c*) when to buy and sell livestock and fodder; (*d*) when to perform the various livestock operations such as shearing and mating; (*e*) what machinery and buildings are to be purchased and when; (*f*) what fencing and clearing is justified; (*g*) whether long-term investment in additional land is warranted and, if so, when; (*h*) whether to borrow or use internal financing; and (*i*) which labor source to use—permanent or casual, farm labor or contractors.

As the participant manager has the opportunity to reassess the situation on a monthly basis, he must balance short-term contingency measures against longer-run strategic plans. Initially students can be overawed by being asked to "manage" a farm. However, a careful mix of instruction and consultation can guide them through this critical period.

At the time the participant manager takes over his farm, no activities are in progress. He must, therefore, formulate a whole-farm plan and begin to implement this plan. The formulation of the plan (in detail for the first year and in outline for three years at least) is a major task. The approach that we encourage is to begin with a lecture and subsequent calculation of simple activity budgets leading to the derivation of a matrix of gross margins. Once these calculations have been carried out for all feasible enterprises, the student managers select a combination of activities as a starting plan for their farm, using simplified manual programming. They are then encouraged to modify their initial plan based upon the results of partial and parametric budgets and to assess whether the modifications yield a "better" result. The partial budget is constantly used once simulated management begins, and it is important that students quickly learn to use this simple tool with speed, skill, and confidence. From the outset each manager is required to establish his own economic goals. Thus, the assessment of whether one plan is "better" than another is an individual and personal judgment each student manager must make.

At this stage, students begin to appreciate the need to clarify such concepts as variable and overhead (fixed) costs and the value of understanding the various measures of profit. In fact, this early stage (before the computer simulation begins) is an important segment of the course, since it also provides the student the opportunity to become familiar with the farm to be managed. Students unaccustomed to actively participating in the teaching-learning process take time to "warm up," and we have found it essential to be enthusiastically patient while students get adjusted to the challenges of the course.

Once each student manager is reasonably satisfied with his whole-farm plan, simulated management commences. All decisions are made and results received on a monthly basis, and this keeps the class "on its toes" for the first year of simulated activity. Students soon recognize deficiencies in their expectations and hence in their overall farm plans. By now they realize the relatively arbitrary nature of their original plan and begin to look for a more rational and objective approach. As their original approach involved simple programming using a matrix of gross margins and activity details, it is only a small conceptual step to construct a full linear programming (LP) matrix. Despite a lack of formal instruction most students can construct a simple LP matrix for their farm in less than three hours. To save time, we do not try to solve each student's matrix. Instead a fairly sophisticated LP matrix and solution for a "representative" farm, almost identical to their farms in resource endowments, is made available to each student manager. Having constructed their own simple matrix they have a good conceptual idea of what the more complicated (realistic) matrix means. Furthermore, the solution is also of great interest. They want to know how it was obtained. They perceive the enormous potential value of the information presented in the form of shadow prices, etc. They quickly recognize the great saving in calculating time once the matrix has been set up. On the other hand, upon trying to implement the LP solution, these classroom managers observe the problems of using "average" year coefficients, of neglecting overhead costs, and many of the other well-known limitations inherent in single-period LP models.

In this atmosphere it is easy to extend the programming concept to more advanced models. For example, a multiperiod LP model for the CTFMG is used to demonstrate how fairly simple modifications can be made to the static LP matrix to investigate the optimal firm growth path. Work is currently underway to develop a Monte-Carlo matrix for the CTFMG and, in time, a full range of programming models will be available.

Segments of the simulation model are extracted for exercises designed to illustrate the production function concept. Potatoes are a profitable crop in the CTFMG, and interest in the management of the potato enterprise is high. A fertilizer production function supposedly based on results obtained on an experiment station near their farm is made available to the students, and they are asked (and shown how) to determine the "optimal" levels at which to apply nitrogen and phosphorus to potatoes on their

farm. Not only is a practical application of production theory portrayed, but since students must act upon the basis of the results of their analysis, the following real world considerations are emphasized: (*a*) the precision and relevance of experimentally determined production functions; (*b*) the complications that weather and price risks introduce into production function analysis; and (*c*) the sensitivity of enterprise profits to suboptimal fertilizer rates. It is difficult, if not impossible, to convey adequately these ideas with a static practical assignment of the traditional variety. Students are shown how to incorporate the results of the production-function analysis into the LP model.

Instruction in Record Keeping and Control Procedures

Our experiences with the CTFMG strongly support the view of Boehlje, Eidman, and Walker (p. 195), who state that the "possibilities to add realism to undergraduate farm management education programs . . . appear unlimited." Although the monthly reports prepared by the computer contain all essential records, a number of supplementary records are desirable—e.g., graphing rainfall and the prices of livestock and fodder, recording and monitoring the use of labor, machinery, and livestock feed, and recording fertilizer treatments and stocking rates. The student quickly learns to appreciate the need for a systematic approach to handling the feedback from the dynamic system that he is managing (manipulating). Students frequently develop and design their own visual aids for this purpose.

Students are also given the opportunity to compare actual and budgeted financial results on a monthly (or quarterly) basis. Each student manager is encouraged to utilize the services of a commercial computerized accounting service that is available to farmers (Bureau of Sugar Experiment Stations, Sturgess and Hampson). This accounting service uses the Australia-wide standardized ACCRA code (Australian Committee for Coding Rural Accounts, Gay). At the beginning of the planning year, budgeted expenditures and receipts (coded by the students) are forwarded to the accounting service bureau. When simulated management begins, actual receipts and expenditures are similarly coded and processed by the accounting bureau. In return the student managers receive monthly (or quarterly) comparisons of actual and budgeted cash flows. This allows students to carefully monitor discrepancies between expectations and actual results. Such discrepancies often call for a change in plans, and students are required to test alternatives using partial budgets. As well as emphasizing the control function, this procedure saves a tremendous amount of arithmetic and familiarizes students with the benefits and mechanics of a computerized accounting service.

In any one run of the game, all farms are subject to the same stochastically simulated weather and marketing environment. The independent decisions of each manager are combined with these environmental factors to determine the outcome for his particular farm. The results for each farm are presented to the participant-manager not only as monthly physical and financial summaries but also in the form of a full set of annual managerial accounts. Samples of the output are contained in Longworth (1973b). After each year of management, students are asked to analyze these annual financial accounts. A diagnostic approach is emphasized based upon the comparative analysis of various measures of efficiency with other simulated farms (Burns). This is facilitated by the fact that all farms are subject to the same environment. Again students are required to translate leads obtained from the comparative analysis into improved plans by means of budgeting procedures.

Instruction in Decision Making

Management can be thought of as the art of making decisions with incomplete information. In an earlier article one of the present authors has discussed the use of management games for providing students with practice in this "art" (Longworth 1969b). In that article farm management is portrayed as a cyclical process, and it is hypothesized that management games enable both the "academic" and the "practical" halves of the management cycle to be demonstrated in the classroom. Our experience with the CTFMG strongly supports this hypothesis.

While all aspects of the course relate to decision making, the practical application of decision-theory techniques is given considerable attention. Students formulate a decision problem of interest to them based upon parameters from the simulation model. Past experience has shown that the use of "canned exercises" is of little value in teaching decision-theory concepts. The specification of a real problem within the decision-theory framework and the acceptance or rejection of the solution based upon various criteria are essential to a thorough understanding. In addition to providing a means by which students can experience all aspects of decision making in a managerial context, the CTFMG helps the student develop a balanced judgment regarding the desirability of formal decision analysis.

In another exercise dealing with risk, each student personally uses a recently developed computer management aid to evaluate the riskiness of various sheep enterprises within the CTFMG (Mill and Longworth). An additional benefit of this exercise is to provide some "hands on" experience in the use of computer terminals and library programs as decision-making aids.

Instruction in the Local (Australian) Institutional Framework

Income tax payments and other institutionally determined outlays frequently represent large unavoidable outlays of cash for Australian farmers. These payments must be made annually in the CTFMG. One important feature of the CTFMG is that the full set of managerial accounts prepared by the model for each farm at the end of each year are set out in the Australia-wide recommended format (Joint Committee on the Standardization of Farm Accounting). This adds realism to the game and leads directly to some understanding of accounting principles. To prepare an annual income tax return, the student must first convert these managerial accounts to tax accounts. This exercise emphasizes the fundamentally different concepts embodied in these two different approaches to farm accounting and highlights the way in which income tax considerations may have an important bearing on management decisions.

The simulation exercise also provides a useful reference point for class discussion of many other institutional issues such as estate planning, workers compensation laws, laws of contract, etc. One institutional-sociological issue we endeavor to raise is the relationship between the farmer and his advisors, e.g., extension agent, accountant, banker, private consultant. Many students gain new insight into this relationship when they act as clients of the commercial accounting bureau.

The Development of a Healthy Respect for Biological Information

Many of our students do not have a rural background nor have they undertaken any serious study of the soil-plant-livestock systems that are the bases of agriculture. The CTFMG provides an ideal framework in which these people can learn to appreciate the need for farm economists to have some basic understanding of these systems. The lack of knowledge (or even awareness) of the complexities and uncertainties that farm managers face is brought home to them in this classroom exercise. Inexperienced students, therefore, have the opportunity to develop an appreciation of the management problems faced by farmers. It is critical to their later success in actual management or in extension-research positions that graduates feel a sense of empathy towards the real world farm manager and his problems.

Our primary concern is that each student appreciate the whole-farm (systems) approach to farm management. They quickly learn to acknowledge that the farm is a closely interconnected system where any decision can have widespread ramifications. Economics is seen as the integrating force that holds the farming system together.

Field Trip

The CTFMG as used at the University of Queensland replaces formal lectures to a considerable degree. Students are given references and texts as they need them (as problems arise) and the occasional brief lecture-explanation during formal class contact periods. However, a large proportion of the students' time is spent in active, self-motivated learning.

In addition to the management simulation and associated exercises and lectures, all students undertake a case study of an actual farm. Students visit these farms in small groups, each group accompanied by an advisor. The purpose of the field trip is to compare and contrast management in reality with management of the simulated farm in the CTFMG. In particular, students are asked to consider and to report upon: (*a*) the influence of goals and attitudes of the manager in determining strategies, including considerations of household-business interrelationships; (*b*) problems of data collection in the real world; (*c*) the physical implementation segment of the management cycle; and (*d*) the additional constraints within which the real world manager must operate (social, technological, institutional, etc.).

An Assessment

The basic question of validation is a difficult one indeed. Tanner has reported a survey of students' attitudes towards various methods of teaching farm management. She is "of the opinion that farm management games do have a place in farm management teaching" (p. 60) although "the results of the student survey are not sufficient to establish clearly the superiority of any one of the methods" (p. 62). The course at the University of Queensland has evolved considerably since the time of Tanner's survey. We prefer to assess the additional costs of our current approach over and above the costs of running a course along traditional lines. If, as indicated below, the additional costs are small, then one does not have to demonstrate dramatic benefits to justify our approach. What then are the costs of using the CTFMG?

The time consumed in reflective decision making normally prevents a student from completing more than two or three years of simulated management if every student is assigned his own farm. If small groups of students (less than or equal to three) collectively manage each simulated farm, it is possible to complete at least five years of activity. Under this arrangement students can gain a better appreciation of the longer term consequences of their decisions. However, every student in each group needs to be completely responsible for at least one whole year of management decisions. Using the University of Queensland PDP-10 com-

puter, it takes thirty-three seconds of computer time to process the decisions for one month for ten farms. On this basis, thirty students operating ten farms for five years would use a maximum of thirty-three minutes PDP-10 computing time. However, the actual amount of computer time required will be less than this since the decisions for more than one month are processed together in the later years of the simulation. This modification significantly reduces the processing time required.

The other significant additional cost associated with the game is the labor required to check and input the decisions. Again on the basis of simulating ten farms, about one and a half man-hours per month of decisions is required. Over the fourteen-week semester we use, therefore, about ninety man-hours of labor more than would be the case with the conventional course. While a further charge for the game manual and other materials used in the simulation could be added, it is doubtful that these relatively inexpensive items are really additional costs. In the absence of the game, alternative exercises and associated materials would have been necessary anyway.

Given the physical measure of required computer and labor time above, the interested reader can calculate the additional costs associated with the kind of exercise described in this paper in his own teaching environment. At the University of Queensland the additional cost per student has been calculated to be $20 (Australian currency).

Conclusions

Recent contributions to this *Journal* have emphasized the need for an improved use of available teaching aids, materials, and methods for subjects such as farm management (Boehlje, Eidman, and Walker; French; Plaxico et al.; Sjo, Orazem, and Biere). In this paper we have described an approach based on a complex, computerized farm management game. Although we do not wish to push the analogy too far, our technique could be compared with the approach to M.B.A. training described by Cohen et al. Our conclusions are subjective and impressionistic, but they are overwhelmingly favorable. The integration of a carefully designed farm management game into a course in farm management greatly enhances the relevance of the course. Students learn to use and critically evaluate various tools of farm management and develop through experience an awareness of the problems that practical managers face. Many professions require such an awareness, and the course is considered to be beneficial for these people as well as for practicing managers.

In Quest of Learning-Teaching Excellence: A Viewpoint

John Sjo

Quality of teaching is so intangible that it is often difficult to recognize, measure, and reward. Outstanding instruction for one student may be miserable instruction for another. Techniques that motivate and excite one student may leave another unmoved. Both the student and the teacher sense and know when learning-teaching situations have been effective. But they are hard pressed to identify how those situations differ from ineffective situations. The changing student-teacher and faculty-administrator relationships and attitudes have affected the learning-teaching environment in universities. In this note, I discuss learning-teaching objectives and the present learning-teaching environment's impact on learning-teaching in agricultural economics.

Objectives of the Learning-Teaching Experience

Learning is very personal, occurring within the individual student but nurtured and brought forth by the teacher. Learning is gaining facts, understanding causal relationships among facts, using that understanding to solve problems and to develop sound judgment, and finally to create ideas that add to knowledge. Although learning can occur only within the individual, the teacher can increase the efficiency of the learning process. Efficiency depends upon the student's ability, motivation, and previous experiences as well as on the learning environment provided by the teacher. The teacher can provide an appropriate learning environment by encouraging, challenging, and exciting the student, by identifying material to be learned, and by providing sources of information. The learning-teaching environment is mutually created by the teacher and the student. Each student-teacher combination requires its unique conditions.

The identification and exposition of the learning-teaching process as best suited to undergraduate instruction in agricultural economics is needed if we are to have more effective learning-teaching situations. Some of our most dedicated and effective undergraduate teachers need to study philosophy of knowledge, theory of learning, and theory of communication and then apply those studies to develop knowledge transfer processes for learning-teaching agricultural economics. The subject matter, in our case agricultural economics, is fairly well mastered by most agricultural economists. Differences in the quality of teaching come less from differences in subject matter knowledge than from differences in the effectiveness of our interpersonal relationships with students.

Even without much knowledge of the learning process some agricultural economists have been great teachers. Great teachers have identifiable common characteristics. In addition to being a master of the subject they teach, they cause those who hear them to want to share that mastery. They accept students as worthy and significant individuals, are sensitive to their feelings and needs, and hear their views and ideas as meaningful. They awaken students to their full potential and urge them to develop it. They light the spark of creativity in students. But above all great teachers are honest in word and deed each time they touch a student's life.

Deterrents to Learning-Teaching

Effective teaching results primarily from the creativity and craftsmanship of the individual teacher. Factors such as quality of instructional facilities, equipment, institutional arrangements, and employment conditions are not the difference between outstanding and poor teaching. Excellence in the foregoing conditions does not assure outstanding teaching, and lack of facilities will not cause poor teaching. The great teacher rises above the conditions to fulfill his creativity and craftsmanship potential.

Yet, environmental factors can increase the incentive for a teacher of any level of competence to fulfill his or her potential. Today, certain factors are deterrents to effective teaching. Because each teacher perceives his environment differently and has had a different set of experiences, the deterrent factors will affect each teacher differently. In my judgment those affecting learning-teaching most are student evaluations of teachers, increasing size of classes, third party liability, formulated budgeting,

John Sjo is a professor of agricultural economics at Kansas State University, Manhattan.

Contribution No. 590, Department of Agricultural Economics, Kansas Agricultural Experiment Station, Kansas State University. Many of the ideas in this paper were developed by the SOB group (Sjo, Orazem, Biere) in its quest for excellence in undergraduate study at Kansas State University. The paper is a revision of a talk presented to the 1975 Student Section of the American Agricultural Economics Association meetings.

entrance and placement testing, and changing attitudes of teachers and students.

Student evaluations of teachers provide students with the opportunity to inform teachers about student reactions to their classes. Until recently, student evaluations were limited to use by the faculty member as a basis for improving instruction. Now, student evaluations are becoming a part of the administrative evaluation of faculty and affects tenure, promotion, and pay. There are several disincentives to quality teaching when student evaluations are used as a part of administrative decisions. Student evaluations, when given anonymously, may violate the teacher's rights because he is unable to confront and answer his critics. If the students identify themselves on the evaluation, they then must accept responsibility for the evaluation and may be subject to a liability suit.

Most student evaluation instruments emphasize how well the student liked the teacher rather than what the student learned. That criterion may mean that teachers will shift from effective teaching methods to popular ones that assure they are better liked. Being liked and being effective in teaching may not be the same thing. Galbraith has expressed concern that student participation in administrative decisions leads to a lowering of standards. If he is correct, current grade inflation may partially result from student evaluation of faculty.

Student evaluations of instruction are effective instruments for improving instruction but must be used cautiously for pay, promotion, and tenure purposes. Most students lack the experience to make judgments on overall faculty performances. More importantly, because they are at the university for so short a time, they are not accountable for those judgments.

Total expenditures for higher education have been increasing rapidly because of increasing enrollment, inflation, and new programs. To meet citizen concern about higher total expenditures, university governing bodies and administrators have sought ways to increase productivity. The usual way has been to increase the average size of classes. The number of students met is an inadequate proxy for educational output so citizens are misinformed when lower per-student-credit-hour expenditures are presented as evidence of increased teaching productivity. For many teachers the pressure to increase class size is a disincentive for effective teaching. We do not know what lessening the students' individual significance at the very time it is highly important to them does to their motivation for and attitude toward learning. Almost universally they resent mass treatment in large classes. Their whole future learning may be stunted.

There are alternatives to a larger class size when confronted with rising costs. Total enrollment may be restricted to keep costs down. Cost savings may be implemented in graduate, rather than undergraduate, instruction. Priorities among programs may be established and low priority, high cost programs terminated.

Student liability suits against faculty, administrators, and the university and faculty liability suits against administrators and the university are profoundly affecting teaching programs.[1] Administrators having to defend salary, promotion, and termination decisions either in or out of court have sought ways to reduce the chance of liability suits. They have developed and used objective methods of evaluation supported by quantitative data. They have found ways to spread responsibility, such as using student and faculty evaluation data and advisory and grievance committees.

Teachers concerned with having to defend their evaluation of students have attempted to devise testing and grading schemes that reduce the grounds for student grievances; for example, using only objective tests where the quality of the answer cannot be debated.

The threat of liability suits has caused some faculty to choose teaching methods having the least chance of physical harm to students. Class trips and field work in some instances have been discontinued because of possible liability. Often the safest methods are less than the optimum learning method. State universities as a part of the state government have been immune to suit. That made the individual teacher and student fully responsible for student safety. The Kansas Supreme Court in the "Wichita State football case" (most of the football team and coaching staff were killed in a plane crash) ruled the State (University) itself could be held liable and subject to suit. That means the teacher and student, at least in Kansas, no longer stand alone on the liability issue.

Reaction to the threat of liability has caused both administrators and faculty to narrow the range of evaluation and to put all individuals as near the mean as possible. Failure to differentiate quality of instruction by faculty and quality of learning by students removes what has been an important part of the achievement incentive. Without some new incentive, the quality of both learning and instruction will decline.

The trend to quantify information and to substitute predetermined formulae for subjective judgments in resource allocation decisions in universities has several implications for undergraduate instruction. Allocating resources based on the previous year's data has the effect of perpetuating trends. If agricultural economics enrollment was up last year, this year's agricultural economics allocation is increased. Increased resources may cause expansionary efforts not justified by the market for graduates.

In my judgment, U.S. education experts are ob-

[1] Kansas State University has a suit pending resulting from an application of its faculty evaluation procedures.

sessed with determining the learning potential of students. From kindergarten through graduate school, students are given batteries of "intelligence" tests. The justification has been that the information on a student's learning ability assists the teacher and counsellor. Unless used cautiously such information can have a negative effect on the student. Telling a student his scores indicate that he will be an A, B, C, or D student may become a self-fulfilling prophecy. Aren't the results of the tests influenced by too many variables to be taken too seriously? Isn't even one chance in twenty of harming a student too great a risk to take?

In the last decade faculty, students, and administrators have greatly changed certain attitudes. Most such changes have been positive (e.g., the greater openness of the interrelationships among the three groups and the demand for recognition of individuality), but some of the changes, perhaps a small portion of the total, are disincentives to learning and teaching. The negative feeling of students and many teachers toward learning facts, classifications, and definitions has caused teachers to shy away from requiring memorization. That type of learning has little prestige, yet it is important and necessary. Many teachers prefer teaching problem solving and evaluative learning. Students, in their demand for relevancy, judge their learning experience by how problem and present-time oriented it is. Asking today's students to use the storage capacity of their brains and to memorize tabs a teacher as hopelessly old fashioned. Yet most introductory courses are learning the language and facts of that discipline. Both require memorization.

We suffer today from the learning-can-be-fun syndrome, when in fact most learning is a tedious, time-consuming effort that requires self-discipline. Techniques making learning fun are best suited to the once-over-lightly courses. In-depth study often is plain drudgery, and teachers should be honest about it. Classroom instruction that places emphasis on learning through experience rather than through reading and listening may similarly cause students to underestimate the need for self-discipline and effort in the learning process.

The "too-theoretical" criticism of some students and faculty has sent us searching for immediate relevancy. A curriculum emphasizing methods of application (how to do something) shortchanges students. What they learn from that may have higher marginal value in the first years after graduation but diminishes rapidly thereafter. Concepts, principles, and theories must be the basis for agricultural economics instruction because they are relevant longest. It is twenty to thirty years after graduation that the professional peak of a career occurs. A curriculum must assure effectiveness then as well as in the first years. Theories are for the long pull—to be used again and again, to be applied to new problems as they occur.

Students and teachers often fail to realize that students have a responsibility in setting the learning environment. Their receptivity, creativity, and evaluative skills contribute to a teacher's effectiveness. A class cannot sit back and leave the learning-teaching environment to be set by the teacher alone. What happens between the student and the teacher is important; both share in the responsibility of creating an effective learning environment.

Until agricultural economists committed to improving teaching make as rigorous a use of learning theory, teaching methods, and communication technology as research economists have made of logic, mathematics, statistics, and computer technology, there will be little real improvement. Occasionally great teaching will occur through luck, intuitive ability, and trial and error. Outstanding learning-teaching thus resulting cannot be broken into separate processes, identified, classified, recorded, and passed from teacher to teacher. The real hope for more effective learning-teaching lies in an agricultural economist who is able to integrate learning-teaching knowledge and agricultural economics so that the process of developing teaching skills can be transferred among agricultural economists and taught as an integral part of a graduate program as research methodology is today.

A Note on Food Stamp Reform

Dennis H. Sullivan

In a recent paper, the food stamp voucher scheme was extensively analyzed in the framework of Pareto optimal redistribution (Giertz and Sullivan). This note employs a part of that analysis to compare the current scheme to one aspect of the Dole-McGovern "reform" proposal.

The present scheme sells a fixed quantity of food stamps to each recipient for a cost less than their face value.[1] The difference between the cost of the stamps and their face value is called the "bonus value" and is, in addition to any administrative expenses, the donors' cost. Figure 1 illustrates this situation on the recipient's indifference map (see Olsen). The horizontal axis measures food (F) and the vertical axis nonfood (Y), so that the slope of the budget line before subsidy ($Y'F'$) is $-P_F$, the relative price of food. The recipient is then offered the alternative of purchasing F^* food stamps, F^* being determined by family size, at a cost M^*, approximately 30% of income net of several deductions.[2] The recipient's feasible consumption set is then bounded by $Y'bcd$, where the line segment F^*c is of length $Y' - M^*$, and the "bonus value" measured in terms of food is the length of the line segment ac.

In the Dole-McGovern proposal, the "bonus value" worth of stamps is given to recipients free. In figure 1 this generates the feasible consumption set bounded by $Y'ed$, containing point c.

There are three possible outcomes. Outcome 1, illustrated by indifference curve U_1, is that the recipient optimizes by choosing a point between c and d, regardless of the scheme. Outcome 2, illustrated by U_2 and U'_2, is that the recipient chooses point c under the present scheme and some point along ec under the Dole-McGovern scheme. Outcome 3, illustrated by U_3 and U'_3, is that the recipient chooses a point along $Y'b$ under the present program (i.e., refuses to participate) and some point along ec (quite possibly e) under the Dole-McGovern scheme. Comparison of these outcomes serves to compare the welfare results of the schemes.

Outcome 1 is identical to that which would occur if the recipient were given an income transfer T^*. Thus, the recipient is indifferent among that income transfer and the two stamp schemes. The donor would also be indifferent if the actual outcome could be observed. Since the donor only observes the operation of the scheme and not its results, however, Dole-McGovern may still be preferred to an income transfer in that the recipient is known to consume at least the value of the free stamps. Also, the present scheme may still be preferred to Dole-McGovern in that the recipient is known to consume at least F^* food (see Giertz and Sullivan). The very fact that food stamps, not income, are the chosen forms of the transfer suggests that the donors have at least some concern about food consumption as opposed to low income (see Daly and Giertz).

In Outcome 2, the recipient's welfare is improved by changing to the Dole-McGovern scheme unless $MRS_{FY} = P_F$ at c, in which case the recipient is indifferent. Though the donors may for the reason stated above again prefer Dole-McGovern to an income transfer, the outcomes are identical. This suggests that the donors are unlikely to be indifferent between the current program and the Dole-McGovern scheme. In particular, if the utility interdependency is wholly goods-specific, so that the donors always prefer larger recipient food consumption to smaller (for any given donor cost), the Dole-McGovern proposal cannot possibly effect a change that meets the Pareto criterion. The recipient, after all, becomes better off precisely by reducing food consumption.

Outcome 3 is yet a different situation. The Dole-McGovern proposal removes all disincentives to participation (except, of course, any social opprobrium) and would thus doubtless increase the participation rate among eligible families. Barring the very unlikely situation that food is an inferior good, all of the newly participating families would consume more food. The problem is that the new participants run up the program's cost. Whether the benefits of increased participation exceed the additional costs is an empirical question with no obvious answer.

The main conclusion of this analysis is that the argument that the Dole-McGovern proposal will improve the welfare of the current participants at no cash cost to the Treasury is not very strong. It

Dennis H. Sullivan is an assistant professor of economics at Miami University, Oxford, Ohio.

This note is a direct outgrowth of discussions with colleagues J. Fred Giertz and Philip Cotterill.

[1] Purchases of one-quarter, one-half, or three-quarters of the total allotment at a pro rata cost are legally possible for all families except those that pay by deduction from welfare payments. Only about 7% of the recipients actually elect to make fractional purchases.

[2] For historical reasons, the proportion is somewhat less than 30% at the bottom of the income scale, while the effective marginal tax rate also occasionally varies from 0.3 for smoothing purposes.

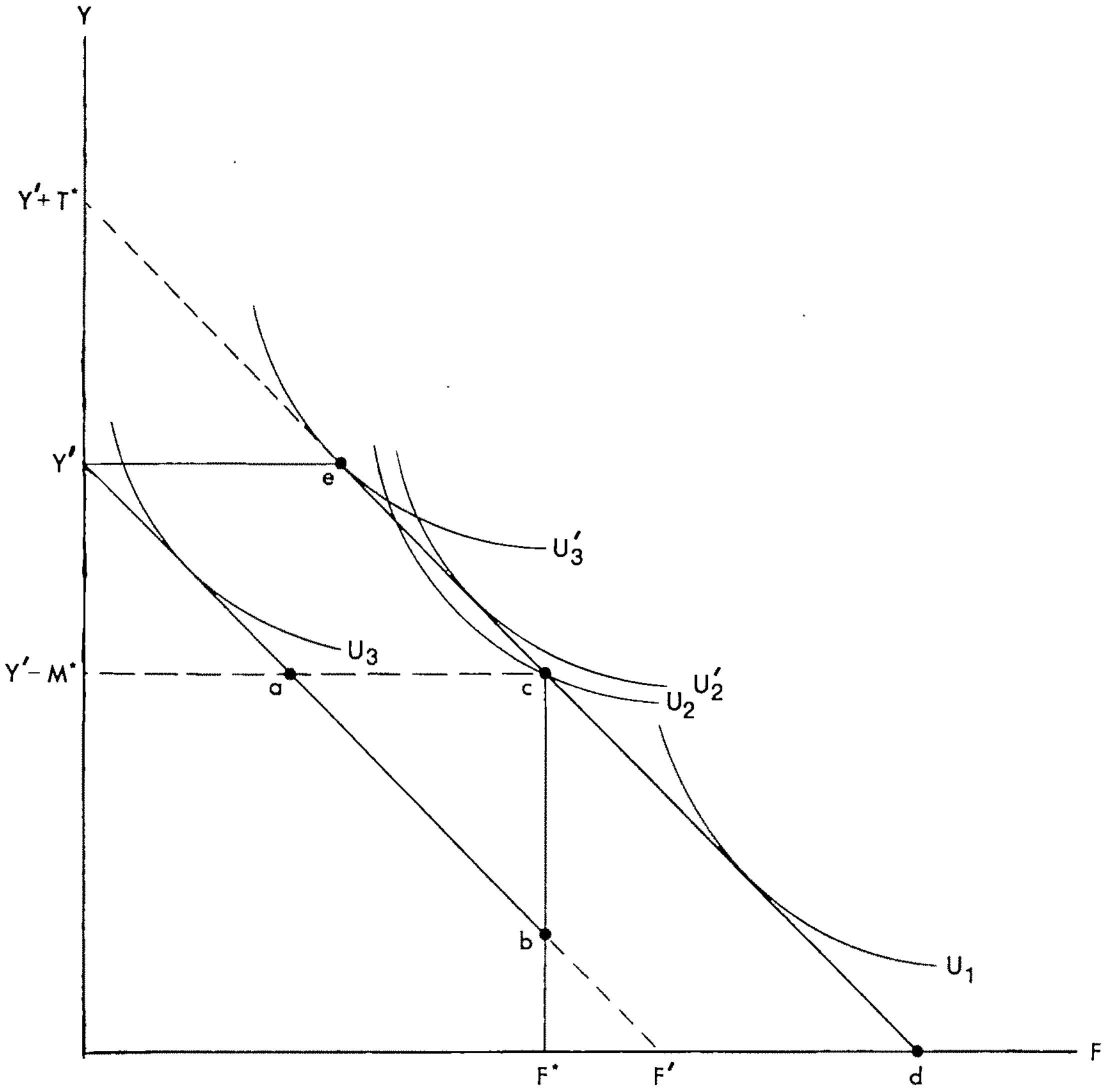

Figure 1. Outcomes of voucher schemes with various recipient indifference maps

ignores the manifest fact that the improvement in recipient welfare comes from recipients reducing their food consumption below the "nutritionally adequate" level used to establish F^* in the first place. If donors are concerned about ability to purchase an adequate diet and not about the purchase itself, food stamps should be abolished and replaced with a guaranteed income.

The real arguments for the Dole-McGovern proposal must therefore be sought elsewhere. The most obvious argument is the increase in participation. Though nonparticipating eligibles are difficult to count because of the complexity of the eligibility criteria, many believe that full participation would increase the number of recipient households by 50%. In so far as this high rate of nonparticipation indicates widespread presence of outcome 3 preference maps, rather than inertia or social stigma, the potential for increased participation is very great. The character of the new participants, however, is that they will not by preference consume a "nutritionally adequate" diet, or they would participate in the current program. We certainly may not infer that donors will be willing to subsidize small and uncertain increases in new participants' food consumption from the fact that they subsidize a large and certain level of food consumption by the current recipients. Since the Dole-McGovern scheme would actually cause some participants (outcome 2 variety) to reduce their food consumption, there is good reason to doubt that the Dole-McGovern reform reflects donor preferences, given the substantial costs.[3]

[3] The marginal conditions for the trade-off among participants, cost, and the stamp allotment are extensively discussed in Giertz and Sullivan, available from the author.

The potential for substantially increased participation suggests the existence of an additional set of interested parties: the agriculture industry. On the reasonable assumption that the increase in food consumption by outcome 3 participants exceeds any decrease by outcome 2 participants, demand for food would increase and so would factor rents to food suppliers. This external effect is not only of questionable magnitude but, unlike the interdependency between donor and recipient, is purely pecuniary and thus not a valid cause for public intervention under the usual externality criteria. Public finance texts do not determine the parameters of political coalitions, and the preferences of the farm bloc may be in practice the most important of all.

Nutrition and Nonnutrition Components of Demand for Food Items

A. A. Prato and J. N. Bagali

Much of the concern over inadequate human diets has been directed at less developed regions such as Africa, Latin America, and the Far East. Over the past decade, there has developed a growing concern over the causes and effects of inadequate nutrition in America (Mayer, Gifft). As a result, concerned individuals have argued and worked for national policies to alleviate nutritional inadequacies. The development of such policies can be aided by a better understanding of how nutritional and nonnutritional factors affect food choices.

Current knowledge pertaining to nutritional and nonnutritional determinants of food demand is based on studies in four areas: (*a*) estimation of conventional food demand and expenditure relationships, (*b*) estimation of nutrient demand relationships, (*c*) formulation of minimum-cost human diets, and (*d*) impacts of food and nutrition programs on nutrient intake. The first group of studies provides estimates of food consumption or expenditure elasticities with respect to prices, income, and other household characteristics (Raunikar, George). In the second group are studies that estimate demand relationships for specific food nutrients by regressing the nutrient intake associated with actual food consumption on traditional price, income, and household variables (Adrian and Daniel, Kelsey). Studies in the third group concentrate on formulating diets that satisfy a variety of nutrition and nonnutrition constraints (Foytik, Langier, Balintfy, Prato). The fourth group analyzes nutrient intake of families receiving various forms of food assistance and/or nutrition education (Feaster, Madden, Gorham).

While these studies have contributed to the understanding of food purchase behavior or diet choices, the underlying relationship between diet selection and food purchases is not well understood. This lack of understanding is due in part to the absence of behavioral models and empirical studies that deal specifically with the nature and relative importance of the nutritional and nonnutritional factors that affect food demand.

The objectives of this paper are to develop a model for measuring the nutrition and nonnutrition components of demand for food products, to compare the nonnutritional demand structure of forty-two meat, poultry, and fish products over different consumer groups, and to determine how food expenditure, region, and urbanization affect the nonnutrition component of demand for these food products.

A. A. Prato is an associate professor in the Department of Economics at Colorado State University, Fort Collins, and J. N. Bagali is a former graduate research assistant in the Department of Food and Resource Economics at the University of Florida, Gainesville.

Model Specification

The model assumes that the consumption of any food item can be decomposed into nutrition and nonnutrition components. Let $q_i^{(1)}$ represent the nutrition component, $q_i^{(2)}$ the nonnutrition component, and q_i the observed consumption of the ith food. The model specifies that $q_i = q_i^{(1)} + q_i^{(2)}$. While additivity does not allow for interaction between nutrition and nonnutrition components, it simplifies the derivation of $q^{(1)}$ and $q^{(2)}$ from q.

Let $z = Bq$, where z is an $r \times 1$ vector of nutrients actually consumed by the individual, B is an $r \times n$ matrix of nutrition coefficients that is identical over all consumers (b_{ij} is the amount of nutrient i contained in food j before cooking), and q is an $n \times 1$ observed food consumption vector. $q^{(1)}$ is defined as the food vector that provides z at minimum cost, i.e., $z = Bq^{(1)}$ and $p'q^{(1)}$ is a minimum so that $p'q \geq p'q^{(1)}$. Alternative specifications of $q^{(1)}$ are possible. For example, $q^{(1)}$ could be defined as the food vector that provides the recommended dietary allowances (RDA's) of nutrients established by the National Research Council. While the RDA specification for $q^{(1)}$ is appealing from a nutrition standpoint, it is less satisfactory in a behavioral sense because not all consumers know the RDA's. Moreover, consumers may not attempt to achieve their RDA's even if they have knowledge of them.

If $q = q^{(1)}$, the consumer is selecting those foods that provide z at minimum cost. This reflects nutritional efficiency in food choices. If $q \neq q^{(1)}$, it is possible for the nonnutrition component of a food item ($q_i^{(2)} = q_i - q_i^{(1)}$) to be positive or negative, which implies nutritional inefficiency. This means the nutrients were not obtained from the most economical (minimum-cost) foods.

Two hypotheses are tested. The first hypothesis is that nutritional inefficiencies exist in consumers' food choices. The second hypothesis is that nutritional inefficiency increases with respect to residual food expenditure ($e^{(2)} = m_f - p'q^{(1)}$, where m_f is total food expenditure).

The first hypothesis is tested by estimating $e^{(2)}$ for different consumer groups and observing the frequency with which it is positive or negative. The second hypothesis is tested by estimating an Engel function for each food item. This function relates residual expenditure on the ith food item ($e_i^{(2)} = p_i q_i^{(2)}$) to total residual food expenditure ($e^{(2)}$). A positive relationship supports the second hypothesis.

Food items can be aggregated into four major groups: (*a*) meat, poultry, and fish, (*b*) vegetables and fruits, (*c*) milk, cream, and cheese, and (*d*) other food items. In 1965, these groups accounted for 36%, 18%, 13%, and 33% of total household food expenditure in the United States (USDA). The nutrition coefficients matrix (B) was only available for the first group (as defined in the 1965 USDA Household Food Consumption Survey). For this reason the empirical analysis was limited to the forty-two food items in the red meat, poultry, and fish group. The spring sample of households was used because it is more representative of annual U.S. food consumption patterns and three times larger than samples for the other seasons (7,500 versus 2,500). The survey reports average quantity consumed and expenditure per household per week on each of forty-two items in four regions, Northeast (NE), North Central (NC), South (S), and West (W), in three urbanizations, urban (U), rural nonfarm (RNF), and rural farm (RF), and in several income classes.

Procedure

Nutrient intake vectors contained eleven nutrients: z_1 = energy (calories), z_2 = protein (grams), z_3 = fat (grams), z_4 = carbohydrates (grams), z_5 = calcium (milligrams), z_6 = iron (milligrams), z_7 = vitamin A (international units), z_8 = thiamine (milligrams) z_9 = riboflavin (milligrams), z_{10} = niacin (milligrams), and z_{11} = ascorbic acid (milligrams).

Letting j denote region, k urbanization, and l income class, $\bar{q}_{jkl}$ is the average food consumption vector and $\bar{e}_{jkl}$ is the average food expenditure vector for the jkl class. The average price vector $\bar{p}_{jkl}$ was computed by dividing each element of $\bar{e}_{jkl}$ by the corresponding element of $\bar{q}_{jkl}$. All consumption, expenditure, and nutrient intake vectors were converted to per capita figures using the average family size (r_{jkl}), i.e., $\tilde{q}_{jkl} = \bar{q}_{jkl}/r_{jkl}$, $\tilde{e}_{jkl} = \bar{e}_{jkl}/r_{jkl}$, and $\tilde{z}_{jkl} = \bar{z}_{jkl}/r_{jkl}$. The nutrition components were obtained by solving the following linear programs for $\tilde{q}_{jkl}^{(1)}$: min $\bar{p}'_{jkl}\,\tilde{q}_{jkl}^{(1)}$ subject to $B\tilde{q}_{jkl}^{(1)} \geq \tilde{z}_{jkl}$ and $\tilde{q}_{jkl}^{(1)} \geq 0$, where $\tilde{z}_{jkl} = B\tilde{q}_{jkl}$ is the vector of consumed nutrients. Since the data contained 104 region-urbanization income (RUI) classes, the linear programming models yielded 104 solution vectors. These were then used to derive the nonnutrition component and residual expenditure for each RUI class, namely, $\tilde{q}_{jkl}^{(2)} = \tilde{q}_{jkl} - \tilde{q}_{jkl}^{(1)}$ and $\tilde{e}_{jkl}^{(2)} = \bar{p}'_{jkl}\,\tilde{q}_{jkl}^{(2)}$.

Two statistical models were used to analyze the nonnutrition component. The first model is obtained by constrained maximization of a Stone-Geary utility function (Stone, Geary). This yields the following linear expenditure system after correction for induced heteroscedasticity (Kmenta, pp. 256–58):

$$\tilde{y}_{ijkl}^{(2)} = \beta_{ijk}\,\tilde{m}_{jkl}^{(2)} + v_{ijkl}, \tag{1}$$

where $\tilde{y}_{ijkl}^{(2)} = \sqrt{n_{ijkl}}\,\tilde{e}_{ijkl}^{(2)}$, n_{ijkl} = the number of families consuming good i in each RUI class, and $\tilde{m}_{jkl}^{(2)} = \sum_{i=1}^{42} \tilde{y}_{ijkl}^{(2)}$. Equation (1) can be fitted by ordinary least squares to obtain an estimated residual expenditure slope for each of the forty-two meat, poultry, and fish items in each region-urbanization class (504 slopes in total).

The second statistical model consists of a single equation for each commodity that combines the observations over all region-urbanization classes. The following analysis of covariance model is used (Scheffé, pp. 207–13):

$$\tilde{y}_{ijkl}^{(2)} = \mu_i + \alpha_{ij} + \gamma_{ik} + \beta_i\tilde{m}_{jkl}^{(2)} + \epsilon_{ijk} + v_{ijkl}, \tag{2}$$

where μ_i is the overall mean, α_{ij} is the region effect, γ_{ik} is the urbanization effect, β_i is the residual expenditure slope, ϵ_{ijk} is an interaction term, and v_{ijkl} is a disturbance term assumed to be spherical normal. Estimation of equation (2) for each of the forty-two food items was based on 104 observations.

Results

Linear programming was used to obtain the minimum-cost diet (nutrition component) for each of 104 RUI classes. Table 1 gives the twenty-four meat, poultry, and fish items that entered these diets most frequently. Except for sirloin steak, the items conform to a priori expectations concerning economical and nutritious meat items. Regression results based on equation (1) indicate that with the exception of six items the β_{ijk} (or simply β) coefficients (estimated residual expenditure slopes) are positive. With the exception of a few veal, lamb, and poultry items, between one-half and two-thirds of the β coefficients for each commodity (when estimated for all region-urbanization categories, for regions over all urbanizations, and for urbanizations over all regions) are statistically significant at the 5% level. Elasticities computed from the β coefficients are generally greatest for beef products, which is consistent with results obtained in other studies (George). Elasticities for cured ham, bacon, and fresh pork chops are relatively high, although somewhat below elasticities for ground beef and round steak.

Except for salt pork, the remaining pork products

Table 1. Economically Nutritious Meat, Poultry, and Fish Items Based on Least-Cost Diets[a]

Food Item	Frequency with Which Item Entered Least-Cost Diets (104 Possible)	Rank Based on Relative Frequency
Liver	104	1
Salt pork	90	2
Sirloin steak	79	3
Salmon, canned	75	4
Lamb, ground	20	5
Other variety meat	20	5
Turkey	19	6
Chicken	18	7
Fish, frozen	9	8
Other fresh pork	9	8
Bacon	5	9
Beef, ground	3	10
Beef stew	3	10
Ham	3	10
Other cured pork	3	10
Beef roast, rump	2	11
Other raw beef	2	11
Pork loin	2	11
Veal, ground	2	11
Beef, canned	1	12
Frankfurters	1	12
Lunch meat, canned	1	12
Sausage	1	12
Tuna, canned	1	12

[a] An economically nutritious food is one that entered at least one of the 104 minimum cost diets computed for the 104 observations.

have positive but small β coefficients. Coefficients for lunch meats are positive and rather high for uncanned meats and frankfurters. The coefficients for chicken are greater than for the more popular beef items, while coefficients for turkey are negative except in two RUI classes. Fresh fish and canned tuna have the highest β coefficients in the fish group. Canned salmon exhibits negative β coefficients.

Results for the minimum-cost diets and the regression analysis based on equation (1) support the hypothesis that nutritional inefficiency exists in food consumption. Evidence consists of (*a*) the large number of popular food items, especially beef and chicken, that do not appear to be economically nutritious foods (table 1), (*b*) the fact that residual expenditure ($e^{(2)}$) is positive for all 104 consumer groups analyzed, and (*c*) the predominance of positive and significant β coefficients. The latter finding also supports the second hypothesis because positive and significant β coefficients imply that the nonnutrition component increases with respect to residual expenditure.

Results for equation (2) show that β_i (residual expenditure slope) is positive and significant (5% or less) for all four beef steak items; chuck and ground beef; pork chops, pork loin, and ham; veal chops; uncanned lunch meat; chicken and canned tuna. Region and/or urbanization effects are statistically significant for round steak, porterhouse, and other steak; ground beef; pork chops and ham; veal chops; and fresh fish. Interaction effects are statistically significant for ground beef, salt pork, veal chops, and fresh fish.

Table 2 reports the frequency and rank of urbanization (γ_k) and region (α_j) effects for seven major meat groups composed of the original forty-two items. Frequencies show the proportion of estimated main effects that are positive. A positive (negative) main effect implies that the nonnutrition component for that region or urbanization is above (below) the overall mean nonnutrition component (μ). For ease of interpretation, interaction effects are ignored.

Nonnutrition components for beef and pork are highest in urban areas and lowest in rural nonfarm areas. Beef's component is highest in the West and lowest in the South, while the opposite holds for pork. For the remaining food groups, excluding poultry, the nonnutrition component is greatest in urban areas and lowest in rural farm areas. Veal and lamb components are greatest in the Northeast. Variety meats are highest in urban and rural nonfarm areas and the West. Fish is highest in urban areas and the Northeast. In summary, rankings show that urban areas have the highest nonnutrition component over all food groups except poultry. Regional differences are less systematic. However, the Northeast or West has the highest component for all groups except pork.

Table 2. Relative Importance of Nonnutrition Component by Region, Urbanization, and Food Group

	Urbanization Effect			Region Effect			
Food Group	Urban	Rural Nonfarm	Rural Farm	NE	NC	S	W

Policy Implications and Limitations

Knowledge of the nutrition and nonnutrition components of the forty-two meat, poultry, and fish items analyzed here can be helpful in the design and administration of programs to alleviate nutritional deficiencies. Based on these components, it is possible to classify meat items according to the relative importance of their nutrition and nonnutrition components. Consumption of those items having a relatively large nutrition component (as demonstrated by the linear programming solutions) should be encouraged, while consumption of items having a relatively large nonnutrition component should be discouraged.

In cases where a family is receiving nutrition education, the program aide could encourage the use of foods having important nutrition components (as defined herein). Results for the forty-two food items analyzed in this study suggest that the ability of income-enhancing food programs, e.g., food stamps, to increase the intake of high nutrition component foods may be quite limited. In particular, even though higher income families spend more on food, they do not necessarily have nutritionally better diets because the additional income is spent on foods having high nonnutrition components. The evidence also shows that the relative economic efficiency with which additional food nutrients are acquired decreases with respect to food expenditure.

For the majority of U.S. households that do not participate in food and nutrition programs, alternative approaches to reducing nutrient deficiencies are required. One possibility is to fortify and enrich those foods having significant nonnutrition components. This approach essentially boosts the nutrition component of foods favored for nonnutritional reasons. Changing the methods of processing and preparing foods could enhance their nutritional component.

The method and analysis presented here have certain limitations. The linear expenditure system is better suited to broad complementary categories of commodities than to individual food items. Moreover, the linear Engel curves derived from this expenditure system may not be appropriate over wide income or food expenditure ranges. Many of the socioeconomic variables that are likely to affect the nonnutrition component could not be accounted for in this study due to the aggregated nature of the data. Use of less aggregated household data, e.g., data on individual families, would permit a more comprehensive analysis of nonnutrition components.

Additivity of nutrition and nonnutrition components is somewhat restrictive because it precludes interaction effects. Significant interactions would diminish the appropriateness of the method and the accuracy of the results. The composition of the nutrition component is also restrictive because it includes only nutrients for which recommended intake levels have been established. Other nutritional motivations such as bulk and variety of diet could be incorporated into the model if standards pertaining to these factors were available.

Finally, the empirical analysis is based on only forty-two meat, poultry, and fish items. Exclusion of other food items leads to nutrition components that are suboptimal with respect to all foods; that is, the consumed nutrients are not really obtained in the most efficient manner because food selections

outside the meat-poultry-fish group are not permitted. Accordingly, the empirical analysis should not be judged in terms of its accuracy but rather as an example of how to apply the theoretical model and interpret results. Clearly, the analysis needs to be expanded to all food items. Despite these limitations, this paper presents one approach to analyzing the simultaneous effects of nutrition and nonnutrition factors on the food and diet choices of U.S. households.

Possible Implications of Voids in USDA Cattle Slaughter Data

Kendell Keith and Wayne D. Purcell

An important service provided by the U.S. Department of Agriculture is the gathering and publication of production, price, and related data on major agricultural commodities produced and marketed in the United States. Much of the agricultural research conducted in land grant universities, branches within the USDA, and private industry is based on such data. Since commodity analysis is a major justification for gathering and publishing the data, the extent to which the published series match the data needs of analysts should be continually examined.

The primary purpose of this note is to discuss a void in the set of published cattle and calf slaughter data that seriously restricts fundamental analysis of the cycle in cattle numbers. Measurement of the response by beef producers to changes in the level of cattle prices is first complicated by the fact that beef and dairy slaughter are reported only as an aggregate figure. The analytical value of published slaughter series is hampered even more by the absence of a breakdown of nonfederally inspected slaughter into the four classes of cattle. Three analyses are employed to demonstrate that the actual magnitude of cow slaughter and interyear variation in cow slaughter are well disguised in existing data. Three areas of research are then outlined to demonstrate how the missing data series limit analysis.

Presently, monthly slaughter series are published for the following categories: (*a*) total commercial cattle slaughter, (*b*) total federally inspected cattle slaughter, (*c*) federally inspected cattle slaughter subdivided into four classes—steers, heifers, cows, and a class called bulls and stags, (*d*) commercial calf slaughter, and (*e*) federally inspected calf slaughter. To persons unfamiliar with livestock slaughter data, omissions in the reported data of potential importance to analysts are not obvious. Slaughter data not contained in these categories are percentages of male and female calf slaughter and commercial nonfederally inspected cattle slaughter subdivided into the classes of steers, heifers, cows, and bulls and stags.

Since 1944, federally inspected slaughter has been published for the identified classes of steers, heifers, cows, and bulls and stags. Commercial slaughter not under federal inspection has never been separated into classes. To estimate total commercial slaughter in the various classes, most researchers in the past have assumed that the breakdown of federally inspected slaughter is a usable approximation of the breakdown of total commercial slaughter. Because federally inspected cattle slaughter currently makes up about 90% of all commercial cattle slaughter, any estimation error attributable to the assumed comparability between total commercial and federally inspected slaughter would appear to be small. The error in estimation by the technique described, however, is likely much larger than most researchers presume. Considerable evidence suggests total commercial cow slaughter is underestimated by applying the percentage breakdown of federally inspected slaughter to nonfederally inspected slaughter.

But an accurate measure of cow slaughter appears to be the one series most essential to productive research dealing with cattle numbers and the beef cycle. The total number of cows slaughtered is a determinant of future cow inventories, which in turn measure slaughter potential and the phases in each recurring cattle cycle. For decision purposes, therefore, accurate measures of interyear developments in cow slaughter become very important.

Because total commercial cow slaughter has never been reported, the hypothesis that cow slaughter is the principal component of cattle slaughter in plants not under federal inspection is difficult to test. In the following section the results of three separate analyses are presented. None of the analyses constitute a conclusive test of any hypothesis as to the level of cow slaughter in nonfederally inspected plants. But taken in combination, the findings offer strong indication that cow slaughter as a percentage of total slaughter is substantially larger in nonfederally inspected plants.

Cow Slaughter Calculated from Replacement Heifer Inventories

Beginning in 1965, the USDA modified several of the data series on cattle inventories. Two additions to the published inventory series were heifers intended for replacement in the beef cow herd and heifers for replacement in the milk cow herd. By making a few reasonable and defensible assump-

---

Kendell Keith is a research assistant and Wayne D. Purcell is a professor of agricultural economics at Oklahoma State University, Stillwater.

tions, figures on replacement heifers can be utilized in calculating estimates of cow slaughter.

During a recent nine-year period, January 1965 to January 1974, the inventory of cows on farms increased 5.513 million head (USDA). Assuming an annual cow death loss of 2.7%, total cow deaths in the years 1965–73 were 11.931 million head.[1] The total number of heifers held back for herd replacement for the nine-year period was 94.078 million head. Assuming over the nine-year interval the sum of the annual differences between heifers intended for replacement and actual replacement heifers entering the herd was 0, equation (1) may be used to approximate total commercial cow slaughter for the period:

$$\text{(1)}\quad \begin{array}{lcl} \text{(Heifers)} - \text{(Growth)} & & \\ 94.078 \; - \; 5.513 & & \\ \quad - \text{(Deaths)} & = & \text{(Cow Slaughter)} \\ \quad - \; 11.931 & = & 76.634. \end{array}$$

Total federally inspected cow slaughter for the nine-year period was 52.150 million head. Estimated nonfederally inspected cow slaughter would therefore be 24.484 million head (76.634 − 52.150).

Total commercial slaughter that was not federally inspected was 43.433 million head for the January 1965 through December 1973 period. Using the estimate of 24.484 million head, an estimated 56.4% of the commercial slaughter not under federal inspection was cow slaughter.

Cow Slaughter from Cow Inventories and Replacement Rates

The analysis used above is not applicable for any period before 1965, the year in which the published series on replacement heifers were begun. Another method of estimating cow slaughter over a period of several years that uses a different set of assumptions can be developed. Equations (2) and (3) present the relationships:

$$\text{(2)}\quad \text{Milk Cow Slaughter}_{t-1} = \left[\frac{(MCH_{t-1} - MCH_t)}{2\, MCH_{t-1}} + MRR - 0.027\right] MCH_{t-1},$$

and

$$\text{(3)}\quad \text{Beef Cow Slaughter}_{t-1} = \left[\frac{(BCH_{t-1} - BCH_t)}{2\, BCH_{t-1}} + BRR - 0.027\right] BCH_{t-1},$$

where MCH = milk cow herd, BCH = beef cow herd, MRR = estimated milk replacement rate needed to maintain a constant herd size, BRR = estimated beef replacement rate needed to maintain a constant herd size, and t = time (years).

[1] The cow death estimate of 2.7% allows for a maximum of a 1% death loss in mature cattle other than cows during the period. In comparison, a lower estimate of 2.4% results in an average of a 1.4% death rate in other cattle, while a higher estimate of 3% is associated with a 0.56% death estimate in cattle other than cows.

The only major assumption used in equations (2) and (3) was one concerning the nature of growth or decline in cow inventories. The asserted relationship is that increases (decreases) in the inventory of cows is caused by equal proportions of decreased (increased) cow slaughter and increased (decreased) holdings of replacement heifers. This assumption is less defensible than those utilized in the previous analysis. The two equations are not likely to furnish an accurate measure of cow slaughter over a short interval. But, for the time period of study in this analysis, the assumption is reasonable and provides a means to generate useful estimates.

The death rate of cows was again assumed to be 2.7% per year. Average replacement rates required to maintain a constant herd size were calculated on the basis of heifers intended for replacement during 1965–74. For beef cattle the replacement was 0.1611 per year, and for dairy cattle the replacement rate was 0.2935 per year. Given that these two figures were estimates for the 1965–74 period and might not be particularly applicable to the 1950–64 period, other possible replacement rates were considered and used in equations (2) and (3) to estimate total commercial cow slaughter for the fifteen-year period. Table 1 displays the results of the slaughter estimations.

Total commercial cattle slaughter for the 1950–64 period was 361.048 million head of which 86.499 million head were not federally inspected. Federally inspected cow slaughter for the period was 74.120 million head. Given the possible range on total commercial cow slaughter of 109.13 to 129.51 million head, a range of 40.5 to 64.0 can be placed on cows as a percentage of total nonfederally inspected slaughter.

Relation of Federally Inspected and Nonfederally Inspected Slaughter

As a final test to determine if cow slaughter is the major component of nonfederally inspected commercial slaughter, several equations were estimated. Annual federally inspected cow, steer, and heifer slaughter were tested to see how well they explained year-to-year variations in nonfederally inspected slaughter. Regressions were run on annual time-series data from 1950 to 1973:

Table 1. Estimated Commercial Cow Slaughter Given Alternative Average Replacement Rates, 1950–64

	Milk Replacement Rate		
Beef Replacement Rate	0.29	0.27	0.25
	---- million head ----		
0.16	129.51	123.07	116.63
0.15	125.76	119.32	112.88
0.14	122.01	115.57	109.13

$$(4)\quad SLAT = \underset{(0.733)}{5037.29 + 0.1957\, STR} \underset{(1.23)}{- 158.68\, TIME}, \quad R^2 = 0.24 \quad S = 906.12;$$

$$(5)\quad SLAT = \underset{(0.494)}{6155.13 + 0.1886\, HEIF} \underset{(0.97)}{- 132.11\, TIME}, \quad R^2 = 0.23 \quad S = 912.35;$$

and

$$(6)\quad SLAT = \underset{(2.52)}{3988.71 + 0.4677\, COW} \underset{(3.36)}{- 82.84\, TIME}, \quad R^2 = 0.40 \quad S = 804.01;$$

where $SLAT$ = commercial slaughter not federally inspected, STR = federally inspected steer slaughter, $HEIF$ = federally inspected heifer slaughter, COW = federally inspected cow slaughter, $TIME$ = time (numbers 1 to 24 used to take into account the declining nonfederally inspected slaughter), and S = standard error of estimate. Numbers in parentheses are estimated t-statistics.

None of the estimated equations have good statistical fits, but the coefficients and t-test statistics appear to support the two previous analyses. Federally inspected steer and heifer slaughter were not statistically significant in the equations tested. In equation (6) federally inspected cow slaughter is significant at the 0.05 level as an explanatory variable. The coefficient on the COW variable indicates that any change in federally inspected cow slaughter is positively associated with a change of approximately half the magnitude in nonfederally inspected commercial slaughter. This testing procedure, although not conclusive, gives strong indication that cow slaughter comprises a substantial percentage of nonfederally inspected commercial slaughter.

Cow Slaughter Data: Key to the Cycle

Cattle price levels in 1974, resembling the conditions of the early 1950s, emphasized again the need for a better understanding of the cattle cycle. The recurrence of the cattle cycle is due in part to decisions at the cow-calf level of production. Cow-calf producers simply act in a rational profit-maximizing manner given the information base they use in making decisions to increase or decrease herd size. Better price-outlook information could diminish the severity of peaks and troughs in the cycle and thus reduce the risk involved in raising cattle.

For persons who have not attempted practical applications, such as outlook analyses using available slaughter data, specific problems created by the lack of data on nonfederally inspected slaughter go unrecognized. To better demonstrate the benefits that could result from more precise data on nonfederally inspected slaughter, three areas of analysis of the cattle cycle are discussed. Examination of these areas in more detail should demonstrate that the lack of data on nonfederally inspected cow slaughter is a major barrier to effective analysis of the cattle cycle.

An excellent approach to gaining an understanding of the relationships involved in the cattle cycle is to trace cattle inventories to their eventual destinations. However, such a rudimentary analysis as this is impossible without the use of two assumptions, both of which are at best difficult to defend. First, the relative amounts of male and female calf slaughter must be determined in some subjective manner. The percentages of each class slaughtered in nonfederally inspected facilities are unknown. The statistical results presented earlier helped show that this latter variable is not easily estimated. With no accurate method of tracing inventory data to slaughter or death, few if any measures exist to verify whether reported inventories are at levels they should approximate given slaughter during the previous year.

A second area of analysis impeded by the data void is the nature of growth and decline in cow numbers. Through the phases in the cattle cycle, the proportion of total growth comprised of increased heifer holdings is simply not known to an acceptable degree of accuracy. A comparison of recent levels of cow slaughter with those during 1953–54 suggests that a significant inverse relationship may exist between the average age of the beef cow herd and the time lag involved between a price decline and reduced inventories. A test to confirm this relationship would necessarily include a method of estimating the average age of the cow herd. The lack of adequate data forces any approach that is tried to rely on largely indefensible assumptions about the makeup of nonfederally inspected slaughter.

A third area of research is closely related to available knowledge on herd growth. More orderly growth in future beef cow numbers is not an impossible task. Relatively stable growth patterns in both U.S. population and per capita income simplify projections of future levels of beef demand. To meet future demand and maintain more stability in growth, information regarding the number of replacement heifers required for various growth rates is needed. Useful estimates of required holdings of heifers are difficult to achieve without an acceptable measure of total commercial cow slaughter.

Given present knowledge of the percentages of each class of cattle in commercial slaughter, no technique exists to verify the accuracy of either inventory or slaughter data. Also, no acceptable means is available to describe the nature of growth in cow numbers, which implies inadequate resources with which to analyze the cattle cycle.

Thus, analysts are unable to verify or quantify many of the assumed relationships believed to be important causal factors of the cycle. Given the situation, only vague notions of expected behavioral responses by cattle producers to given price levels or changes in price can be developed.

The decline of nonfederally inspected slaughter as a percentage of total slaughter suggests that the importance of knowing its makeup by classes is diminishing with time. The rate of decline in the nonfederally inspected percentage has slowed substantially, however, and has even shown a slight increase since 1973. A continuation of the present system of reporting slaughter numbers will likely create perplexing problems for analysts for many years to come.

Acreage Response to Policy Variables in the Prairie Provinces

Karl D. Meilke

Several recent attempts have been made to estimate the acreage response of Canadian wheat, oats, and barley to changes in price (Capel, Schmitz, Schmitz and Bawden, Missiaen and Coffing). The estimated elasticities of wheat acreage response to wheat price have been found to vary from 0.42 to 0.88 in the short run and from 0.62 to 1.30 in the long run. The wide range of elasticity estimates are due in part to the different definitions of wheat price employed in each study.[1] Capel used the Canadian Wheat Board international wheat agreement price for No. 2 northern wheat during March at Fort William. Schmitz used the latest final price (including the final payment) prior to seeding, while Missiaen and Coffing used the farm price of wheat lagged one year as did Schmitz and Bawden. Since there seems to be disagreement about which price farmers respond to, a short discussion of Canadian grain pricing practices may be useful.

The Canadian Wheat Board is a crown corporation with monopoly control over the marketing of wheat, barley, and oats produced in the Prairie provinces and the Peace River area of British Columbia. The board pays producers an initial payment for grain delivered to it, pools the grain for sale, and returns the profits from the pool to producers in a final payment. The initial payment is a floor price with the Canadian government making up the difference if the average selling price is below the initial payment (Missiaen and Coffing).[2] Initial plus adjustment payments for wheat have ranged from \$1.40 to \$3.75 per bushel between the 1949–50 and 1973–74 crop years.[3] Proceeds over and above the initial plus adjustment payment are paid to producers in a final payment made approximately eighteen to twenty-four months after the crop is planted. Final plus interim payments for wheat since 1949–50 have ranged from nothing on the 1968–69 pool to 82.8¢ per bushel on the 1973–74 pool.[4] Barley and oats are handled in a similar manner to wheat, although in separate pools.

Given these pricing practices of the Canadian Wheat Board, it is hypothesized that grain producers react to two different prices in determining what crops and how much to plant: the initial plus adjustment payment, which has been quite stable, and the final plus interim payment.[5] None of the acreage response studies mentioned earlier differentiate between farmers' reactions to changes in initial payments and changes in final payments.

This paper reports on a study undertaken to determine if Prairie farmers react differently to changes in initial and final payments in making their wheat, oats, and barley planting decisions. To test this hypothesis, acreage response functions are estimated using initial and final payments as separate variables. These functions are then compared in terms of expected signs, goodness of fit, and estimated elasticities to response functions incorporating only one price variable. If farmers do react differently to changes in initial and final payments, this information can be used to influence the acreage devoted to wheat, oats, and barley grown in the Prairie provinces. An example is given in the paper of how initial payments can be varied in order to achieve acreage targets.

The Model

Acreage response functions of the following general form (equations (1) and (2)) are estimated for wheat, oats, and barley grown in the Prairie provinces:

Karl D. Meilke is an assistant professor in the School of Agricultural Economics and Extension Education at the University of Guelph, Ontario, Canada.

The author acknowledges the helpful comments on an early draft by L. Martin, J. Groenewegen, B. Jolly, D. MacLaren, W. Tomek, and the *Journal* reviewers. This project was funded in part by the Ontario Ministry of Agriculture and Food and Agriculture Canada.

[1] The only paper presenting quantitative estimates of barley and oats acreage response is Missiaen and Coffing, and the estimated acreage response elasticities are based on statistically insignificant price coefficients.

[2] It should be noted that in the fall of 1973 a new Canadian feed-grain policy was implemented. Under the new policy it is no longer necessary for Prairie grain producers to sell their grain to the Canadian Wheat Board, although this option is still available. With the new feed-grain policy, the acreage response of farmers to changes in initial payments may be different than it has been during the study period. For a discussion of this program, see the report by the Canada Grains Council.

[3] In the empirical analysis, the initial payment variables include adjustment payments in years when an adjustment was made. Adjustments (increases) in the initial payment are normally made in the spring of the year when it is clear that selling prices will be well above the initial payment level announced at the start of the crop year. Adjustment payments are retroactive to the beginning of the crop year and have been made in seven out of the twenty-five years under study for wheat, eight for barley, and four for oats.

[4] Interim payments are advances on the final payment and have been made quite frequently for wheat, i.e., ten out of the twenty-five years under study. In the empirical analysis interim payments are added to the final payment for that year.

[5] In the remaining discussion the terms initial and final payments refer to variables defined as initial plus adjustment payments and final plus interim payments.

Sources: Canadian Wheat Board, and Statistics Canada.
Note: variable definitions: A_i^t = acreage harvested in Prairie provinces (million acres); IP_i^{t-1} = initial plus adjustment payments ($/bu.); FP_i^{t-1} = final plus interim payments ($/bu.); Z_1^{t-1} = marketings of wheat divided by on-farm carry-in plus production of wheat; Z_2^{t-1} = yield of wheat divided by the yield of oats per acre; PL^{t-1} = an index of Canadian Farm Products (animal) prices during April through March (1935–39 = 100, where $i = w$, wheat; $i = o$, oats, $i = b$, barley; and t and $t - 1$ = time periods.

$$(1)\quad A_i^t = f_1(IP_i^{t-1}, IP_j^{t-1}, FP_i^{t-1}, FP_j^{t-1}, Z_i^{t-1}, A_i^{t-1}, \epsilon_{i1}^t),$$

and

$$(2)\quad A_i^t = f_2(P_i^{t-1}, P_j^{t-1}, Z_i^{t-1}, A_i^{t-1}, \epsilon_{i2}^t),$$

where A_i^t = acreage of crop i in year t, IP_i^{t-1} = initial payment plus adjustment payment for crop i in year $t - 1$, IP_j^{t-1} = initial payment plus adjustment payment for competing crop j in year $t - 1$. FP_i^{t-1} = final payment plus interim payment for crop i in year $t - 1$, FP_j^{t-1} = final payment plus interim payment for competing crop j in year $t - 1$, Z_i^{t-1} = other lagged variables that may shift the acreage response curve, $P_i^{t-1} = IP_i^{t-1} + FP_i^{t-1}$, $P_j^{t-1} = IP_j^{t-1} + FP_j^{t-1}$, and $A_i^{t-1} = A_i^t$ lagged one year.

In equation (1) the influence of initial and final payments are included as separate variables, while in equation (2) they are combined into a single measure of price.[6] In general we would expect the coefficients on variables IP_i^{t-1}, FP_i^{t-1}, A_i^{t-1}, and P_i^{t-1} to be positive, while the coefficients of IP_j^{t-1}, FP_j^{t-1}, and P_j^{t-1} would be negative. Variables employed in the empirical analysis that are identified as Z_i^{t-1} above include livestock prices (PL^{t-1}), marketings of wheat as a percentage of production plus on-farm carry-in lagged one year (Z_1^{t-1}), and the yield of wheat relative to the yield of oats lagged one year (Z_2^{t-1}).

Including a lagged dependent variable among the list of independent variables in equations (1) and (2) is equivalent to assuming a geometric distributed lag model. Nerlove has shown that the geometric distributed lag can be generated in any of three ways. Basically, the assumption about how the dis-

[6] Given the lag in the dispersement of final payments, it would seem appropriate to include the final payments variable in the acreage response function with a two-year lag. When this was done the coefficients on the final payment variables were almost always statistically insignificant. One explanation for this behavior may be that farmers anticipate the level of the final payment. In fact, it would seem likely that farmers could forecast fairly accurately the level of the final payment by comparing the Wheat Board's selling prices during the year to the level of initial payments. This hypothesis is strengthened by the fact that a simple regression of final payments on average selling prices and initial payments explains about 90% of the variation in final payments for all three crops.

tributed lag is generated affects the form of the error term in the equation estimated. In practice, how the geometric distributed lag is generated is unknown, and it may be wise to correct for serial correlation to preserve the consistency of the parameter estimates.

Empirical Results

Equations were estimated using three estimation procedures: (*a*) ordinary least squares, (*b*) ordinary least squares with the Hildreth-Lu correction for serial correlation, and (*c*) a seemingly unrelated regression procedure (Kmenta, pp. 517–28). Without exception the parameter estimates obtained from the three estimation procedures were nearly the same. Consequently, only the ordinary least squares results are reported in this paper.[7]

The acreage response functions presented in table 1 are linear in actual values and estimated using crop year data from 1949–50 through 1974–75. Student t-values are given in parentheses below each coefficient and the coefficient of determination adjusted for degrees of freedom ($\bar{R}^2$) and Durbin's h-statistic are reported.[8] Short-run and long-run elasticities calculated at mean values are given below each equation.

Wheat

Equations (3) and (6) present the results of estimating the acreage response for wheat (table 1). All of the variables in equations (3) and (6) have the expected signs and large t-ratios. The short-run elasticity of wheat acreage with respect to the initial payment for wheat (IP_w^{t-1}) is 0.53, while the cross elasticity with respect to the initial payment for barley is −0.69. The short-run acreage response with respect to changes in the final payment on wheat (FP_w^{t-1}) is 0.08 and −0.05 with respect to the final payment on barley (FP_b^{t-1}). The statistically significant coefficients on the final payment variables confirm the hypothesis that final payments have an effect on wheat acreage. The small elasticity estimates on the final payment variables are somewhat misleading in that it is not uncommon for the final payment to vary by 50% from one year to the next. The long-run elasticities in the model are approximately twice as large as the short-run elasticities.

The Canadian Wheat Board in addition to setting prices also controls the marketing of wheat through the use of marketing quotas. In some years quotas have been "open" so farmers could deliver as much grain to the Board as they want, while in other years marketing quotas have been quite restrictive and have forced Prairie farmers to store or feed the grain in excess of their quota. The variable (Z_1^{t-1}) is used as a proxy for the restrictiveness of marketing quotas and is calculated as marketings of wheat to the Board divided by production plus on-farm carry-in during crop year $t-1$. This variable ranged in value from 40% to 80% during the 1949–50 to 1973–74 crop years. A high value indicates that farmers have been able to market grain freely during the past year, while small values indicate that marketing quotas have been restrictive. Consequently, the expected relationship between Z_1^{t-1} and wheat acreage is positive, and this relationship is confirmed by the estimated short-run elasticity of 0.24.

The variable (D_{70}) is a 0-1 dummy variable equal to 1 in 1970–71 and 0 for all other years. This variable is included to account for the Lower Inventories for Tomorrow (LIFT) Program when farmers were paid not to produce wheat. The coefficient on the D_{70} variable indicates that wheat acreage was 12.09 million acres smaller in 1970–71 than it would have been in the absence of the program.[9] Neither livestock prices nor the yield of wheat relative to either barley or oats appeared to play a role in wheat acreage response, and these variables were eliminated in the final wheat response specification.

Equation (6) indicates the effect of combining the initial and final payments into single measure of price on the estimated acreage response function. The estimated direct price elasticity (0.35) from equation (6) is somewhat smaller than the elasticity with respect to the initial payment in equation (3). It is also smaller than any of the wheat price elasticities estimated by Schmitz and below the range of elasticities selected as representative by Missiaen and Coffing (p. 82).

The strong cross-price elasticities of wheat acreage with respect to both barley initial and final payment variables in equation (3) and barley price in equation (6) are contrary to the results of Schmitz, Missiaen and Coffing, and Capel in which they had difficulty in identifying strong substitute relationships.

Barley

The acreage response of barley is assumed to be a function of lagged initial and final payments on barley (IP_b^{t-1}, FP_b^{t-1}) and wheat (IP_w^{t-1}, FP_w^{t-1}) as well as livestock prices (PL^{t-1}) and the restrictiveness of wheat marketings (Z_1^{t-1}).[10] All of the vari-

---

[7] The author will furnish the regression results for the Hildreth-Lu and seemingly unrelated estimation procedures on request.

[8] Durbin's h-statistic is used to test for serial correlation in equations that include a lagged dependent variable.

[9] There has been some discussion in the literature on the effect of the LIFT program on the acreage planted to wheat in 1970–71. Equation (3) indicates 12.09 million acres less wheat was planted in 1970–71 than would have been planted without the program. This is somewhat more than the estimate of 9.95 million acres made by Sahi and Craddock.

[10] Marketing quotas were also applied to barley, but this vari-

ables in equations (4) and (7) have the expected signs and large t-ratios.

The estimated direct- and cross-price elasticities of barley acreage response with respect to initial payments are quite elastic and approximately ten times larger than the elasticities with respect to final payments. When the two payments are combined into one measure of price as in equation (7), the estimated price elasticities are considerably more inelastic than indicated by the elasticities with respect to initial payments. The direct-price elasticity of 0.70 from equation (7) is similar to Missiaen and Coffing's upper estimate of 0.66.

Livestock prices have played an important role in determining the acreage of barley. Equation (4) indicates a 1% increase in the index of livestock prices will result in a 1.08% increase in barley acreage. Marketing restrictions on wheat also tend to influence the acreage of barley as indicated by the elasticity with respect to Z_1^{t-1} of -0.57.

Serial correlation is not a problem in either equation (4) or (7) as indicated by Durbin's h-statistic. In terms of goodness of fit, both equations (4) and (7) explain about 80% of the variation in the acreage planted to barley.

Oats

The acreage response estimates for oats are similar to those obtained for barley with the following exception. In comparing equations (5) and (8), the direct- and cross-price elasticities, with respect to initial payments, from equation (5) are nearly the same as those in equation (8) in which a single price term is used. This differs from the results for barley, where the response with respect to initial payments was much greater than with respect to total price.

The elasticities for oats acreage with respect to the initial payments on wheat and oats are of the same magnitude as in the wheat acreage response function but much less elastic than for barley. The final payments on wheat and oats have estimated short-run elasticities of 0.10 and -0.09, respectively. The estimated direct-price elasticity from equation (8) of 0.62 is much larger than the estimate of Missiaen and Coffing of 0.29.

Variable Z_2^{t-1} is the yield of wheat divided by the yield of oats lagged one year. The negative sign indicates that when wheat yields increase relative to oat yields the acreage of oats declines.

The coefficient of determination is quite low in both equations (5) and (8). Neither the restrictiveness of wheat marketing quotas nor a similar variable for oats improved the fit of the equation. Likewise, the variables, lagged livestock prices, and the number of milk cows on Prairie farms failed to improve the fit. Including a time trend in the oats equation improved the fit of the function slightly but only at the expense of decreasing the statistical significance of the lagged dependent variable. Obviously, some factor important in decreasing the acreage of oats has been omitted from the acreage response function, but this study can offer little guidance as to what it might be. Serial correlation is more of a problem in the oats functions than for wheat or barley, although when a correlation for serial correlation was made, the parameter estimates in equations (5) and (8) were affected only marginally.

Policy Implications

The initial payment variables included in the above equations can be considered policy variables in the sense they are specified within limits by the Canadian Wheat Board. As such they can be adjusted in order to guide farmers in their planting decisions towards some target acreage. The target acreages can be determined after careful consideration of the overall effects of different crop production levels on price and supply stability in both the grains and livestock sectors. Even so, production targets will not always be met even if acreage targets are. Separating the variance of total production into that accounted for by yield and acreage changes indicates that approximately 37% of the output variation in wheat is due to acreage changes while 43% and 45% of the variation in barley and oats output is due to changes in acreage (Burt and Finley, Goldberger). This analysis implies that considerable output variation around the target level would still exist even if actual acreage equaled the desired level.

To illustrate how initial payments could be set to achieve acreage targets, assume that in the spring of 1973, 26 million acres of wheat, 12.5 million acres of barley, and 6 million acres of oats were established as target acreages for crop year 1974–75. (These are the acreage levels indicated as desired in the spring of 1975 [Canadian Livestock Feed Board].) The question is how would initial plus adjustment payments in crop year 1973–74 have to be modified in order to achieve the stated acreage objectives for crop year 1974–75. This can be determined by using equations (3), (4), and (5) with the desired acreage of each crop replacing A_w^t, A_b^t, and A_o^t. Using equation (3) as an example and substituting 26.0 for A_w^t gives equation (9):

$$(9)\quad 26.0 = 10.25 + 7.98\, IP_w^{t-1} - 16.00\, IP_b^{t-1} + 6.89\, FP_w^{t-1} - 6.05\, FP_b^{t-1} + 9.37\, Z_1^{t-1} + 0.48\, A_w^{t-1}.$$

Inserting the relevant values for the nonpolicy predetermined variables and solving for IP_w^{t-1} in terms of IP_b^{t-1} gives equation (10):

$$(10)\quad IP_w^{t-1} = -0.41 + 2.0\, IP_o^{t-1}.$$

Following a similar procedure, starting with equations (4) and (5) and solving for IP_b^{t-1} and IP_o^{t-1}

able was found to be statistically insignificant in explaining barley acreage.

results in equations (12) and (13), giving a three-equation model containing three unknowns $—IP_w^{t-1}$, IP_b^{t-1}, and IP_o^{t-1}:

$$(11) \qquad IP_b^{t-1} = -0.31 + 0.72\, IP_w^{t-1},$$

and

$$(12) \qquad IP_o^{t-1} = -0.01 + 0.34\, IP_w^{t-1}.$$

Equations (10), (11), and (12) indicate the initial plus adjustment payment level that needs to be paid in the spring of 1973–74 to bring forth the acreage desired for crop year 1974–75. The actual mechanism would most likely involve making an adjustment payment in the spring of 1973–74 equal to the difference between the initial payment announced at the start of 1973–74 and the level of payment necessary to bring forth the desired acreage level for crop year 1974–75.[11]

Table 2 presents the actual acreage of wheat, barley, and oats in 1974–75, the acreage predicted by the model, the actual initial payments, the target acreage, and the initial payments necessary to achieve the target acreages. The results of the analysis are very surprising in that the desired acreage of all three crops was greater than actually harvested and yet the initial payments necessary to bring forth this additional acreage are all lower than actually paid. The direct- and cross-price elasticities for wheat and barley with respect to initial payments explain this phenomena. The cross-price elasticity of wheat acreage with respect to the initial payment on barley is approximately one-third larger than the elasticity with respect to the initial payment on wheat. Similarly, in the barley acreage response, the cross-price elasticity with respect to wheat acreage is about 10% greater than the direct-price elasticity. Consequently, because of the large cross-price effects, decreasing the initial price on both wheat and barley will cause the acreage of both to be increased. After determining the level of payment for wheat, all that remains is to lower the initial payment on oats until the desired level of oats acreage is achieved.

Of course, even if the above rules are followed in setting initial payment, the actual level of acreage in any year is not likely to equal the desired level. Variable weather and exogenous factors accounted for by the error term in the equations will lead to discrepancies between actual and planned acreages. Nevertheless, the acreage response functions can be used as a guide for policy makers in setting initial payment levels. Even if the policy maker disagrees with the elasticity estimates in the above equations, he can substitute his own estimates and observe the effect on the outcome.

It should be pointed out that the decision on initial plus adjustment payments this year will also affect the determination of payment levels next year. A relatively high initial payment this year implies a small final payment entering next year's supply equation, thus requiring an adjustment in the initial plus adjustment payment next year, assuming equal selling prices in each year, to maintain acreage at the previous level.

[11] Since 1971 initial payment levels for the following crop year have been announced in advance of planting in the spring. Therefore, it could be argued that since 1971 this is the price farmers use in making their planting decisions. In this analysis it was felt that the use of adjustment payments causes enough uncertainty that farmers are more likely to use actual payment levels in the spring than initial payments announced for the next crop year in their decision making.

Table 2. An Example of the Initial Payment Levels Required to Achieve Acreage Targets

	1974–75 Acreage (million acres)		
	Wheat	Barley	Oats
Actual	22.9	10.9	4.8
Predicted by model	23.1	10.9	4.8
Target	26.0	12.5	6.0
	1973–74 Initial Plus Adjustment Payments ($/bu.)		
Actual	3.75	2.25	1.10
Target	2.45	1.46	0.82

Voluntary Rural Savings Capacities in Taiwan, 1960–70

Marcia L. Ong, Dale W Adams, and I. J. Singh

A large amount of attention has been given to mobilizing capital in and from rural areas of low income countries. In most cases, involuntary techniques such as taxes, price manipulation, forced labor, and expropriation of products have been used to do this. Rarely have policy makers considered voluntary techniques for stimulating rural savings. In part, this is due to the stereotype widely applied to rural savings behavior. This stereotype depicts rural households as having low incomes and very high consumption propensities. The lack of adequate household data on income, consumption, and savings has discouraged research that might test these assumptions (Mikesell and Zinzer).

In the following, we provide information on rural household savings and some of its determinants in Taiwan during the 1960s. Taiwan is one of the few countries that has systematically collected farm-household data for a number of years that are rich enough in detail to allow such analysis. In addition, the agricultural sector in Taiwan has experienced rapid economic and social development over the past three decades. Overall, agricultural output has increased at a rate in excess of 5% per year since the early 1950s, while the value of agricultural exports has more than tripled. The benefits from this rapid growth have been relatively equitably spread (Oshima). Furthermore, Taiwan is one of only a handful of countries that has aggressively promoted mobilization of voluntary savings in rural areas. We will argue later that these positive policies toward voluntary rural savings, rather than frugal cultural characteristics, make the Taiwan experience almost unique with regard to rural savings mobilization.

Data Used

The household data used in this study came from a farm record-keeping project. In 1953, ten agricultural vocational schools began helping a number of rural households to maintain records of their economic activities. The responsibility for the program was transferred to the local Farmers' Associations in 1960, and the Provincial Department of Agriculture and Forestry began close supervision of data collection and tabulation. Participating households were mainly located in the three major rice regions from 1960 through 1963. As can be noted in table 1, the number of participating households was more than doubled in 1964 to 535 as the project was expanded to the five additional agricultural regions on the island. From 1965 to 1970, 400 to 500 rural families kept household records each year. Many of the participants remained in the project for more than one year.

The data collected by this project are very reliable. Households voluntarily record their economic activities daily, and supervisors carefully check and aggregate this information on a regular basis. A number of consistency checks on the data showed it to be very complete and dependable. The data are more complete and reliable than information collected by most cross-sectional household surveys. Household members have a difficult time recalling for surveys small, fragmented consumption decisions that cover extended periods of time. Most households also underreport income in surveys.

As might be expected, households that voluntarily participate in record-keeping projects are not completely representative of the population. A comparison of the households in the record-keeping project and households included in a representative, island-wide rural sample survey in 1962 and 1967 show some important differences (JCRR). In 1962, for example, record-keeping households owned an average of 1.3 hectares of farm land, while the sample survey households owned 1.12 hectares. In 1967, the record-keeping households owned an average of 1.39 hectares, while survey households had only 1.08 hectares. Record-keeping households owned, therefore, 20% to 30% more farm land than the average farm family. At the same time, there was little difference in average family size between the two groups. In 1962, record-keeping households had average incomes and consumption expenditures that were 60% and 47%, respectively, above the average survey household. In 1967, there was much less difference between the two groups. Record-keeping household incomes were 29% greater and consumption expenditures only 2% greater than survey household figures. As was suggested earlier, it is likely that the survey data underreported household incomes. The

Source: Ong.
[a] *YBAR* equals average net farm family income; *CBAR* equals average household expenditures, and *N* equals number of individuals residing in the household during the year. Current New Taiwan dollar (NT$) figures were converted to 1970 prices using general index of prices received by farmers published by the Bureau of Accounting and Statistics, Provincial Government of Taiwan: 1960 = 81.0, 1965 = 89.2, and 1970 = 100.0.
[b] APS is the average propensities to save calculated at mean farm family income and household expenditure levels for each year (1 − *CBAR/YBAR*).
[c] These are estimates of the linear per capita consumption function $(C/N)i = a_0 + a_1\ (Y/N)i$.
[d] MPS is the marginal propensity to save calculated at the arithmetic mean income and expenditure levels for each year $(1 - a_1)$.
[e] Figures in brackets are t-values for the slope coefficients. All coefficients are significant at the 1% level.

real differences between the incomes of the two groups is probably less than the above percentages indicate. Because of the relatively homogeneous nature of farms in Taiwan, the record-keeping households come closer to representing the entire population than would similar accounts in other higher income countries. Nevertheless, the savings capacities of the record-keeping households reported in the following may overstate somewhat the savings capacities of average rural households in Taiwan.

Methodology

Savings capacities are estimated in this study through income consumption relationships. Savings are defined as total net household income (Y) minus total household consumption (C). Consumption includes the value of all purchased goods for the household as well as products produced and consumed on the farm. This includes costs for household operations, education, and health and purchases of consumer durables. (See paper by Adams, Canh, and Chin for further detail on these items.) To the extent that education expenses and consumer durable purchases contain savings components, the following estimates of household savings are underestimated.

To remove the effect of the size of the family, income and consumption information was converted to per capita figures by dividing through by the number of people living in the household (N). Initially, four functional forms were used in the analysis: linear, quadratic, semi-log, and double log. As Ong points out, results from the linear and double log forms consistently gave the highest F-ratios and smallest standard errors. Since both of these functional forms gave roughly the same statistical results, the coefficients for the linear form are used in the following discussion. The linear form used was

$$(C/N)_i = a_0 + a_1\ (Y/N)_i + u_i,$$

where u = the residual term. This per capita function was estimated using ordinary least squares. Cross-sectional data for eleven consecutive years (i), 1960–70, were analyzed.

Propensities to Save

Yearly per capita income and consumption figures for the record-keeping households are shown in table 1. It can be noted that average per capita income of the record-keeping households increased in real terms by almost 50% over the eleven-year period, a compounded rate of almost 4% per year. Household expenditures also increased substantially over the period, though at a slightly slower rate than did incomes. This resulted in a gradual increase in the average propensity to save (APS) over the 1960–68 period. The very high APS's of the record-keeping households during the period under study are impressive. In the early 1960s, households were saving roughly one-fifth of their incomes. In the 1964–68 period, rates of savings increased to roughly one-quarter of total income. The sharp down turn of APS in 1969 was due in part to very adverse weather that seriously affected agricultural production and incomes. Part of the decrease in APS in 1969 and 1970, however, may also have been caused by the large increase in availability of very attractive consumer goods that began entering rural markets in the mid-1960s (Freedman). The decline in the average saving rates may also have been due to lower rates of return to on-farm investments in the late 1960s, which may have further discouraged household savings.

Information on the marginal savings behavior is also given in table 1. Estimates of the short-run marginal propensities to save (MPS) throughout the 1960s were fairly high, ranging from one-third to two-thirds of marginal income. The substantial variability in MPS from year-to-year plus the overestimation bias of short-run estimates limit the ability to specify savings behavior from cross-sectional data. Despite this, marginal savings appear to have been quite high.

Other Determinants of Savings Capacities

Studies by Mizoguchi, Noda, and others have suggested that savings performance among households may vary considerably depending upon farm size (often used as a proxy for income) and upon source of income. To test this, the Taiwan households were grouped into three farm-size categories: less than 1 hectare, 1 to 2 hectares, and more than 2 hectares. A second classification of the households was based on the ratio of income derived from on-farm agricultural activities to total household income. Average and marginal propensities to save among these different subgroups for the period 1960–70 are presented in table 2.

A review of the average propensities to save by farm size groups shows that APS's almost always increase with farm size. In part, this reflects the favorable impact on savings of higher incomes,

Table 2. Average and Marginal Propensities to Save by Farm Size Groups and Income Source Groups for Record-Keeping Households in Taiwan, 1960–70

[a] Average propensity to save equals 1 − household expenditures/household income.

[b] One hectare (ha.) equals 2.47 acres.

[c] Marginal propensity to save is calculated at the arithmetic mean income and expenditure levels for each year. As in table 1, results are from a linear function form.

which in turn are associated with farm size. In a separate study of the same data, Chin found a very close, positive relationship between household income levels and APS's. The generally higher APS's and MPS's among the larger farms also suggest that households with more farm land may have had more profitable on-farm investment alternatives for their savings than did smaller landowners. A further point worth noting in table 2 is the relatively high APS's and MPS's among households in the smallest farm-size groups and that the marginal savings behavior of households with small farms was not vastly different from households with larger land areas.

Also shown in table 2 is a breakdown of APS's and MPS's by income-source ratios. Households with the highest ratios received a larger part of their total income from on-farm agricultural activities than did households with low ratios. These APS's and MPS's were fairly consistent in showing better savings performance among high ratio households. These results tend to confirm Noda's findings in Japan, that households that are close to full-time farming units tend to have larger savings propensities than do those households that derive a substantial part of their income from outside their own farming operation. As with the farm-size situation, these income ratios may be associated with overall income levels of households as well as reflect profitability of on-farm investment opportunities.

The record-keeping households were also grouped by their eight regional locations and by two household-dependency ratios (Ong). Neither of these breakdowns shed additional light on savings behavior. Savings patterns in various geographic regions of Taiwan appear to be very similar. Likewise, there appears to be little difference in savings performance between high and low dependency ratio households.

Implications

As indicated before, the data used in this study tend to overstate average rural savings capacities in Taiwan. The households studied have higher than average incomes, they are progressive farmers, and the cross-sectional estimates reported here overestimate long-run MPS because of the transitory income effect. We feel this upward bias is largely offset, however, by our exclusion from savings in the study all expenditures on education and consumer durables. During the 1960s, the average record-keeping household used 10% to 15% of its total consumption in these activities (Adams, Canh, and Chin). Half or more of these expenditures could have been defined as savings with strong justification. These data, plus other indicators, reinforce the conclusion that very large voluntary savings capacities emerged in rural Taiwan during the 1960s. The large increase in financial savings in rural areas and the rapid increase in total on-farm assets are physical evidence of substantial savings capacities (Tuan). The well-documented transfer of capital out of the agricultural sector, the sharp increases in rural human capitalization, and the widespread accumulation of consumer durables in rural areas lend further weight to the argument that a surprisingly large part of the rural product in Taiwan during the 1960s was voluntarily saved.

It might be aruged that the large rural savings capacity found in Taiwan during the 1960s is a special case, that Taiwanese are somehow culturally endowed with large doses of frugality. We do not feel that household characteristics are the major explanation of Taiwan's remarkable savings performance. We also do not feel that the substantial increases in rural incomes during the 1960s make the Taiwan experience unique. Individual farm households and major agricultural regions in a number of other less developed countries also are experiencing high rates of growth in incomes. We conclude that Taiwan's savings performance is due to appropriate policies rather than unique behavioral characteristics. Household savings were strongly stimulated by two sets of incentives. The first set included price policies, new technology, marketing facilities, land-tenure adjustments, and public-investment programs that gave strong incentives for on-farm investments. The second set of savings incentives flowed to farmers through financial markets. The physical presence of savings institutions in most rural areas (postal savings, farmers' associations, and commercial banks) gave rural people the opportunity to save. These institutions provided the convenience, stability, liquidity, and security necessary to attract savings. Furthermore, Taiwanese policy makers were very agressive in using attractive interest rates on deposits to induce savings. During the 1950s and 1960s, interest rates on deposits were adjusted, sometimes monthly, to assure positive real returns to financial savers (Tuan).

The Taiwan experience during the 1960s seriously challenges the low saving capacity stereotype that has been routinely applied to rural households. We feel that using a more realistic notion of rural saving behavior in economic planning should receive a high priority in the development profession.

The Marketed Surplus of a Subsistence Crop: Paddy Rice in Taiwan

Dennis L. Chinn

The price response of the marketed surplus of subsistence crops is a topic of major concern to agricultural planners in developing countries. Recent attempts to measure the relevant elasticities by Bardhan, Haessel, and Toquero et al. have significantly added to understanding the magnitudes involved but seem to possess potentially serious methodological limitations. First, they do not explicitly consider the "barter component" of marketed surplus. Haessel recognizes the existence of in-kind disposals but assumes them to be fixed by contractual arrangements and hence insensitive to changes in price. If the barter component is large, even a small response to a change in price may be important for policy purposes. A second limitation is the assumption that sales and on-farm consumption are strict complements, so that it is necessary to consider the price response of either marketing or consumption but not both. While this results in considerable simplification, it ignores the farmer's additional option of simply adding to (or subtracting from) existing stocks.

The present paper considers the marketed surplus of paddy rice in Taiwan, a case in which the barter component is important. For a sample of farm households in the middle rice region of Taiwan, paddy rice used to pay in-kind household and farm expenses amounted to over 60% of cash rice sales for the period 1962–72. The simple approach adopted disaggregates total marketed surplus into cash sales and barter components and also allows for separate estimation of the price and output elasticities of on-farm consumption. A further departure from previous studies is that the estimation is based on time-series data. The approach generates what appear to be quite reasonable estimates of the price and output elasticities and suggests that the numerical results of studies that ignore the barter components of marketed surplus may require qualification.

Dennis Chinn is an assistant professor of economics at the Food Research Institute, Stanford University, California.

This study was made possible by Dale Adams, who made available the data on which it is based. The data were drawn directly from the individual records of the Taiwan Farm Record-Keeping Project with the cooperation of the Joint Commission on Rural Reconstruction, Taiwan, and support from the U.S. Agency for International Development. Partial support for the author's research was provided by the same source under the auspices of the Stanford project on the political economy of rice in Asia. The helpful comments of Keith Acheson and *Journal* referees are gratefully acknowledged. Any remaining weaknesses are the responsibility of the author.

Following a brief discussion of the nature and limitations of the available data, the estimated structural equations are described, the elasticity estimates derived, and the conclusions summarized and qualified.

Data

The basic identity of the farm household rice economy is

$$(1) \quad QOUT = QSOLD + HOUSKD + FARMKD + QCONS + \Delta STOCKS.$$

Total rice output for a given year (*QOUT*) can be disposed of in several ways. It can be sold for cash in the free market (*QSOLD*), bartered for household consumption items (*HOUSKD*), used to pay in-kind farm expenses including land rents and taxes (*FARMKD*), consumed directly by the farm household (*QCONS*), or added to end-of-year stocks ($\Delta STOCKS$), the final term representing a positive or negative residual. Paddy rice not consumed on the farm or added to existing stocks is assumed to eventually find its way into market channels, so total marketed surplus (*MS*) is given by

$$(2) \quad MS = QSOLD + HOUSKD + FARMKD.$$

Most of the data used in this study are drawn from the Taiwan Farm Record-Keeping Project, which was initiated in the early 1950s and took its present form in 1960.[1] The analysis is restricted to sample households in the middle rice region for the period 1962–72. From the farm records an annual time series for the average sample household can be derived for each item in equation (1).

The figures for total paddy rice output (*QOUT*) were originally reported in quantity terms, while *QSOLD* was estimated by dividing the annual receipts from rice sales by the average annual free market paddy rice price (*PRICE*).[2] The items re-

[1] Summary data from the Taiwan Farm Record-Keeping Project as published each year since 1960 by the Department of Agriculture and Forestry of the Provincial Government of Taiwan were not sufficiently detailed for purposes of this study. The time series used were constructed from the individual farm household records.

[2] It was not possible to derive an implicit price series from the farm-household records. The time series for *PRICE* is the annual average free market price of paddy rice as reported in Chen, Hsu, and Mao (p. 23).

corded in the farm records include in-kind household expenditures, in-kind farm expenditures, and total staple food consumption in value terms for each year 1962–72. Since rice was the primary medium for in-kind transactions (and the primary staple food crop), dividing by the average paddy rice price for each year yields estimates of total direct household use of paddy rice, paddy rice used to pay in-kind farm expenses (*FARMKD*), and direct farm household consumption of paddy rice (*QCONS*) in quantity terms. Subtracting the last from the first yields a residual estimate of paddy rice bartered for household items excluding direct consumption (*HOUSKD*).

Other data used in this paper include total farm household income from all sources (*TOTINC*), the average paddy rice yield (*AVGYLD*), the total number of family members (*TOTFAM*), the total farm land owned by the household (*TOTFLAND*), and the fertilizer-rice barter ratio (*FERTRICE*).[3]

Table 1 presents some important trends for the average sample farm household for the period 1962–72 broken into three subperiods. The average size of holding (*TOTFLAND*) increased somewhat as did total rice production (*QOUT*). The share of total output sold for cash (*QSOLD*) increased from 0.44 to 0.55, while the proportion consumed by the farm household (*QCONS*) fell only slightly from 0.28 to 0.25. For each subperiod the sum of the barter components (*HOUSKD* + *FARMKD*) accounts for about 30% of total output. The term $\Delta STOCKS$ was estimated as a residual, and the negative entry for each period may in part reflect some in-kind consumption of staple crops other than paddy rice.[4] Over the period total farm household income (*TOTINC*) doubled, while the proportion of total income attributable to rice declined from 0.46 to 0.29, reflecting both the increase in part-time farming and to a lesser extent the shift in the crop mix over time.[5]

The strengths of the farm household record-keeping data are the number of years for which the records are available that makes time-series analysis possible and the extraordinary amount of detail that makes it possible to disaggregate total marketed surplus of paddy rice. As always, however, there is no "free lunch," and these strengths are balanced by potentially serious weaknesses. First, for each year the sample size is quite small. An average of seventy-one households in the middle rice region participated in the record-keeping project during 1962–72, the minimum being forty-nine in 1967 and the maximum eighty-one in 1963. Second, and most importantly, the sample households were selected by the agricultural cooperative associations, and the extent to which they are representative of farm households in the middle rice region as a whole cannot be determined. The obvious danger is that spurious correlation might be introduced simply through the choice of sample households. In any case there is nothing that can be done about either the small sample size or the apparent lack of randomness in the sampling process. While it is the author's belief that the potential gain in insight far outweighs the costs of potential errors, the difficulties of interpreting the average sample farm household for each year as one observation in a time series should be kept in mind.

Estimated Equations

The approach of this study is to fit a simple model of farm household behavior to the time-series data described above and to derive estimates of price and output elasticities for the components of total marketed surplus and on-farm consumption. The model consists of five equations, one for each element of equation (1), except for the residual term $\Delta STOCKS$. All variables are expressed in natural logarithms, the equations are estimated by ordinary

[3] During the period under consideration, chemical fertilizer supplies were distributed by the government monopoly in exchange for paddy rice. The variable *FERTRICE* is the barter ratio measured in kilograms of paddy rice per kilogram of fertilizer. See Lee for a brief description of the system. The time series for *FERTRICE* was taken from Chen, Hsu, and Mao (appendix, table 9).

[4] If in-kind staple food consumption includes commodities other than paddy rice, then the estimation procedure adopted here will overstate *QCONS* and impart a negative bias to $\Delta STOCKS$. The residual term may also include a statistical discrepancy because the price series is an average annual price series and is from an independent source and hence may not be identical to the actual prices received by the sample farm households.

[5] The proportion of total farm-household income from farm sources declined from 0.85 for 1962–65 to 0.64 for 1970–72, while rice receipts as a proportion of total farm receipts declined from 0.54 to 0.46.

Table 1. Selected Trends for the Average Sample Household, 1962–72

Time Period	*TOTFLAND*[a] (chia)	*QOUT* (kgs.)	Proportions of *QOUT*					*TOTINC* (U.S. $)	Proportion of *TOTINC* from Rice[b]
			QSOLD	*HOUSKD*	*FARMKD*	*QCONS*	$\Delta STOCKS$		
1962–65	1.07	7,034	0.44	0.12	0.23	0.28	−0.07	880	0.46
1966–69	1.19	7,656	0.48	0.09	0.22	0.24	−0.03	1,111	0.43
1970–72	1.31	8,177	0.55	0.12	0.16	0.25	−0.08	1,717	0.29

[a] 1 chia = 0.97 ha.
[b] The farm-record data do not allow allocation of costs between individual crops or other farm activities. The contribution of rice to income from farming is assumed to be equal to the ratio of total rice receipts to total farm receipts. This ratio times the share of income from farming in total income then represents the share of *TOTINC* from rice.

least squares, and the t-ratios are shown in parentheses:[6]

$$(3) \quad QOUT = \underset{(3.148)}{0.710\, PRICE(-1)} + \underset{(24.001)}{0.941\, AVGYLD}, \quad R^2 = 0.740;$$

$$(4) \quad QSOLD = -3.400 + \underset{(1.892)}{0.677\, PRICE} + \underset{(4.090)}{1.338\, QOUT} - \underset{(0.868)}{0.632\, TOTFAM}, \quad R^2 = 0.871;$$

$$(5) \quad FARMKD = \underset{(1.402)}{0.339\, PRICE} + \underset{(17.777)}{0.744\, QOUT} + \underset{(8.722)}{0.531\, FERTRICE}, \quad R^2 = 0.926;$$

$$(6) \quad HOUSKD = 2.266 - \underset{(2.863)}{2.315\, PRICE} + \underset{(3.533)}{0.795\, TOTINC} - \underset{(0.527)}{0.308\, TOTFAM}, \quad R^2 = 0.588;$$

and

$$(7) \quad QCONS = 4.171 - \underset{(1.168)}{0.349\, PRICE} + \underset{(1.132)}{0.309\, QOUT} + \underset{(0.885)}{0.538\, TOTFAM}, \quad R^2 = 0.404.$$

In principle, a change in price can affect output through an induced increase in yield or acreage or both. In the sample data the crude correlation coefficient of *AVGYLD* with the price series lagged one year (*PRICE*(−1)) was −0.09, while that for land devoted to paddy production was 0.63, suggesting that any positive effect of lagged price on output over time came from the acreage side. Equation (3) attempts to capture that effect. The constant term had a low t-ratio and the equation was reestimated without it. The coefficient of *PRICE*(−1) implies that (holding *AVGYLD* constant) a 1% increase in price would correspond to a 0.7% increase in paddy rice output in the following year.

Equations (4) and (7) relate *QSOLD* and *QCONS* to the average free market price in the current year (*PRICE*), total paddy rice output (*QOUT*), and the total number of family members (*TOTFAM*). In both equations the *TOTFAM* coefficient has a small t-ratio, but the coefficient is of expected sign. Equation (7) is a bit suspect in terms of statistical fit, but the coefficients of *PRICE* and *QOUT* have the expected signs and do appear to be of reasonable magnitudes.[7] Attempts to relate *HOUSKD* to the same three variables were unsatisfactory, so *TOTINC* was substituted for *QOUT* and the result is shown as equation (6).[8] Paddy rice used to pay farm expenses (*FARMKD*) is quite adequately explained by *PRICE, QOUT,* and the fertilizer-rice barter ratio (*FERTRICE*), the last term being included to reflect the importance of the barter of paddy rice for fertilizer as a component of *FARMKD*. As in equation (3), the constant term had a low t-ratio and was eliminated. Thus, with minor problems the set of log-linear equations (3) through (7) seems to be a satisfactory representation of the farm household rice economy.

Estimated Elasticities

This section describes the construction of table 2. Since the estimated equations are log-linear, the coefficients represent constant elasticities. The coefficients of *PRICE* in equations (4), (5), and (7) represent short-run (output held constant) price elasticities of *QSOLD, FARMKD,* and *QCONS,*

[6] The decision to impose the constant elasticity functional form on each equation reflects our interest in the distinction between long-run and short-run price elasticities (with and without the induced effect on output) rather than variations in the elasticities over the ranges of the explanatory variables. The gain in analytical simplicity seems well worth the potential loss in statistical goodness of fit.

[7] Due to the poor statistical fit of equation (7), an alternative equation for *QCONS* with *TOTINC* in place of *QOUT* was estimated:

$$QCONS = 4.443 - \underset{(3.100)}{1.375\, PRICE} + \underset{(2.818)}{0.348\, TOTINC} + \underset{(2.084)}{0.667\, TOTFAM}, \quad R^2 = 0.648.$$

This equation gives a better statistical fit but yields what seems to be an overly high estimate of the long-run price elasticity of *QCONS*, −1.15.

[8] Equation (6) was fit to data for the years 1960–72 since each of the variables involved was available for 1960 and 1961. The other equations were estimated for the period 1962–72.

Table 2. Estimated Elasticities

	Short-Run Price Elasticity[a] (1)	Long-Run Price Elasticity[b] (2)	Output Elasticity[c] (3)
QOUT	—	0.71	—
MS	0.22	0.97	1.06
QSOLD (0.62)	0.68	1.63	1.34
FARMKD (0.24)	0.34	0.87	0.78
HOUSKD (0.14)	−2.01	−1.80	0.30
QCONS	−0.35	−0.13	0.31

[a] The price elasticity in the absence of any change in output.
[b] The price elasticity including the induced change in output.
[c] The induced response to an exogenous change in output.

respectively. For *HOUSKD*, equation (6), there is an additional current price effect through the *TOT-INC* term. Earnings from rice increase in proportion to current price, and since for the period 1962–72 rice accounted for about 38% of total farm household income, the short-run price elasticity of *HOUSKD* is $-2.315 + (0.38)(0.795) = -2.01$. The coefficients of *QOUT* in equations (4), (5), and (7) represent short-run (price held constant) output elasticities. The short-run output elasticity of *HOUSKD* is $(0.38)(0.795) = 0.30$. The short-run price and output elasticities of total marketed surplus (*MS*) are calculated as weighted sums of the respective elasticities of the component parts *QSOLD*, *HOUSKD*, and *FARMKD*. The weights (shown in parentheses in the table) are the shares of *MS* for 1962–72. The short-run price and output elasticities are given as columns 1 and 3, respectively, of table 2.

The long-run price elasticities of *QSOLD*, *FARMKD*, and *QCONS* shown in column 2 were calculated by substituting equation (3) into equations (4), (5), and (7) and summing the coefficients of the current and lagged price terms. The coefficient of *PRICE*(−1) in the reduced form of equation (6) is $(0.38)(0.71)(0.795) = 0.21$. Adding this to the short-run price elasticity yields a long-run elasticity of −1.80. The long-run price elasticity of total marketed surplus was calculated in the same way as the short-run price and output elasticities.

Conclusions and Qualifications

The following conclusions can be drawn from the numerical results.

(*a*) The short-run price elasticity of total marketed surplus is positive, while that of on-farm consumption is negative, suggesting that for a given level of paddy rice output, an increase in the market price would induce farmers to market a higher proportion of that output. Farm households in Taiwan respond to changes in price both as sellers and as consumers.

(*b*) In the long run, including the induced effect on output, a 1% rise in price would result in a 0.97% increase in total marketed surplus. On-farm consumption would decline but only by 0.13%. Hence, price policies designed to stimulate output would also stimulate the transfer of staple food output from the peasant farming sector to the urban sector.

(*c*) An exogenous 1% increase in output, say, through an increase in average yield due to the introduction of new high yielding rice varieties, would result in an increase in total marketed surplus of 1.06% but would also result in a 0.31% increase in on-farm consumption of paddy rice.

(*d*) There is significant variation between the elasticities of the components of total marketed surplus. The long-run price elasticity of *QSOLD* is quite high at 1.63, that of *FARMKD* is almost half that at 0.87, while that of *HOUSKD* is negative and quite large at −1.80. The output elasticities of the three items are all positive but differ significantly in magnitude. Hence, the disaggregated approach seems justified. The output and price elasticities of total marketed surplus are substantially lower than the corresponding elasticities of *QSOLD*. This suggests that neglecting the barter components of total marketed surplus may result in serious overestimation of the price and output responses.

Some qualifications of these conclusions should be noted. The absolute magnitudes of the long-run price elasticities depend on the lagged response of output to price. The imposed log-linearity of the equations precluded more detailed specification of the lag structure of the production response, and it is conceivable that the estimated price response is inaccurate.[9] However, given the small number of observations, itself a severe limitation, it seems unlikely that a more detailed lag distribution would yield much better results. A perhaps more serious qualification has to do with the data problems mentioned previously. If the composition of the sample households changes systematically from year to year there may be spurious correlations between some of the variables and the price series. There is no reason to assume that the sample is not representative, and in any case there is simply not much that can be done about it. Again, it is the author's belief that the benefits of using the data for time-series analysis far outweigh the costs of potential errors.

[9] In spite of the simplicity of equation (3), the estimate of the price elasticity of paddy rice output (0.71) is only slightly higher than other estimates. For example, estimates of long-run price elasticities of rice acreage for regions of the Philippines and the Punjab cited by Krishna range from 0.15 to 0.62, while for prewar Japan Hayami and Ruttan estimate the elasticity to be between 0.4 and 0.6. The consequences of overestimation of the price elasticity of output in the present context would be a too high estimate of the long-run price elasticity of total marketed surplus and a too low (in absolute value) estimate of the price elasticity of on-farm consumption.

The Political Economy of Rural Development in Latin America: An Interpretation: Comment

W. Whitney Hicks

In an article in this *Journal*, Alain de Janvry argues that increased poverty among marginal farmers (*minifudistas*) in Latin America leads to an increase in family size and ". . . poverty thus leads to more poverty" (p. 495). This implies not only that fertility is high in low income rural areas but that as income decreases fertility increases. De Janvry feels that the ". . . ecological and demographic contradictions in the subsistence sector . . . (are) . . . an integral part of the dynamics of growth in peripheral economies of the world capitalist system . . . (and that his theory that includes these ecological and demographic contradictions in the subsistence sector) permits identification of the variables that affect rural poverty and understanding of the political economy of alternative strategies aimed at alleviating it" (pp. 495–96).

I will argue on both theoretical and empirical grounds that poverty and the mining of land in rural areas is associated with lower rather than higher fertility and against the existence of ecological and demographic contradictions that lead from rural poverty to increasing family size to even greater poverty.

In the case where children are producer goods (rather than consumer goods (Becker)), de Janvry maintains that "the pressure of poverty in the *minifundio* implies the need to search for additional productive resources. Strict individual economic rationality in the subsistence sector will often lead to mining the land and increasing family size in order to face poverty, and poverty thus leads to more poverty" (p. 495). In contrast to de Janvry's assertion about the consequences of individual economic rationality on fertility, neoclassical economic theory posits that the determinants of fertility in rural areas are the factors that influence the net returns to rural households from additional units of family labor. If, for example, the marginal cost of children is constant and the marginal benefits depend on the available supplies of land, labor, and reproducible capital, increasing family size beyond a point will cause the marginal returns to parents to fall below the marginal cost. Land is a prerequisite for livelihood in rural areas, and when it is scarce the establishment of a household may be delayed or avoided. If the average size of holdings is small, there is an incentive to limit fertility within marriage to prevent further fragmentation of holdings and a further decline in the marginal productivity of labor. This suggests that fertility in rural areas is directly related to land availability and that as population density on the land increases fertility will decrease.

The results of two recent studies for Latin American countries provide empirical support for the above hypothesis. One is a study of the rural population in 166 microregions (which are aggregations of *municipos*) in seven states of South-Central Brazil—Paraná, Mato Grosso, Goiás, Bahia, Minas Gerais, São Paulo, and Rio Grande do Sul (Merrick). Measures of fertility (age-specific fertility rates or births per 1,000 women in five-year age groups [15–19, 20–24, . . . , 45–49] and completed fertility or the number of children ever born to women ages 45–49) from the 1970 population census and of land availability (the ratio of total agricultural land to the total area in the microregion) from the 1970 agricultural census are used to test the hypothesized relationship. Merrick states that

> "Tabular and multiple regression analysis of the data for land availability and fertility rates reveal a strong and relatively consistent tendency for fertility to decline with decreasing land availability. The regression analysis allowed us to control this relation for the effect of differential survivorship and property ownership. The influence of land on fertility was stronger in the current rates (age-specific fertility rates) than for cumulative ones (children ever born to women ages 45–49), with the effect most pronounced in the more important child-bearing cohorts between ages 20 and 34" (p. 27).

A similar study has been made for the rural areas of the thirty-one "states" of Mexico in 1970 (Hicks 1974). In this case the measure of fertility was children ever born to women ages 40–44 and the measure of land availability was arable land per farm worker. A multiple regression model that controlled for differences in female literacy, the crude death rate, and the relative size of the indigenous population showed ". . . that the land variable was positive and statistically significant at the five percent level. (These) results are consistent with the hypothesis that arable land is complementary with labor, and fertility is likely to decline in response to a decrease in arable land per agricultural worker" (Hicks 1974, p. 414).

There is some evidence that the relation between

W. Whitney Hicks is a professor of economics at the University of Missouri-Columbia.

land availability and fertility is conditioned by the tenure arrangement. Merrick found ". . . that the land scarcity effect is weaker when property ownership is less common. However (he concluded that) more refinement of the property ownership variable is required before definite conclusions on its effect can be reached" (p. 27). A paper summarizing three studies that show differential fertility by land-tenure classes in Mexico suggests that fertility was higher on *ejidos* than on privately owned farms (Sanchez). However, none of the three studies summarized controlled for "land availability," and in each case it appears that arable land per farm worker was greater for *ejidos* than for private properties (Hicks 1967, p. 398).

Further research is needed on the interrelationships between fertility in rural areas, land availability, land tenure status, and the mechanisms by which these factors interact. Easterlin's "bequest" model for explaining fertility differences during frontier settlement in the United States is one example of such research, although this model may not be applicable to Latin America (Easterlin).

In view of de Janvry's failure to support his assertions about the relationship between poverty and fertility, the evidence in support of a direct relationship between fertility and land availability must be tentatively accepted. The "ecological and demographic contradictions" that help to drive de Janvry's model of rural development may not exist.

The Political Economy of Rural Development in Latin America: An Interpretation: Reply

Alain de Janvry

I have argued, along with others (Mamdani), that poverty is a powerful stimulant of higher birth rates and this particularly in the context of semiproletarian subsistence agriculture. There, the conjunction of poverty and the control of some productive resources makes children an essential means of production and protection. The rural poor thus have large families because it is economically rational for them to do so. Improvement in the material conditions of life—increased control of productive resources, larger access to income-generating activities, consumption levels covering subsistence needs, greater safety of survival, and social security—diminishes this function of children and gradually transforms them into consumer goods, thus leading to a decline in birth rates and to a "demographic transition" (Oechsli and Kirk).

Hicks, like neo-Malthusians, claims the opposite: that rural poverty is associated with lower rather than higher fertility.[1] Yet, the theoretical and empirical evidence he puts forward does not support his assertion. Poverty is unacceptably reduced to land availability under *ceteris paribus* conditions. This fallacious reasoning is tantamount to claiming that the organization of production is unrelated to farm size and that land availability is the only determinant of poverty.[2]

The basic starting point from which a relationship between poverty and fertility can be established is the well-evidenced observation that, even among the most primitive, fertility decisions (desired family size) are rational and ultimately determined by economic criteria (Hawthorn). Completed family size may, however, exceed desired family size due to the crudeness of the control practices used and the uncertainties of planning under conditions of high infant mortality. Yet, this difference is a minor determinant of family size relative to the rationality of choices. Family-planning programs often have succeeded merely to induce those couples already practicing birth control to switch to more efficient, modern methods with only a minor overall affect on family size.

Clearly, the organization of production changes with farm size, and for this reason so does the productive and protective functions of children. On larger farms the marginal revenue schedule of children is shifted downward as nonfamily labor is employed, laborsaving machinery is used, the nature of the tasks performed is more complex and physically demanding, etc. Greater access to credit, information, and protective institutions in general, which is invariably associated with farm size, reduces the social security function of children. Better standards of living for the children and school attendance increase their marginal costs. As a result, larger farms tend to be associated, *mutatis mutandis*, to smaller family size.

Because of the insufficiency of land resources controlled relative to subsistence needs, the vast majority of poor rural households are semiproletarians.[3] In the resulting division of labor, the women, the young, and the old become the prime agriculturalists. Because of the primitive nature of techniques and the pressure of poverty, a highly labor-intensive production pattern is followed that allows for no idle labor and to which all but the very young and very old participate. Even the most limited improvements, such as raising a goat or a pig (animals are the saving accounts of subsistence peasants), imply the need for additional child labor. As for tenants, the more hands a family can muster, the more land a family may be able to contract from the landlords.

Use of hired labor is not a substitute for one's own children to cover labor needs simply because overexploitation of labor within the family can be so much greater and the total claim of the family on the lives of its children until adulthood prohibits existence of a labor market for rural children. As Mamdani observes,

---

Alain de Janvry is an associate professor of agricultural and resource economics at the University of California, Berkeley.

[1] For example, Garret Hardin, who claims that "more food means more babies."

[2] For empirical support, Hicks refers to his study of Mexican rural fertility. Both the data used and the variable specified are highly inadequate; the data are aggregates for the states of Mexico, while we are dealing here with individual fertility behavior! The variable used for land availability is arable land per worker in each state without accounting for the distribution of the land and for land quality. In states of high land fertility, rural population density is high, and large commercial farms and also a large number of poor subsistence farms providing labor to the commercial sector are found. Under the typical dual Latin American land-tenure system, a high level of land per worker can just as well mean that a majority of the rural population lives under extreme poverty.

[3] According to the Inter-American Committee for Agricultural Development, semiproletarian rural households (subfamily farms) account for 44% of all rural households in Argentina, 61% in Chile, 72% in Colombia, 78% in Brazil, 88% in Ecuador, and 91% in Guatemala (see Barraclough).

> "Given a very small income, to have to hire even one farmhand can mean disaster. If such a farmer is merely to survive, he must rely on his family for the necessary labor power. If he is to think of any advancement, which every farmer in such a precarious situation does, he must add to his family labor force and thus augment his resources" (p. 76).

Children not only fulfill a role as production agents in subsistence agriculture but also provide protection. They provide security to parents against health hazards, disability, and old age, against unemployment, and against structural and economic changes to which the work process has to be adjusted when parents may not have the needed flexibility to do so. In some cases a large family is needed for sheer physical defense of scarce productive resources in a ferociously competitive environment ruled by the laws of survival.

As poverty increases, children will be induced to migrate away from the family at an earlier age, and as the migration age decreases procreation of more children is needed to maintain a constant stock of working children—a stock that itself has to increase with poverty. While the migrants cease to perform as production agents on the farm, they continue to insure protection; they can provide material support to their parents if adversity strikes, and the parents can join them in the city in their old age to benefit from the public hospital and other public services unavailable in the rural areas. Thus, while the private cost of a migrated child is 0, the return is by no means negligible. Through migration, optimum family size in the subsistence sector is brought yet closer to biological maximum.

While we know that the great mass of births comes from that half of humanity that is both rural and poor, very little quality empirical research has been done on the rationality of fertility in this context. Both detailed case studies and farm surveys are needed for this purpose. Such analyses should rank high on the agenda of research priorities.

Interaction of Energy and Food Prices in Less Developed Countries: Comment

Panos A. Konandreas and Richard Green

Timmer, in a recent article in this *Journal*, examined the interaction between energy and food prices in less developed countries (1975). (This also applies to a previous article by Timmer in 1974.) His analysis was based on a simple macromodel consisting of an aggregate production and an aggregate consumption function for one of the major food grains. While this analysis reveals some interesting insights and suggests some important policy recommendations for developed and less developed countries alike, these conclusions are conditional on the magnitudes of price elasticity of demand (α) and energy elasticity of supply (γ), as we will show. Timmer failed to examine the conditions under which a new food-grain price equilibrium (called long-run equilibrium) is reached as a result of an exogenous change in the price of energy. A new equilibrium might not exist. In fact, it does not exist for most of the values of α and γ provided by Timmer. The purpose of this note is to clarify this issue within the framework of a dynamic model with lagged adjustment in two interrelated markets.

The simplified model used by Timmer with the time dimension introduced is

$$Q_{st} = A_s E_{t-1}^{\gamma}, \tag{1}$$

and

$$Q_{dt} = A_d P_{ot}^{\alpha}, \tag{2}$$

where Q_{st} and Q_{dt} = quantity of food grain produced and consumed in year t, respectively, E_{t-1} = energy input in year $t - 1$, P_{ot} = price of grain in year t, and γ and α = response elasticities of supply and demand with respect to energy input and price of grain, respectively. The three basic assumptions explicitly or implicitly made by Timmer are (*a*) in the short run, farmers treat the price of grain P_o and the price of energy P_e as given; (*b*) farmers do not foresee a change in the price of grain at period $t + 1$ as a result of a change in the price of energy input at period t; and (*c*) the supply of energy is independent of the conditions in the grain market, e.g., an increase in the price of grain will not affect the supply of energy.

Assuming the behavior of producers in the short run to be as described in (*a*) and (*b*) above, the assumption of profit maximization yields a short-run demand function for energy inputs:[1]

$$E_t = A_s^{\frac{1}{1-\gamma}} \gamma^{\frac{1}{1-\gamma}} P_{et}^{\frac{1}{\gamma-1}} P_{ot}^{\frac{1}{1-\gamma}}, \tag{3}$$

or

$$E_t = A P_{ot}^{a}, \tag{4}$$

where $A = A_s^{\frac{1}{1-\gamma}} \gamma^{\frac{1}{1-\gamma}} P_{et}^{\frac{1}{\gamma-1}}$ and $a = \dfrac{1}{1-\gamma}$.

The new price level of food grains at $t + 1$ is determined by equating the demand and supply functions

$$A_d P_{ot+1}^{\alpha} = A_s E_t^{\gamma}, \tag{5}$$

$$P_{ot+1} = A_s^{\frac{1}{\alpha}} A_d^{-\frac{1}{\alpha}} E_t^{\frac{\gamma}{\alpha}}, \tag{6}$$

or

$$P_{ot+1} = B E_t^{b}, \tag{7}$$

where $B = A_s^{\frac{1}{\alpha}} A_d^{-\frac{1}{\alpha}}$ and $b = \dfrac{\gamma}{\alpha}$. Substituting equation (4) into equation (7) gives

$$P_{ot+1} = B A^{b} P_{ot}^{ab}. \tag{8}$$

Equations (4) and (7) describe the dynamic behavior of the system.

After n periods the price of grain and the resulting demand for energy are

$$P_{ot+n} = A^{b\sum_{r=0}^{n-1}(ab)^r} B^{\sum_{r=0}^{n-1}(ab)^r} P_{ot}^{(ab)^n}. \tag{9}$$

and

$$E_{t+n} = A^{\sum_{r=0}^{n}(ab)^r} B^{a\sum_{r=0}^{n-1}(ab)^r} P_{ot}^{a(ab)^n}. \tag{10}$$

This system is stable if P_{ot+n} converges to an equilibrium, which is the case if and only if

$$\lim_{n\to\infty} \sum_{r=0}^{n} (ab)^r \text{ and } \lim_{n\to\infty} (ab)^n$$

Panos Konandreas is a postgraduate research agricultural economist in the Department of Agricultural Economics and Richard Green is an assistant professor of agricultural economics, an agricultural economist in the Agricultural Experiment Station, and on the Giannini Foundation at the University of California, Davis.

Giannini Foundation Research Paper No. 418.

[1] By assumption (*b*), that is, producers apply a certain level of energy inputs with the anticipation that output price in the next time period (harvest time) is the same as the current output price, the expected profit at period $t + 1$ is given by $\Pi_{t+1} = P_{ot} Q_{st+1} - P_{et} E_t$. Maximizing this expression with respect to E_t yields equation (3). An error in Timmer's article in the derivation of the expression for E_t is carried forward in the other relationships.

exist. Both of these limits exist if and only if $|ab| < 1$, in which case

$$\lim_{n\to\infty} \sum_{r=0}^{n} (ab)^r = \frac{1}{1-ab} \text{ and } \lim_{n\to\infty} (ab)^n = 0.$$

Therefore, the condition that makes the system stable is $|ab| < 1$ or equivalently

$$(11) \qquad \left|\frac{\gamma}{\alpha(1-\gamma)}\right| < 1.$$

Assuming the above condition is satisfied, then the equilibrium (called long-run equilibrium) levels of the price of food grain, demand for energy input, and grain supply are, respectively,

$$(12) \qquad P^*_o = \lim_{n\to\infty} P_{ot+n} = A^{\frac{b}{1-ab}} B^{\frac{1}{1-ab}},$$

$$(13) \qquad E^* = \lim_{n\to\infty} E_{t+n} = A^{\frac{1}{1-ab}} B^{\frac{a}{1-ab}},$$

and

$$(14) \qquad Q^*_s = A_s E^{*\gamma} = A_s A^{\frac{\gamma}{1-ab}} B^{\frac{a\gamma}{1-ab}}.$$

Substituting for A, B, a, and b into equations (12), (13), and (14) gives

$$(15) \qquad P^*_o = \gamma^{\frac{\gamma}{\alpha(1-\gamma)-\gamma}} A_s^{\frac{1}{\alpha(1-\gamma)-\gamma}} A_d^{\frac{\gamma-1}{\alpha(1-\gamma)-\gamma}} P_{et}^{\frac{\gamma}{\gamma+\alpha(\gamma-1)}},$$

$$(16) \qquad E^* = \gamma^{\frac{\alpha}{\alpha(1-\gamma)-\gamma}} A_s^{\frac{\alpha+1}{\alpha(1-\gamma)-\gamma}} A_d^{\frac{1}{\alpha(\gamma-1)+\gamma}} P_{et}^{\frac{\alpha}{\gamma+\alpha(\gamma-1)}},$$

and

$$(17) \qquad Q^*_s = \gamma^{\frac{\alpha\gamma}{\alpha(1-\gamma)-\gamma}} A_s^{\frac{\alpha}{\alpha(1-\gamma)-\gamma}} A_d^{\frac{\gamma}{\alpha(\gamma-1)+\gamma}} P_{et}^{\frac{\alpha\gamma}{\gamma+\alpha(\gamma-1)}}.$$

The above equilibria exist only if the stability condition (11) is satisfied. If condition (11) does not hold, equilibrium is never reached and the system explodes. Timmer failed to notice this important point even though he obtained the same equilibrium expressions.[2] His expressions were derived by a mere substitution, and he failed to distinguish the time component involved. Implicit in his derivation was the assumption that, for large n, $P_{ot+n+1} = P_{ot+n}$, which implies that convergence was assumed or else that the system was forced to converge.

It is interesting to explore the stability region of the system, for the whole spectrum of elasticities, α and γ. Table 1 provides the values of the "stability" variable $\frac{\gamma}{\alpha(1-\gamma)}$ for different values of α and γ. The values of table 1 are graphed in figure 1. For any $\gamma < 0.5$, there exist several values of α that make the system stable. However, for $\gamma \geq 0.5$, no value of α results in a stable system. Timmer, in illustrating the differences in the elasticities between the short and long run, used $\gamma = 0.25$ (for which he cites another work by Timmer and Falcon, to which the authors did not have access, for this empirical evidence) and $\alpha = -0.20$. The "stability" variable for these values of γ and α becomes $\left|\frac{\gamma}{\alpha(1-\gamma)}\right| = 1.25 > 1$. Therefore, the system is unstable, long-run equilibrium does not exist, and thus a comparison between short and long run is meaningless. Accepting the empirically supported value of $\gamma = 0.25$ gives very discouraging results. The system converges only if the price elasticity of demand is at least 0.35 in absolute value and even in this case equilibrium will not be reached until after a considerable period of time. Price elasticities of the demand for rice for Asia range between -0.10 and -0.30 (Rojko, Urban, and Naive). For none of

[2] Note again the minor differences in the exponents that are the result of an error in Timmer's original article.

Table 1. Values of $\left|\frac{\gamma}{\alpha(1-\gamma)}\right|$

Value of γ	Value of α -0.05	-0.10	-0.20	-0.30	-0.50	-1.00
0	0	0	0	0	0	0
0.05	1.053	0.526	0.263	0.175	0.105	0.053
0.15	3.529	1.765	0.882	0.588	0.353	0.176
0.25	6.666	3.333	1.666	1.111	0.666	0.333
0.50	20.000	10.000	5.000	3.333	2.000	1.000
1.00	∞	∞	∞	∞	∞	∞

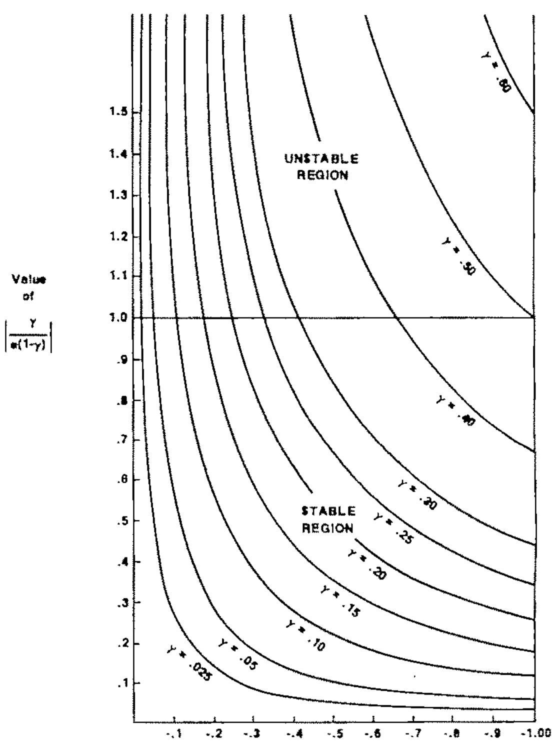

Figure 1. Relationship between α and γ in the stable and unstable regions of the model

these values of α (assuming $\gamma = 0.25$) is the system stable.

Although this analysis provides some clear insights into the dynamics of grain production and prices, one should be aware of the *ceteris paribus* conditions of the model. As Timmer points out, the effect of other variables influencing supply and demand should be examined. Substitution between energy and nonenergy inputs due to changes in relative prices, technological changes in grain production, and shifts in the demand due to population, income, and tastes have been ignored. Therefore, conclusions from this kind of model are qualitative in nature, indicating the tendencies of the effects of a change in the energy component, and one should refrain from any quantitative suggestions. A much more comprehensible model, empirical in nature, would be required for such an analysis.

Interaction of Energy and Food Prices in Less Developed Countries: Reply

C. Peter Timmer

I am indebted to Konandreas and Green for carefully setting forth the existence and stability conditions for long-run equilibrium for the simple macromodel I used to examine some interrelationships between energy and food prices in LDC's. The authors are quite right. I assumed such an equilibrium existed and simply solved for it. Fortunately, our answers are the same.

The addition that Konandreas and Green make is the delineation of production and consumption parameters that are consistent with a stable long-run equilibrium. Unfortunately, the parameters used in the original article did not meet this criteria, although those used in the most recent version (Timmer), based on much more reliable empirical study (David) than the original (Timmer and Falcon), are consistent. Of course, inconsistency of empirical parameters with long-run equilibrium for the macromodel can be as easily interpreted as a failure of Cobb-Douglas specifications to hold over broad ranges than as a case of incorrect parameters. This reinforces the observation that the macromodel primarily offers qualitative perspective on the energy-food price relationship.

In his discussion when the paper was originally presented, Castle argued that "maximum physical product" had been wrung from the model and that only careful empirical study could carry us much further (p. 246). I agreed with both points at the time, and now Konandreas and Green make the same plea. After consideration of possible empirical applications, I now think that the only purpose of the model was to remind us that we all live in an interdependent world where everything affects everything else. It is an elementary point but one that is frequently forgotten. Attempts to quantify it are not likely to be very rewarding.

Some Problems in Estimating the Demand for Outdoor Recreation: Comment

Jack L. Knetsch and Frank J. Cesario

In an interesting discussion of attempts to estimate the demand for outdoor recreation facilities, McConnell outlines the importance of the value placed on time as it influences decisions to make trips to recreation areas.[1] It is suggested that because time can be expected to have a negative influence on such decisions, estimates of demand curves derived using the travel-cost method are likely to be seriously biased unless models explaining trip quantities include a measure of total time of the outing rather than just the time incurred during travel. We do not think that this is necessarily the case. Disagreement in points of view may be due in part to a possible misinterpretation by McConnell of the mechanics of the travel-cost method and the rationale underlying it and in part to the failure of McConnell's (admittedly) simple model to capture the essence of alternative ways in which people may actually make decisions.

People contemplating a trip to a recreation facility presumably take account of both the money costs and the time costs, the latter reflecting total time of travel as well as duration of stay at the site. Certainly the total time commitment is a consideration having an important bearing on trip frequencies. However, this phenomenon is reflected in the observed numbers of people going to the site from different areas; i.e., people facing a two-hour drive to a facility for a day's outing weigh the whole days's time spent on this activity against the use of this same time in visiting alternative opportunities that may be located at different distances away or against doing something else entirely. Again, the point that seems to have been overlooked is that the observed visit frequencies are the outcomes of these weighting processes.

To perhaps better illustrate the role of travel time in recreation trip decisions, two views of these decisions can be taken. First, on any given outing it may be hypothesized that recreation seekers compare options for performing similar activities.[2] For example, on hot summer days the choice is generally between going to swimming pool A or swimming pool B; in winter periods, the choice is between skiing area A and skiing area B, and so on. The choice of an activity is the initial decision and the choice of where to go is a second decision, conditional upon the first. In these typical cases it is difficult to envision that the time spent on site would be considered as anything but fixed and independent of location. The relevant tradeoffs are between the attractiveness of alternative areas and the cost (time and money) of reaching them.

Second, in contrast to the first case, at the other extreme it might be argued that the time on site may diminish as the travel distance increases, thereby implying that there is a fixed total time allocated to a particular outing—say, a few hours, an afternoon, or a whole day. This assumption, which also might be considered as quite realistic, again implies that the distribution of visits to sites is determined by travel costs of which time cost is a major component.

Both of the above assumptions appear to be reasonable and it remains for empirical work to shed light on which one best describes actual behavior in different situations. But the main point remains that it is not the lack of an accounting for total time of the whole trip that is the source of difficulty in obtaining reasonable estimates of demand curves using the travel-cost method.

The so-called travel-cost method makes use of a visit-estimation model capturing the relationship between the number of trips from varying origins and the generalized costs of making these trips. A demand schedule is then imputed from this visit-estimation model by hypothesizing increasing costs to visits and estimating the consequent expected decreases in visitation. If only the money costs of travel are used in the analysis, the resulting demand and benefit estimates are subject to a serious bias (Cesario and Knetsch). This bias is caused by the implicit assumption that the only reason underlying visit rate (i.e., visits per capita) variations between origins of trips located at varying distances away from a park is the difference in money outlays. Of course, this is not likely to be the case. In particular, the time required to travel different distances

Jack L. Knetsch is a professor in the Department of Economics and Commerce at Simon Fraser University, Burnaby, British Columbia, Canada, and Frank J. Cesario is an assistant professor in the Department of Environmental Engineering at Cornell University, Ithaca, New York.

[1] In addition to the travel time issue, McConnell addresses two other important issues in recreation demand modeling: choice of an appropriate unit for measuring consumption and choice of an appropriate specification of the demand function. We do not comment here on these other issues.

[2] The focus here is on recreation trips that are made within the framework of fixed total time budgets. Thus, this analysis is not useful for comparing, say, an afternoon outing with a trip of several days' duration.

would be a major reason for the observed variation in visit rates, an assertion that is well supported both theoretically and empirically.

Thus, when the model predicts that numbers of visits will decline with increased money costs, the decrease is consistently overestimated if time cost is not included. In reality, the visit rate for any origin is expected to decrease with an increase in money cost but not to the extent indicated by the observed distance-decay function (which in essence reflects only effects of money costs) since time costs remain constant at the original level. For instance, with respect to a particular origin, if money costs equivalent to an added distance of 30 miles were added to money costs associated with an original distance of 20 miles, the visit total for the origin in question could not realistically be expected to be that of an origin 50 miles from the park. The new money outlay would be that associated with travel over 50 miles, but the time cost is still that which was associated with the original 20 miles.

The demand curve is then conservatively biased for all points except the zero "price" point. More visits would in fact be expected for each assumed money cost increase than would be calculated directly from the model. The problem of demand curve bias is therefore due to ignoring travel time and not from a failure to take account of the total time needed for the whole enterprise. While better insights into why demands for the use of recreation areas might well result from more attention to the effects of time constraints, the problem of dealing with travel time in imputing demand curves seems to depend on determining its relative weight in a generalized cost function.

Some empirical work is beginning to provide interesting results in establishing the needed values. A study by Mansfield suggests that the weight or importance of time in overcoming greater distances to recreation sites is perhaps of greater importance than the money costs involved. As he notes, the issue is the disutility of time traveling to a recreation facility and not that of traveling, say, within a park. Some further travel time results with implications for recreation modeling are provided by Cesario in which the results of a number of travel time studies are reported. The results suggest that times values from one-fourth to one-half of wage rates might well be appropriate on the average. The impediment of time might well vary, for example, with the nature of the scenery or local amenity or other factors. Travel time would be less of a burden for a journey through semispectacular landscapes than one through more drab countryside, and the weights for the variable measuring the importance of travel time could in principle at least reflect this. Future research should provide some valuable insights into these questions.

Some Problems in Estimating the Demand for Outdoor Recreation: Reply

Kenneth E. McConnell

The Knetsch and Cesario comment is valuable because it encourages thinking about how recreationists make decisions. Knetsch and Cesario take issue with my result that the cost of total time, not simply the cost of travel time, be added to the per unit travel costs of a trip.

In their comment, Knetsch and Cesario raise two basic issues. (*a*) A more realistic model would permit time on site to vary as per trip costs vary. (*b*) In a two-stage decision-making process, the recreationists choose first the amount of time per activity and second at which site to participate in the activity. Knetsch and Cesario assert that in such a framework time spent on site is considered fixed and hence not part of the costs of recreating. I will discuss each of these issues separately.

A utility maximization model is best at bringing out the implications of assumptions. It abstracts from the many realistic details that are important for decision making. In my paper, in order to concentrate on the demand for trips, I assumed that trips are of fixed length. The conclusions are not based on the assumption that the length of a trip is fixed. The model can be modified so that time spent per trip (a_j) is also a choice variable. However, even when the time spent per trip is a choice variable, it can be demonstrated that the recreationists consider the opportunity cost of the time used by the whole trip and not simply the travel time.

In my paper, the decision-making process is such that the individual chooses simultaneously which site to visit and how many trips to take. The recreationist compares in his mind the enjoyment he gets from participating in an activity at a particular site with the opportunity costs of the time and money required by a trip. It is important that the individual consider both the activity and the site simultaneously, because the same activity engaged in at two different sites may result in substantially different experiences. For example, swimming at a crowded pool is a very different experience from swimming in a lake in a natural environment with few people. Each trip to a particular site must be worth at least the travel cost plus the opportunity cost of the total time spent on the trip. Otherwise, the individual would not go. This can be seen clearly by rewriting equation (8) of my paper (p. 331):

$$(1) \qquad (\partial U/\partial r_j)/\lambda = c_j + a_j m_T.$$

The term on the left is marginal money value of a trip to the jth site. The term on the right is the marginal cost of a trip to the jth site. For the recreationist to ignore the total time spent on the trip, the opportunity value of time (m_T) must be 0.

Knetsch and Cesario have outlined a rather different process of decision making, which involves two stages. First, the recreationists decide in which activity (camping, swimming, etc.) they will engage. Second, they decide on which site they will engage in the activity. By making the assumptions of the decision-making process explicit, it can be demonstrated that the value of total time and not simply travel time should be measured as part of the cost of the outing.

Suppose that the individual has completed the first stage of decisions by choosing the optimal quantities of each recreation activity per period, denoted by T^*_i—the optimal number of trips of swimming, skiing, etc. The second stage of decision making is investigated, where the individual chooses r_{ij}, the number of trips of the ith activity at the jth site. (For simplicity, we assume that all trips are the same length so that the $a_j = 1$.) Let utility depend upon r_{ij} and let c_{ij} represent the travel costs required to engage in activity i at site j. The second stage problem is to maximize with respect to r_{ij}:

$$U(r_{ij}) - \lambda(\sum_i\sum_j c_{ij}r_{ij} - y^*) - \sum_i\psi_i(\sum_j r_{ij} - T^*_i),$$

where y^* = the amount of income to be spent on recreation. At the optimum,

$$(2) \qquad \partial U/\partial r_{ij} = \lambda c_{ij} + \psi_i \text{ for all } i \text{ and } j.$$

Condition (2) states that the recreationist engages in activity i at site j up to the point when its marginal utility ($\partial U/\partial r_{ij}$) equals the utility opportunity cost of expenditures plus ψ_i. The multiplier ψ_i is interpreted as the marginal utility of another trip in the ith activity. It is the opportunity cost of going to site j rather than another site. Then equation (2) can be given exactly the same interpretation as equation (1). The optimum allocation of time and income to r_{ij} is such that the marginal value of r_{ij} (in money terms) equals the opportunity cost of time plus the

---

Kenneth E. McConnell is an assistant professor in the Department of Resource Economics at the University of Rhode Island, Kingston.

Contribution No. 1669 of Rhode Island Agricultural Experiment Station.

out-of-pocket costs of getting to the site. The cost of a trip, whether one approaches it via the Knetsch-Cesario two-stage decision or via a simultaneous consideration of site and activity, should include the opportunity costs of the total time on the trip.

Although this two-stage approach reaches the same conclusion, it seems unrealistic. It requires that the recreationists choose their activity without considering the site. Having selected the activity, recreationists then choose from the sites where the activity is available. At the second stage, the recreationists must choose the site to visit regardless of the quality of available sites and despite the fact that they could do something else with their time. Such a decision-making process has the implication that aggregate participation in any recreation activity is independent of congestion or other site quality variables of the activity. In fact, site quality variables would affect only the distribution of trips among sites and not the total number of trips.

The result that rational allocation requires the recreationist to consider the opportunity cost of total time is useful because it permits us to reinterpret benefit estimates that omit the total cost of time. The result may also be useful in explaining negative or insignificant income elasticities that researchers occasionally obtain for various recreational sites. Time costs and income are highly correlated. At some point, as income increases, the negative effect of the higher cost of time may outweigh the positive effects of higher income. However, a regression that includes income and omits the cost of time would impart a substantial downward bias to the income coefficient.

In conclusion, the opportunity cost of the recreationists' time is important in the decision-making process and should be considered as part of the per unit cost of a trip. Not only does it improve measurement of net benefits but it helps in understanding the determinants of recreation participation.

The AAEA Membership: Employment and Mobility Patterns

Anne E. Peck and Emerson M. Babb

Perceptions of one's profession are very subjective. For agricultural economists this subjectivity is increased because of the diversity of employment opportunities both within the profession and within even the academic component of that profession. Thus, data that can be used to provide more objective views are of interest, making individuals aware of more general patterns within the profession. Both Helmberger and Boddy have provided data on the market situation for agricultural economists in 1970, while Gray (1973a, b) has offered some interesting analyses of changing interest areas within the profession. This note summarizes data obtained in the 1971 survey of members of the American Agricultural Economics Association (AAEA). The first section summarizes this data to describe general employment patterns of agricultural economists, defined here as members of the AAEA. Then, some characteristics of the mobility of members are considered. Particular interest focuses upon academicians, and several measures examine the extent of inbreeding on faculties of agricultural economics.

The AAEA membership data that were published as the "Handbook-Directory" of the AAEA in 1972 pose several problems for these analyses. Initially, all student members and all incomplete responses were eliminated. The remaining 2,075 members constitute this sample of the agricultural economics profession. It is a biased sample, representing mostly individuals who have obtained advanced degrees. Thus, the analyses should be extrapolated to the profession at large with a great deal of caution. The data constitute a snapshot of the profession, and that picture is now somewhat dated. Consequently, the material presented here is primarily descriptive. Interesting patterns do emerge, however, and these may stimulate others to seek further for explanations.

Current Employment Patterns

General characteristics of employment patterns and education levels of the AAEA members are summarized by the data in table 1. AAEA members are mainly advanced degree holders, employed in either academics or some level of the government. Approximately 96% of the AAEA members held an advanced degree, while nearly three-quarters of them held a Ph.D. degree. Viewed by employment categories, nearly 65% of the members were academics and 24% were in government employment.

These concentrations underline the biases involved in viewing the AAEA members as a representative sample of the agricultural economics profession. Data provided by Helmberger from the 1970 American Science Manpower survey sponsored by the National Science Foundation (NSF) can be used to approximate the extent of this bias. The NSF survey attempts to achieve a broad representation of professionals in specified areas. In addition to the membership lists of the professional organization, their lists contain individuals attending professional meetings, those subscribing to professional journals, and alumni of various institutions.[1] For agricultural economists thus defined, only 55.5% were academics while 30% were employed in government in 1970. Interestingly, the NSF data showed that 93.5% of agricultural economists had advanced degrees. The concentration at the Ph.D. level was not as high as that in the AAEA data, however, with only 57.5% of the surveyed individuals holding Ph.D.'s.

Within the degree categories, some similarities appear between the AAEA members' survey and the NSF survey. For instance, of AAEA members with Ph.D.'s, 73.4% were employed as academics in 1971. The NSF survey data showed 72.5% of Ph.D. holders were academics in 1970. Similarly, of the AAEA members with Ph.D.'s, 5.7% were employed in business while 19.1% held jobs in government. The analogous figures from the NSF survey were 2.6% and 19.5%, respectively. Thus, individuals with Ph.D.'s appear to be proportionately represented in the AAEA survey. With this result, further analysis of current employment patterns considers only those AAEA members who have received Ph.D.'s, that is, only that portion of the

Indiana Agricultural Experiment Station Journal Paper No. 6090. The authors wish to thank Bruce Scherr for assistance in assembling the data and Glenn Nelson, Lee Schrader, W. G. Tomek, and two anonymous reviewers for their helpful comments and criticisms.

[1] In 1970, the NSF survey classified 1,501 individuals as agricultural economists. This compares with the 2,075 AAEA members represented here. The difference is primarily in definition of an agricultural economist. Individuals with specialties in international trade, economic development, and econometrics were classified as economists in the NSF reports. No information on an individual's specialty was available in the AAEA survey.

Table 1. The Distribution of the AAEA Members by Current Employment and by Highest Degrees, 1971

	Highest Degree Held			
Current Employment	B.S.[a]	M.S.	Ph.D.	Total
Academic	15	188	1,135	1,338
Business	25	72	89	186
Government	33	170	295	498
Nonprofit institutions	1	2	17	20
Other[b]	3	20	10	33
Total	77	452	1,546	2,075

[a] Includes five members who indicated that no degree had been received. Of these, four were currently employed in academic institutions and the other was employed in government.
[b] Other includes self-employed, retired, and types of employment not identified.

sample that appears most nearly representative of the profession.

In the AAEA survey, individuals were asked to indicate where they had taken their various degrees. One hypothesis is that graduate training and occupation choice are independent. Equivalently, the hypothesis is that the institution from which a degree was taken had no influence on the job choice. Table 2 summarizes the current employment data by school from which the degree was obtained. Only schools that had given degrees to more than five AAEA members were separately listed. Because of the negligible importance of two of the employment categories, nonprofit institutions and other, they have been omitted here. The figures in the employment categories are percentages, making comparisons among schools more clear. However, the last column of data in this table contains the actual total number of AAEA members who had Ph.D.'s from these schools. Thus, the relative contribution of each of these schools in supplying Ph.D.'s can be easily seen.

A chi-squared test was performed to test the hypothesis of independence between current employment and the school from which the Ph.D. was received. The hypothesis was rejected at the 4% level. Thus, there were significant differences in the employment choices among the graduates of the individual institutions. The reader may find the school-by-school data interesting though no clear patterns emerge. Six schools (Purdue, Iowa, Michigan State, Minnesota, Cornell, and Wisconsin) clearly dominate as suppliers of AAEA members with Ph.D.'s. A total of 733 members received their degrees from one of these institutions, that is, nearly one-half of the total membership who have Ph.D.'s.

Mobility Patterns

The 1971 members' survey was not designed to provide data for an analysis of individual's movement either between or within particular employment categories. The questionnaire provided a relatively small space for individuals to describe previous employment (Handbook-Directory, pp. F–G). Furthermore, respondents were not explicitly encouraged to include details on all previous positions.[2] Thus, the data used in the following analyses are likely to be biased downward, underestimating mobility within the profession. The extent of this bias is unknown. All reported previous employment was counted in an effort to minimize the extent of the bias. For individuals who were currently academics, sabbatical and other leaves of absence were counted as previous jobs. For analysis of some questions of mobility, such as of the criteria upon which a job-change decision was made, this procedure would be inappropriate. However, interest here centers on diversity and movement within the profession, and leaves of absence contribute to both these aspects of mobility.

The data in table 3 summarize individuals' reported current and previous employment. Most obviously, they suggest that academicians are relatively mobile, both among schools and among occupations. Almost 70% of the individuals who were currently at universities had been employed at other universities. This no doubt reflects the effects of including leaves of absence as previous employment. More interestingly, of those currently employed in other occupations, a relatively large percentage had been employed as academicians previously. In fact, university employment is nearly always the largest category of previous employment. The only exception is with government employees, a larger percentage of whom had held some other position in government. These data suggest that AAEA members are relatively mobile individuals within the profession.

The academic component of the membership appears to be highly mobile, even if the effects of the various data problems are considered. This suggests that faculties of agricultural economists are quite diverse, in general, bringing together a wide range of backgrounds and experiences. The remainder of this analysis attempts to investigate this hypothesis. Only AAEA members who are currently academics are included. Further, these members are sorted by schools; thus, the unit of observation is a faculty of agricultural economists. The implicit assumption is that a faculty can be represented by its AAEA members. For an individual school, this assumption may cause some difficulties. Thus, the major results here are presented in terms of regional aggregates of schools. Selected information on individual schools is presented in table 4.

With the AAEA member data, three measures of

[2] There are some studies of the mobility of academicians more generally. Sample questionnaires designed specifically to investigate mobility questions are available in Marshall, pp. 139–42, and Brown, pp. 199–205.

Table 2. Employment Patterns of the Graduates of Major Ph.D.-Granting Institutions, AAEA Members, 1971 [a]

School	Percentage of Ph.D.'s Employed in: Academics	Business	Government	Total Number of AAEA Members with Ph.D.'s from Specified Institution [b]
California [c]	76.1	8.7	12.0	92
Stanford	83.3	0	8.3	12
Connecticut	77.8	0	22.2	9
Florida	75.0	8.3	16.7	12

Ohio State	75.0	9.7	13.9	72
Oklahoma State	79.6	4.1	16.3	49
Oregon State	75.9	3.4	13.8	29
Pennsylvania State	76.9	5.1	17.9	39
Tennessee	80.0	10.0	10.0	10
Texas A&M	83.3	0	16.7	18
Washington State	75.0	12.5	12.5	16
Wisconsin	74.8	1.0	24.3	103
Simple average [d]	74.0	4.9	19.6	
Weighted average [e]	72.8	5.7	19.6	
All other schools	82.4	5.9	11.8	102
Weighted average for total population	73.5	5.7	19.1	1,546

[a] The figures in this table pertain to only those members of the AAEA who had obtained Ph.D's. Only institutions that granted more than five Ph.D.'s to AAEA members are specifically listed here. All other institutions are aggregated in the "Other" category.
[b] The percentage figures may not add to 100 for every school as two employment categories, nonprofit institutions and other, have been omitted. However, the figures for total number of graduates, entered in the last column, include individuals in those two categories as well as the three primary ones.
[c] Includes both Berkeley and Davis campuses.
[d] The average percentages for the twenty-nine schools listed above.
[e] Weighted average percentages take into account relative sizes of the institutions being aggregated. The unit of observation is the individual rather than the school.

Table 3. Mobility of AAEA Members among Occupational Groups

Current Employment Status	Percentage of AAEA Members Who Have Held Positions in an Employment Status Different from Current Position [a]: Academic	Business	Government	Foundation	Other
Academic	68.7	8.0	25.7	1.7	6.3
Business	41.6	39.5	24.3	1.1	5.4
Government	44.2	9.4	57.8	1.9	5.0
Foundation	60.0	10.0	25.0	25.0	10.0
Other [b]	51.5	9.1	30.3	0	30.3

[a] For example, for members currently employed as academics, 68.7% have held positions in other academic institutions, 8% have had business experience, 25.7% have had government experience, and 1.7% have had foundation experience.
[b] Other includes self-employed, retired, and types of employment not identified.

Note: Only schools with at least ten AAEA members on their staffs are included.
[a] Includes both the Davis and Berkeley campuses.

diversity of staffs were constructed. The first, the percentage of staff members who had received their Ph. D.'s from that same school, is the traditional measure of inbreeding. The second, the percentage of staff members who had received at least one degree from that same school, measures inbreeding with a somewhat broader definition. Finally, information on previous employment was utilized to calculate the percentage of a department's staff who had never held a position outside that state.

Table 5 presents the results of these calculations, averaged over five regional groupings of individual schools. Schools in the North Central region are clearly the most inbred. Nearly a third of their staffs have received their Ph. D.'s from the school of their current employment, and more than 50% of their staff have taken at least one degree there. These are nearly twice the averages for the other regions. The rankings of the other groups of schools change considerably between these two measures. The similarity of the measures and the changing rankings suggest that an element of individual choice may be involved in returning to a school where a degree had been obtained. Hiring of a

Table 5. Diversity in Faculties of Agricultural Economics Departments, AAEA Members, 1971[a]

Region	Staff with Ph.D.'s from School of Current Employment	Staff with at Least One Degree from School of Current Employment	Staff Never Worked Outside of State[b]
		%	
Northeast[c]	15.7	34.8	39.7
South	10.1	35.8	45.8

Mountain, Plains, and Southwest	7.9	37.8	36.1
Pacific	16.6	27.9	37.1

[a] Averaged over schools in each region with more than ten AAEA members. School specific data are reported in table 4.
[b] Experience outside of state includes any government or business position held previously, as well as other academic positions.
[c] Northeast: Connecticut, Maine, Maryland, Massachusetts, Cornell, Penn State; South: Alabama, Polytechnic Institute, Arkansas, Florida, Georgia, Kentucky, Louisiana State, North Carolina State, Clemson, Tennessee, Virginia Polytechnic Institute, West Virginia; North Central: Illinois, Purdue, Iowa State, Michigan State, Minnesota, Missouri, Ohio, Wisconsin; Mountain, Plains, and Southwest: Arizona, Colorado State, Idaho, Kansas State, Montana State, New Mexico State, Nebraska, North Dakota State, Oklahoma State, South Dakota State, Texas A&M, Wyoming; Pacific: California, Stanford, Oregon State, Washington State, Hawaii.

department's own Ph.D. students to fill staff vacancies is often guided by policy decision within a department or a university. However loosely enforced, there usually are guidelines of some sort. This is not as often true when an individual has taken another degree, a B.S. and/or an M.S., from the school. Further, at least one study of academic mobility presented evidence of a tendency for academics to wish to return to a region they know, their "home" region.[3] Thus, the second measure may reveal the combined influences of departmental policies and individual desires.

The third measure of diversity of departments' faculties results in a completely different ranking of the schools. From the information available on previous employment, this measure provides an estimate of the percentage of staff members who appeared to have never worked outside of the state of their current employment. Graduate school experience was excluded, but business and/or government experience was considered sufficiently different from academics so as to be included as outside work experience. By this measure, the faculties of southern schools appeared to be least diverse. These same schools were not highly inbred, suggesting that there is a relatively low turnover rate in the faculties of these schools.

Taken together, the data in table 5 suggest a significant amount of regionalism in departmental faculties. If hiring of one's own Ph.D. students is not particularly excessive, perhaps there are significant intraregional trading patterns among schools within the various regions. The regional employment ratio constructed below provides an indication of the extent of trading among schools within each of the five regions. If each region were viewed as a single school, the ratio is simply the percentage of the staff of that school who obtained their Ph.D.'s there divided by the percentage of the graduates of that school in the total population of schools. Alternatively, it is the actual percentage of inbreeding given the population. The calculations in table 6 are all weighted averages, since concern is with distributions within the population of academics. Finally, using weighted averages allowed inclusion of all schools in each region, even those with less than ten AAEA members.[4]

From table 6, the North Central region is clearly the largest supplier of academics with Ph.D.'s. Fully 45% of AAEA members currently employed as academics received their Ph.D.'s from a North Central school. Since this region contains most of the largest schools, it is not unexpected that a large percentage (62.5) of staffs of these schools obtained their Ph.D.'s from schools in this same region. This gives a relatively low regional employment ratio of 1.4, that is, staffs of these schools are regionally inbred only 1.4 times the expected level of inbreeding given the population. The results for the southern schools are at the opposite extreme. While only 7.3% of all the academics in the AAEA sample received their Ph.D.'s from these schools, 25.7% of these schools' combined faculties had degrees from this region. This is 3.5 times the population distribution, implying an important tendency to hire within the region.

In an applied discipline such as agricultural economics, some regionalism of the staff is to be

[3] The study polled a sample of recent movers in all areas of academics. Individuals were asked to designate regions to which they desired to move. Generally, over half of the respondents desired to return to an area where they had been in school previously, either in high school, undergraduate, or graduate school (Brown, pp. 88–89).

[4] The regions are basically those defined by the schools in footnote c to table 5. Examples of schools included in these weighted averages that were omitted there are Harvard, Chicago, M.I.T., Nevada, New Hampshire, Rutgers, and Rhode Island. These schools have less than ten AAEA members on their staffs, but some have been important sources of members of the AAEA. Each of the previously omitted schools was counted in its appropriate regional aggregate.

Table 6. Intraregional Trading Patterns of Faculties of Agricultural Economics, AAEA Members Only, 1971

	Academics with Ph.D.'s from School in Region[a]	Staff of Schools in Region with Ph.D.'s from School in Region[b]	Regional Employment Ratio[c]
	%		
Northeast	12.6	38.3	3.0
South	7.3	25.7	3.5
North Central	45.1	62.5	1.4
Mountain, Plains, and Southwest	6.6	17.9	2.7
Pacific	8.9	27.3	3.1

[a] The percentage was calculated over the entire sample of AAEA members who are currently academics. Column does not add to 100 because some academics do not have Ph.D.'s and small domestic and all foreign schools have been omitted.
[b] Average taken over all schools in each region, weighted by the number of AAEA members on each school's staff.
[c] Column 2 divided by column 1.

expected. Production practices, cropping patterns, and even crops grown change substantially among regions. Furthermore, when the extension mission of many of these departments is considered, some regionalism is probably desired. How much is desirable is a question not addressed here. The evidence presented suggests that patterns differ substantially among regions. It suggests also that the market for academicians is very imperfect. Finally, much more information is needed to begin to put causes together with the observed differences.

Committee on Agricultural Production Efficiency. *Agricultural Production Efficiency*. Washington: National Academy of Sciences, 1975, 199 pp., $6.50.

Events of the past three years have raised new questions about excess capacity in the U.S. farm production plant. Grain stocks have been worked off, partly by fortuitous expansion of world demand and partly by several years of diverting production potential into idled acres. At the peak, when stocks were drawn down, some 60 million acres available as reserve production plant were our insurance. Programs were modified in each of the last three years to employ part of the idled acres to rebuild some grain reserves. By 1975 all of the idle acres were permitted back in production.

We were then treated to a great shock. Only about 38 million of the 60 million acres apparently came back into production, despite record high prices. Stocks did not get rebuilt. What happened? The causes are not yet all sorted out. As one part of an explanation, the suspicion is beginning to emerge that productivity of this acreage in reserve may have been severely overestimated. The recent events also raise questions about whether we can rely on the estimate of natural resource specialists that we have some 30 million acres in other uses, which could be brought into cropland. A look at acreage in 1975 versus the 1920s would verify that our current cropland base is smaller than the earlier one. But if prices of commodities during 1973–75 do not stimulate significant land development, we must take another look at the economic potential. Was the high recent price level considered temporary by landowners, with a longer term expectation insufficient to support the investment? Or were our calculations of economic potential of cropland base in error?

The possibility that we have fewer units of idle land and potential cropland than we thought focuses added attention on the question of increasing productivity of our current acreage. That is the topic of the monograph under review. In 1971, the National Academy of Sciences constituted the Committee on Agricultural Productivity. Two avenues of concern were expressed. One was general—unease over two decades of increasing emphasis on putting new resources in areas outside agricultural production and on shifting from farm production to development and social problems within the agricultural research funds. The second and precipitating concern was the apparent slowing of the increase in agricultural productivity reflected in the U.S. Department of Agriculture productivity indices. The unprecedented grain exports, the disappearance of our grain reserves, and the energy crisis came while the study was underway. The reevaluation of the capacity of our idled and potential acres comes since publication of the monograph. All emphasize the timeliness of this report.

The book is a wide ranging "report to the public" on the status of agricultural productivity. It is extremely readable and well organized. An early chapter covers the concepts of productivity and efficiency and reviews the various partial and total productivity series produced by the Economic Research Service. It notes with concern the ERS habit of changing base periods or calculation procedures in this extremely vital series with little or no public announcement. In fact, revisions of this type canceled out the apparent productivity dip that was the concern precipitating the formation of the National Academy of Sciences committee. The report suggests a number of measures that could be used to improve the current series.

Two major chapters explore the social assistance to agricultural productivity and the social constraints imposed upon it. The committee emphasizes the need for clearer delineation of the tradeoffs in productivity versus social control in areas of regulation of environment, transportation, and other areas.

Additional chapters describe and evaluate agriculture and the energy situation in a lucid fashion. These provide some general hints on directions for future research. They note that plant agriculture is an energy capturer. Photosynthesis itself is able to gather about 1% of available sun energy. Some half of that is in economic parts of the plant. Net product from animals using these plant products is some 4% to 10% of the total energy in the feeds. They point out that cultural energy—in petroleum, fertilizers, etc.—is used 10 to 100 times more efficiently than is solar energy. The analysis both suggests an emphasis on improved capture of solar energy and an emphasis on plant and animal forms using cultural energy more efficiently. Altogether, the chapters provide a fascinating overview.

Other chapters review potential areas for re-

search breakthroughs in plant and animal areas in the near future, providing both a clear explanation and some guidance on priorities for the layman.

The committee concludes that productivity can continue to increase over at least a decade from known or nearly known sources. They contend that there are limits to which various biological processes can go but also emphasize that striking one limit often stimulates search in another direction, opening unforeseen opportunities. Contending that the lead time from discovery to application is about twenty years, the committee suggests increased funding is necessary for agricultural productivity research in the immediate future.

I would recommend this book to all economists interested in resource allocation in research. It provides a nontechnical insight into biological frontiers. It places energy flow in agricultural systems into better perspective than seen before. The work is broad, benefiting from a wide range of disciplines on the committee. The prestigious sponsoring organization should provide these views with an aura of legitimacy not available to the more traditional advocates of the agricultural establishment. The style of writing aids in making the arguments accessible to a wide variety of informal audiences. The analysis itself also provides an excellent starting place for reassessing priorities in use of existing agricultural production research funds.

George D. Irwin
Farm Credit Administration

Grigg, D. B. ***The Agricultural Systems of the World: An Evolutionary Approach.*** **Cambridge: The University Press, 1974, ix + 358 pp; $24.00, $8.95 paper.**

Here we have a book with wonderful possibilities. From an author who has mastered such a wide scope of the literature on agricultural subjects drawing upon history, geography, and economics, we should take him at his word when he promises to attempt to "describe the chief characteristics of the major agricultural regions of the world and to attempt some explanation of how they came into being" (p. 1). Indeed, we are treated to a smorgasbord of descriptions of farming systems around the world, past and present. For this service alone the book is a valuable (and expensive, in hardback at least) addition to the library of anyone with even a passing interest in the subject. But the promise of learning "how they came into being" is not fulfilled. Perhaps the author's intentions were suggested in his subtitle, "An Evolutionary Approach"; unfortunately, evolutionary and historical explanations in agriculture are no more identical than they are in English history, where the genealogy of the royal family does not quite serve as an adequate history of the British Empire. Grigg's method is more genealogical or sequential, listing the stages in the evolution of farming systems.

True, there are glimpses of how things came to be. Demographic influences, subsidies, and tariffs as well as patterns of landholdings are recognized as important human influences in shaping the course of agricultural development; usually, however, human activity merely conforms to the imperatives of the existing price structure. The exceptions to this statement most frequently are found in the treatment of tropical agriculture, where more direct human intervention is given more prominence. Here, slavery, force, and other factors less amenable to the "evolutionary" treatment are given their due.

While other readers may share my disappointment in the gap between the performance and the promise of the book, they will probably agree that the mass of scholarship at Grigg's disposal makes him one of the very few people from whom such a promise could be taken seriously.

The arrangement of the book is very convenient. Each form of agriculture, such as plantations, dairying, etc., is studied in a separate section that is subdivided by its geographical variants. The latter, in turn, are described along with their "evolutionary" histories. This approach is most rewarding in the section on wet rice farming techniques, which dramatically vary among regions.

Michael Perelman
California State University, Chico

Paige, Jeffrey M. ***Agrarian Revolution: Social Movements and Export Agriculture in the Underdeveloped World.*** **New York: Free Press, 1975, xiv + 435 pp., $15.95.**

This work begins as if it might be a Marxist analysis of the preconditions of revolution in export agriculture. While modern industry has not produced the homogeneous labor force of impoverished workers that Marx and Engels "predicted" (Paige's term, p. 33), much of the export agriculture in the third world appears to have created just such a labor force. By the fiftieth page we hear no more of Marx after having learned that the failure of the rate of profit to decline has allowed the capitalist employers to loosen the chains of exploitation that might have otherwise made any alternative other than revolution a hopeless prospect.

Nowhere does Paige mention Marx's few tantalizing references to the role of highly profitable colonial ventures in shaping the destiny of North Atlantic capitalism, a topic not extensively covered in *Capital,* which was essentially a model of a closed economy (see Rosdolsky, I, pp. 39, 74, and 95). But Paige does not demonstrate a believable concern with Marxist theory; rather his thesis is flatly conventional. For him, capitalism in general

does not lead to revolution, even in export agriculture. Only those variants that Paige terms "constrained capitalism" are conducive to revolution, that is, where landed elites restrict the workings of the market (p. 320).

Paige's analysis of "constrained capitalism" consists in developing a theory of how "variations in the principal source of income of both cultivating and noncultivating classes" (e.g., wage labor, share cropping, etc.) " 'influences' their political behavior in conflict situations" (p. 334). His analysis is based on a model of a "calculus of force" that is "just as orderly and rational . . . as the principles of economics" (p. xi). Indeed, Paige's approach is much like what one would expect from an economist, except that Paige has to go to greater lengths to develop a data base. Reports of "events" in which agricultural laborers in major exporting sectors engaged in collective noninstitutional group-based activity were coded according to various characteristics. These codes then become the dependent variable to be explained by the form of agricultural organization. Revolutionary socialist events are "moderately correlated ($r = 0.39$) with sharecropping systems, agrarian events (such as land seizures, MP) are strongly correlated with commercial hacienda systems ($r = 0.51$), and labor events (such as strikes, MP) are strongly correlated with plantation events" (p. 104).

These broad results are followed by case studies of Peru, Angola, and Vietnam in which these general results are amplified with a detailed analysis of his "calculus of force." Here, Paige demonstrates how peasants and agricultural workers in these nations assess the benefits and risks of political action. The detailed descriptions of the organization of agricultural enterprises in these nations make up the best of Paige's book. Not only are his choices of cases timely, the variation of agriculture within these nations neatly supports his thesis.

Nevertheless, Paige's anti-Marxian conclusion must be taken with a grain of salt. The antirevolutionary hero of Paige's drama is the modern plantation whose progressive technology allows a constantly expanding standard of living. For Paige, revolution is as obsolete in third world agriculture as in modern industry. Reading this sort of conclusion requires an act of faith at a time when modern industry is beset with fundamental problems, not the least of which is the uncertain future exploitation of export economies such as Paige describes.

Paige himself hints at the struggles within export agriculture in the third world. Profits from W. R. Grace's sugar in Peru no longer depend upon its sugar plantations; control of refining marketing gives it every bit as much power as before land reform (p. 142). United Fruits's retreat from production is also recognized. With multinational corporations replacing the traditional landowning elite as the source of exploitation, new forms of political struggle must develop. The paucity of "events" by wage workers on the plantation may just as well mean a temporary pause to develop new tactics as a final outcome in the "calculus of force."

Agricultural economists will certainly benefit from the descriptive sections of the book, especially his treatment of the enormous institutional variations that come in the wake of market fluctuations. Finally, the book develops a valuable picture of how development as well as its absence affects the lives of the working people who grow the export crops in the third world.

Michael Perelman
California State University, Chico

Prescott, James R., and W. Cris Lewis. *Urban-Regional Economic Growth and Policy*. Ann Arbor: Ann Arbor Science Publishers, 1975, x + 220 pp., $12.50.

As stated in the preface, this book deals with numerous problems along the size continuum of subnational regions and issues of policy at the local, state, and national levels. The principal objective is to analyze some of the major difficulties encountered at each spatial level and to suggest how various methods may be used to empirically estimate their impacts.

The book reports on several empirical studies conducted by the authors in the midwestern United States. The book is easy to read; there are several equations, but they are empirical rather than theoretical derivations. The book assumes a basic knowledge of econometric modeling, simulation modeling, discriminant analysis, linear programming, and regression analysis. This book should be of interest to agricultural economists because of its implications for rural development policies and for the research techniques applied to problems in rural-urban regions.

Chapter 1 introduces concepts useful in understanding the subsequent chapters. It contains very brief discussions of bid-rent location theory, export base theory, and central place theory. These discussions are too brief to be useful, and their relevance to the rest of the book is not explained. There is a better discussion of spatial delineation, including political policy regionalization, further on.

Trends in rural development and policy are related to the concepts of central place theory in the next chapter. The discussion of the relationship between rural development and the export base theory is weak; there is no discussion at all relating it to bid-rent theory. There is a good discussion of

four specific rural development policies, but the reader is left wondering if perhaps there may be other alternatives. The chapter relates specifically to two substate regions in Iowa; the explanation of their position in the central place theory hierarchy could be improved.

Chapter 3 describes an econometric model relating population and employment levels in central and peripheral counties to other socioeconomic variables. The explanation of the correlation between variables, both dependent and independent, is good. However, many of the independent variables appear questionable based on the significance of their *t*-values. These variables remain in the econometric equations with little or no explanation. The empirical results generally confirm the advantages to both firms and households of central locations. The analysis of the policy implications flowing from the model is weak, and there is little discussion of the relevance of empirical results to the central place and export base theories introduced in chapter 1.

A brief discussion of water resource development begins chapter 4, but the chapter is concerned mostly with the development of an interregional linear programming model of agricultural commodity flows. Most of the data used is obsolete, given the tremendous changes occurring in the domestic and foreign agricultural situation in the early 1970s. Again, empirical results are not adequately related to rural development policies or to the basic theories underlying the whole book.

Chapter 5 includes a description of a simulation model of the Des Moines, Iowa, labor market area. The model contains demographic (cohort-survival), employment (participation rates and productivity coefficients), output (input-output), final demand (location quotients), and capital (coefficient matrix) equations. The assumptions and basic results of the model are described. There is no discussion, however, of the obvious rural development policies suggested by the model. The chapter also contains a detailed description of an interurban earnings differential model. Development and results of several regression analyses are discussed, but again there is little regional development policy analysis.

In chapter 6 is a detailed discussion of a model used to evaluate the incidence of an Iowa veterans allowance tax. There is a good discussion of the incidence of the tax and of policy alternatives for correcting inequalities, both on the tax payers and the receiving units, as well as of the development of and results from use of discriminant analysis to evaluate four state and local industrial location incentive programs. This chapter is quite empirically oriented and should be of interest to researchers evaluating the incidence and effect of taxation and industrial location policies. Improvements could have been made by relating the empirical results to the central place, export base, and bid-rent theories introduced earlier. The most important conclusion reached in this chapter is that politics, not economics, has been the more important consideration in determining the distribution of incentive programs.

The seventh chapter contains a nontechnical discussion of the proposed Minnesota Experimental City including development problems and direct and indirect goals. There is also a nontechnical discussion of redevelopment problems associated with small urban communities, new towns, and other smaller scale projects. There is a discussion of optimal city size relating it to central place and export base theory.

In the last chapter the empirical and policy results of the previous chapters are summarized. An attempt is made to integrate empirical results, central place and export base theory, and policy implications.

To conclude, the book introduces central place, export base, and bid-rent theory and then attempts to integrate several empirical results with this theory and to discuss rural development policy alternatives. The theories, however, are too briefly introduced and then never adequately related to most of the empirical results. Empirical results, in turn, are not adequately related to policy implications. The result is a presentation of several empirical analyses that are not adequately related to regional growth and policy, as the title of the book suggests.

Reynolds, Lloyd G., ed. *Agriculture in Development Theory*. New Haven: Yale University Press, 1975, x + 510 pp., $25.00.

This is not really a book about the role of agriculture in development theory, as the title suggests. Rather, it is a collection of interesting papers about various aspects of peasant behavior and agricultural development that are relevant to the formulation of theories of economic development. The characteristics of the agricultural sector dealt with in the volume are not explicitly linked to any development theories.

The book contains fifteen papers in addition to the introductory chapter by Lloyd Reynolds, "Agriculture in Development Theory: An Overview." Three of the papers deal with the economics of peasant production, two with the behavior of peasants under alternative tenure systems, three with the generation and diffusion of new agricultural technology, two with agricultural sector performance, three with agriculture, growth, and trade, and two with agricultural development under different economic systems. Some of the papers are purely theoretical, some combine theory with empirical investigation, and some are descriptive in nature. The basic content of several papers has

appeared in other publications, e.g., those by Ruttan, Evenson, and Timmer and Falcon.

I found several of the papers to be especially interesting. The one by Hla Myint, "Agriculture and Economic Development in the Open Economy," deals with the functions agriculture can perform in the process of economic development, i.e., increasing the domestic supply of food and releasing labor for industrial employment, enlarging the size of the domestic market for the manufacturing sector, increasing the supply of savings, and providing foreign exchange earned by agricultural exports. He discusses the degree of compatibility among policies designed to promote these functions of the agricultural sector, including the conflict inherent in providing production incentives to farmers and increasing agriculture's contribution to domestic savings.

Raj Krishna's paper deals with measuring the direct and indirect employment effects of agricultural growth with technical change. He attempts to redress the imbalance in the literature that deals primarily with the direct employment effects of technical change. Krishna shows that the indirect effects on employment may be substantial but not always enough to offset the decline in employment in agricultural production that might result from technical change.

Gerald Helleiner's paper, "Smallholder Decision Making: Tropical African Evidence," is a good review of the literature on peasant behavior in Africa. I agree with Helleiner's contention that "research results from the African continent are not adequately represented in many of the existing general analyses of agricultural development" (p. 27). He provides a good systematic review of the literature dealing with peasant behavior in Africa.

Those interested in agricultural development and its relationship to economic development will find this volume to be a useful reference. It contains material on a wide variety of topics. Each individual will have to decide whether or not there is enough material of interest to warrant the price.

News

Announcements

1976 Meeting Allied Social Sciences Association

The American Agricultural Economics Association will meet jointly with the Allied Social Sciences Association in Atlantic City, New Jersey, 16–18 September 1976. Sessions are being scheduled as follows: (*a*) Food and Agricultural Policy Issues: Round Table Discussion; James Shaffer, Michigan State University, moderator, (*b*) Sources and Effects of Instability in U.S. Agriculture: Recent Experiences; Jimmye Hillman, University of Arizona, chairman, (*c*) Economics of Consumption: Conceptual and Empirical Developments; Rueben Buse, University of Minnesota, chairman, and (*d*) Econometric Modeling of the Agricultural and General Economic Sectors. Program details are available from Kenneth R. Farrell, President-Elect, AAEA, Economic Research Service, U.S. Department of Agriculture, Washington, D.C. 20250.

The American Library Association's Biennial Oberly Memorial Award

The Eunice Rockwell Oberly Memorial Award, consisting of a citation and a cash award, is made to the American citizen who compiles the best bibliography in the field of agriculture or one of the closely related sciences in the two-year period preceding the year in which the award is made. This award has been presented biennially since 1925. The 1977 award will be presented during the annual conference of the American Library Association, June 1977. Deadline for nominations is 15 March 1977. Nominations are to be sent to Mr. David K. Oyler, Chairperson, Oberly Memorial Award Committee, Steenbock Memorial Library, University of Wisconsin, 550 Babcock Drive, Madison, Wisconsin 53706.

New Journal

State and Local Government Review is a triannual publication of the Institute of Government, University of Georgia, devoted to research dealing with the practical problems of state and local government. As a multidisciplinary journal, the *Review* welcomes all articles concerning applied research, university-based public service programs and training, policy making and implementation, and programs in state and local government. Our preference is for manuscripts that would appeal to practioners and to academics. Short- to medium-length articles (11–20 typewritten, double-spaced pages) and notes (10 pages or less) are desired, but longer manuscripts will be considered. For further information, write to Dr. David Billings, Editor, Terrell Hall, University of Georgia, Athens, Georgia 30602. A one-year subscription is $6.00.

Personnel

University of Arizona

Resignation: Paul N. Wilson, former instructor, is with the Agency for International Development, Washington.

Colorado State University

Returns: Huntley H. Biggs is back after a two-year assignment as a development economist for Development and Resource Corporation, Sacramento, working with Iran's Ministry of Water and Power in formulating a national water plan; **Donald M. Sorensen** is back after a two-year assignment as acting assistant director of the Western Rural Development Center, Oregon State University; **Ronald L. Tinnermeier** is back from a two-year special assignment with the Agency for International Development and the USDA Technical Assistance Bureau.

Cornell University

Resignation: Dennis R. Lifferth, former assistant professor of business management, is an agricultural economist for the Welfare Services' Production-Distribution Department of the Church of Jesus Christ of Latter-Day Saints.
Honor: Robert S. Smith, professor of farm finance, received the Superior Performance Award from Lambda Chapter of Epsilon Sigma Pi, the honorary extension fraternity, for his teaching and leadership in the field of farm family financial management and agricultural credit.

University of Florida

Appointment: Lester H. Myers is the director of the Economic Research Division, Florida Department of Citrus.
Leave: John Holt is a visiting professor, Extension Service—USDA, Oklahoma State University, and is working on a project dealing with wheat farm management in an environment of risk and uncertainty.
Resignation: Lawrence A. Halsey is the county extension director of Jefferson County, Monticello.

CED: Commodity Economics Division of the Economic Research Service, USDA; **NEAD:** National Economic Analysis Division of ERS.

University of Georgia

Resignation: Richard J. Mikes, former associate professor of agricultural economics, is an assistant controller, Ruan Transport Corporation, Des Moines, Iowa.

University of Illinois

Appointments: Darrel L. Good, former assistant professor of farm management, Cornell University, is an assistant professor of marketing; **Keith M. Naber,** M.S. Purdue University, is a Farm Business Farm Management fieldman.
Leaves: J. S. Gruebele and **S. C. Schmidt** are on sabbatical leave for one year; **J. C. van Es** is on sabbatical leave for six months.

University of Maryland

Appointments: Norman Bender is a marine extension specialist in the Department of Agricultural and Resource Economics; **Ying-Nan Lin,** Ph.D. University of Tennessee, is an assistant professor.

Michigan State University

Appointment: George Axinn is in Nepal for two years; **Michael Weber** is the agricultural economics advisor to the Michigan State University Brazil Project, University of Ceara, for two years.
Leave: Larry Connor is in the East Lansing area for six months of studying and writing.
Return: Alan Thodey is back after working in Korea.
Resignation: William Haley, former assistant professor, is self-employed.

University of Nebraska

Appointment: Lynn Lutgen, Ph.D. University of Nebraska, is an assistant professor of livestock marketing economics.
Return: Loyd K. Fischer, professor of agricultural economics, is back after serving as a visiting professor of agricultural economics, University of Missouri.
Retirement: A. W. Epp, former professor of agricultural economics, has left after thirty-three years of service.
Honor: A. W. Epp received a Distinguished Service Award from the Nebraska Society of Farm Managers and Rural Appraisers.

University of Nevada

Appointment: Gordon Myer, Ph.D. University of Missouri, is with the Division of Agricultural and Resource Economics.
Retirement: Doyle Spurlock, former public affairs specialist, Federal Extension Service, Washington, and visiting professor, fall 1975, is in Arizona.

New Mexico State University

Appointment: Robert O. Coppedge is a community development specialist in the Extension Service.

North Carolina State University

Appointments: Thomas M. Reynolds and **Grant M. Scobie** are assistant professors of economics and business.

Oklahoma State University

Appointments: John E. Ikerd, Ph.D. University of Minnesota, is an extension economist in livestock marketing; **James N. Trapp,** formerly with Michigan State University, is an assistant professor in the area of commercial agricultural economics.

Oregon State University

Appointment: Ronald A. Oliveira, formerly with the University of Wisconsin, is an assistant professor of agricultural and resource economics.

Stanford University

Appointment: Anne E. Peck, former assistant professor, Purdue University, is an assistant professor at the Food Research Institute.

University of Tennessee

Appointment: Rodney Thomsen, Ph.D. University of Tennessee, is an assistant professor of agricultural economics.

U.S. Department of Agriculture

Appointments: Tim Baker, Economic Research Service, is an adjunct instructor at Michigan State University; **John Connor,** Ph.D. University of Wisconsin-Madison, is with NEAD, Madison, Wisconsin; **Don Ethridge** and **Dale Shaw,** CED, are adjunct professors of agricultural economics at Texas Tech University; **Thomas Lederer,** Ph.D. University of Tennessee, is with the Economic Research Service.

University of Vermont

Resignation: Arthur H. Smith, former assistant professor, is the full-time manager of his own business.

Virginia Polytechnic Institute and State University

Appointment: Steven T. Buccola, Ph.D. University of California, Davis, is an assistant professor.

University of Wisconsin

Appointment: Neil Meyer, area community development agent, Minnesota, is an assistant extension professor and extension community resource development specialist.

Other Appointments

Alvin A. Bedel, Ph.D. University of Tennessee, is with the School of the Ozarks, Point Lookout, Missouri.
Robert Burney, M.S. University of Tennessee, is with Central Soya, Fort Wayne, Indiana.
Samuel T. Cooper, Ph.D. University of Tennessee, is a cooperative extension agent—Manpower, Operation Hitchhike, New York Cooperative Extension Service, Cobleskill.
Khairulah Dawlaty, Ph.D. University of Tennessee, is at the University of Kabul, Afghanistan.
Leonardo Gonzales, Ph.D. University of Tennessee, is with the ADAM Project, Bureau of Agricultural Economics, Quezon City, Philippines.
Morgan Gray, M.S. University of Tennessee, is an analyst in corporation planning and economic research, Goldkist Cooperative, Atlanta, Georgia.
Francisco Samuel Hosken, M.S. Purdue University, is the department head of the Brazilian Cheese Manufacturing Co., Governador Valadares.
John B. Huie is the director of the State Budget Agency, Indiana.
Morris T. Jones, Ph.D. University of Tennessee, is an assistant professor of economics at Baptist College, Mobile, Alabama.
Pham Kham, M.S. University of Tennessee, is with the Economist Outreach Division, International Fertilizer Development Institute, Florence, Alabama.
Alfredo Sfeir-Younis, Ph.D. University of Wisconsin-Madison, is in the Young Professional Program, International Bank for Reconstruction and Development, Washington.
Raymond W. Waldron, M.S. Oregon State University, is with the Ministry of Natural Resources, Government of Honduras.

Obituary

Robert E. Post

Robert E. Post passed away on 6 March 1976 after a long illness. Bob was a lifelong member of the American Agricultural Economics Association and worked with many association members over the years. He authored the *Wheat Situation* report for the U.S. Department of Agriculture from the 1930s until his retirement in 1962.

Post was born in Minnesota in 1896 and earned a B.S. at Michigan State University and an M.S. at the University of Wisconsin. Prior to joining the Department, Bob taught economics for a number of years at South Dakota State University. After joining the USDA, he was a delegate to the first conference to establish an International Wheat Agreement, which took place in London during the summer of 1939. Later assignments involved wartime food planning and analysis of legislative and economic proposals.

Post is survived by his wife, Norine, daughter, Mrs. James Rimmer, and three grandchildren.

RESEARCH DIRECTOR FOR FOREST ECONOMICS AND POLICY

Resources for the Future seeks a director for a program of research on forest economics and policy. The program will be concerned with all kinds of outputs from forests, including, but not limited to, timber, with forests of all ownerships, and with both domestic and international aspects. The director must have demonstrated interest and research ability in natural resource use and management, but not necessarily in forest resources. Persons having had training in forest economics, agricultural economics, economics, forestry, or other social or natural sciences concerned with management of natural resources may apply. Director must have competence to lead a small research staff, to conduct incisive and imaginative research personally, to negotiate cooperative research agreements with colleges and other nonprofit organizations, and to confer with conservation and industry groups. Salary negotiable, dependent on individual's attainments. RFF is an equal opportunity employer. Communications will be held confidential, if so requested, and should be addressed to Hans H. Landsberg, Resources for the Future, 1755 Massachusetts Ave., N.W., Washington, D.C. 20036

University of Minnesota Press

Just published—an invaluable reference work, an excellent book for course use

American Farm Policy, 1948-1973

by **Willard W. Cochrane** and **Mary E. Ryan**

This comprehensive account records and explains American farm policies and programs in the last quarter-century and provides a background and analysis as well. The authors describe in detail the farm policy legislation during the period and the operations of the programs in those years. The program data are derived largely from materials published by the U.S. Department of Agriculture which are now difficult to obtain. The organization of the data into extensive tables makes the work particularly valuable for reference. Since Dr. Cochrane, the senior author, was deeply involved with the farm programs of this period as a critic, analyst, and planner, he has a unique vantage point for the interpretation and appraisal of the policies.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Review by colleagues.** Authors are strongly urged to have their manuscripts critically reviewed by their colleagues prior to submission.
12. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
13. **Page Charge.** All published contributions, with certain specific exemptions, are subject to a charge of $40 per printed page or fraction thereof. Exemptions are granted for book reviews, papers invited by the editor, the presidential address, the fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. Authors who certify in writing that no financial support exists from an employer or granting agency to cover the page charge also will receive an exemption. Payment information and details on the financial exemption statement are provided with galley proofs. One hundred reprints (without covers) are provided if the charge is honored.

American Agricultural Economics Association

President/James T. Bonnen, Michigan State University
President-Elect/Kenneth R. Farrell, Economic Research Service
Secretary-Treasurer/John C. Redman, University of Kentucky
Past-President/James Nielson, Washington State University

Directors

Wallace Barr, Ohio State University
Glenn E. Heitz, Federal Land Bank of St. Louis
Fred A. Mangum, North Carolina State University
Philip M. Raup, University of Minnesota
Howard F. Robinson, North Carolina Agricultural and Technical State University
B. F. Stanton, Cornell University

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying: Members receive this *Journal*.

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices.

Copyright © 1976 by the American Agricultural Economics Association.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except that concerning "Books Reviewed" and "Books Received," should be addressed to the editor, William G. Tomek, Department of Agricultural Economics, Cornell University, Ithaca, New York 14853.

Communications concerning books for review and books submitted for announcement in the *Journal* should be sent to the book review editor, Francis E. Walker, Department of Agricultural Economics and Rural Sociology, Ohio State University, Columbus, Ohio 43210.

Price Support versus Input Subsidy for Food Self-Sufficiency in Developing Countries

Randolph Barker and Yujiro Hayami

Self-sufficiency in food grains has been a publicized goal of government policy in many developing countries. Among various alternatives to achieve this goal, two policy options, output price support and input subsidy, both characterized by the government intervention into market pricing, are evaluated by applying a simple demand-supply model to the Philippine rice economy. The results demonstrate a possibility that a subsidy applied to modern inputs, such as fertilizer, that are being used below optimum can be more beneficial than supporting product prices.

Key words: fertilizer subsidy, food self-sufficiency, foreign exchange, government cost, net social welfare, rice price support.

Many of the nations in South and Southeast Asia that gained independence after World War II have adopted self-sufficiency of food staples as a national policy goal. These countries, whose economies were based on the export of tropical cash crops under colonial rule, have chosen this policy of self-sufficiency in the nationalistic desire to minimize foreign power leverages, and in order to reduce foreign exchange requirements for the import of foodstuffs.

The food self-sufficiency goal can be achieved best, in the long run, through the improvement in physical and institutional infrastructure such as irrigation and research-extension systems, which have the main effects of shifting production functions. However, because such programs require extremely large investments and long gestation periods, there is always a temptation for government to adopt shorter run policies, such as supporting product prices and subsidizing inputs, thus stimulating farm producers to increase food output along existing production functions. The temptation becomes stronger during periods of occasional food shortage and high prices.

Assuming an economy is operating with a high degree of competition in factor and product markets, government interventions in the pricing of products and inputs will invariably result in a net loss in the economic welfare of society. However, ample evidence is available that the level of modern inputs such as fertilizer is much lower than the optimal level (marginal value product equal to marginal cost) due to lack of knowledge, risk aversion, and other reasons. Assuming a large gap between actual and optimum levels in the input of fertilizer, it is possible that the subsidy on fertilizer, which stimulates increase in its application, may result in a net welfare gain to the society. The support of product prices is likely to require more social cost than benefit because, in addition to increasing fertilizer, it will induce the use of traditional inputs such as land and labor above their economic optimum.

In this paper, we attempt to illustrate the effects of such policies by analyzing the programs of rice price support and fertilizer subsidy for achieving self-sufficiency in rice in the Philippines. Benefits and costs associated with these alternative programs and their income distribution effects are estimated and compared with the case of no support or subsidy. Based on the results of estimation, we discuss advantages and disadvantages of these policy

---

Randolph Barker and Yujiro Hayami are agricultural economists at the International Rice Research Institute, Philippines.

The authors are indebted to Gene Bennagen, Masao Kikuchi, and Teresa Lacsina for both computational assistance and theoretical improvement. We have benefited from the comments from Dennis Chinn, Walter Falcon, John Longworth, Scott Pearson, Edwin Price, Ammar Siamwalla, Peter Warr, and the *Journal* reviewers.

alternatives in terms of efficiency and equity criteria.

First, we review the history of rice and fertilizer price policies in the Philippines in order to identify policy goals and constraints in achieving rice self-sufficiency. Second, we develop a model of estimating benefits and costs associated with alternative policy programs. The results of estimation are compared with the actual choice of programs in order to make inference on the motivation and the decision criteria of policy makers.

Goals and Constraints of Rice Policy

Despite the publicized goal of national self-sufficiency, over the past two decades the Philippines has been the second largest importer of rice in Southeast Asia, second only to Indonesia. The Philippine government has operated a price-policy program for rice designed to support a floor price for producers and maintain a ceiling price for consumers. Although a major justification for such a program has been the protection of the income of small farmers, as Mangahas has pointed out, this policy has been biased more in favor of consumers than producers. Considering the critical importance of rice as a wage good, it seems reasonable to assume that the overriding restraint faced by the government in designing a rice policy to achieve self-sufficiency has been the necessity of supplying rice to urban consumers at relatively low prices.

There is, of course, a gap between the price considered appropriate for consumers (consumer ceiling) and the price needed to insure self-sufficiency (farm floor). The Philippine government has never purchased more than about 5% of the domestic rice crop, and as a result the government cannot maintain a margin between the floor price for producers and the ceiling price for consumers much in excess of the normal marketing margin. Given the limitations of the government budget and the desire to supply cheap rice to consumers, it has been difficult to raise the producer price support to the level required to achieve self-sufficiency.

Instead, the government has used its limited resources to import rice when it appeared that the rice price would rise well above the consumer ceiling, especially in election years. Normally, the Philippine and world rice prices are fairly similar. Hence, this policy produces very little drain on government resources. In years of world rice shortage (e.g., 1967 and 1973), the international price rises well above the domestic price and importation is costly. But the basic requirement to supply rice at reasonably low prices has not prevented the government from restricting rice imports in those years when the prices for imported rice are very low (1969–70).

Another policy instrument used by the Philippine government to encourage rice self-sufficiency has been the subsidy on inputs for rice production, especially fertilizer. Over a seven-year period from 1956–57 to 1962–63, the government-supported farmers' cooperatives purchased and distributed fertilizer to rice and corn producers at half the going market price. The recent "world food crisis" and the dramatic rise in fertilizer prices in 1973 triggered by the oil embargo of the Arab nations has once again induced the government to adopt a program designed to subsidize the use of fertilizers. As world fertilizer prices began to rise in 1972, the government assumed control of pricing in the fertilizer industry and initiated a "socialized pricing" program. Despite the four-fold increase in import prices of fertilizer, the price to rice growers was allowed to increase only two-fold, resulting in a subsidy of about 100% in 1974.

A major problem with the fertilizer subsidy as a means of increasing rice production has been the difficulty of limiting the subsidy to the rice sector, that is, preventing the diversion of subsidized fertilizers to the export crop (especially sugar) sectors. In spite of vigorous enforcements under the Martial Law, the diversion became so large that in November 1974, the government was compelled to reduce the rate of fertilizer subsidy for rice producers in order to narrow the gap in fertilizer prices between the rice and the sugar sectors. Subsequently, the reformulation of rice and fertilizer price policies has become a critical agendum.

Model of Policy Evaluation

In this section, we develop a model for estimating the benefits and costs associated with four alternatives for achieving self-sufficiency in rice production. These alternatives include a rice price-support and three fertilizer-subsidy plans—plan A with a subsidy for rice

producers only, involving a two-price system for fertilizer; plan B with a subsidy price for fertilizer the same for all crops; and plan C, the same as plan B but financed in part by an increase in the sugar export tax lessening somewhat the benefits to the sugar sector. Simplifying assumptions adopted for the analysis follow.

First, we assume that none of producers and consumers are large enough to influence market prices; thereby unique schedules can be specified for domestic supply and demand. Second, we assume that a change in fertilizer prices does not significantly affect the use of other inputs.[1] Third, only the rice and sugar sectors that account for over 80% of the total fertilizer consumption are considered, and interactions with other food crops (such as corn) and export crops (such as coconuts) are abstracted from the analysis. The sugar sector includes both sugar planters and millers.[2] Finally, we abstract from the analysis the changes in marketing costs that might be involved with the adoption of rice price-support or a fertilizer-subsidy program.[3]

A simple model of rice price support and fertilizer subsidy in the Philippines is presented in figure 1. SS represents the domestic supply curve for rice.[4] The vertical line D_hH represents the demand curve of producers for home consumption. Here it is assumed that producers' households consume the same quantity of their produce irrespective of prices and sell the rest in the market. (For the support of this assumption, see Toquero et al.) D_mD represents the market demand for the product—the horizontal distance between D_mD and D_hH measures the quantity purchased by urban (nonfarmer) households. The total demand for rice is represented by D_hD_mD.

Normally, the world price of rice (OP_w) has been below the domestic equilibrium price (OP_e) that would have been established at the intersection of D_mD and SS. Without government intervention the Philippines would import AB. Assume first that the price for imported rice is exactly equal to a target price (OP_d) for domestic consumers that the government intends to maintain. If OP_d is the domestic target price, then it will be necessary to have OQ_c available for consumers. There are three possible alternatives: (*a*) import AB, (*b*) support the rice price received by producers at OP_s, or (*c*) subsidize fertilizer prices sufficiently to shift the supply function from S to S'.

The first alternative, which has been the traditional policy of the Philippine government, serves as a standard of comparison for the alternative self-sufficiency policies represented by the price support of rice and price subsidization of fertilizer.[5]

A slight variation of the initial assumption is shown also in figure 1. The world price may be either below the target retail prices ($OP'_w < OP_d$) or above the domestic target retail price ($OP''_w > OP_d$). If the government maintains imports at AB, it will incur a profit in the former case by restricting imports and selling above the purchase price (OP'_w). This policy will protect domestic producers and earn revenue for the government at a cost to the consumer. However, in the latter case when the world price is above the domestic sale price, the import required by the government to maintain the domestic price at OP_d is greater than would occur under free trade. Selling below the purchase or import price benefits the consumers at a cost to the government and the producer. Due to the fluctuation in the world price relative to the domestic target (OP_d), the Philippines in the recent past has

[1] This assumption implies zero cross elasticity in input demand functions. To the extent that fertilizer is a substitute for or complementary with other inputs, especially land, the results of our analysis are biased. Fertilizer is a substitute for land itself, but it has a strong complementarity with irrigation systems that improve land quality. These competitive and complementary relations are highly complex so that it is difficult to identify the direction of the possible bias.

[2] The different effects of price policies on sugar planters and millers is an interesting subject particularly in the Philippines where these two groups operate very independently of one another. However, because of the complexity and data limitation, planters and millers are not identified separately in this analysis.

[3] This is partly because of data limitation and partly because there are many options to administer the same program. For example, price support in buying rice from producers at higher prices and selling to consumers at lower prices can be administered either through the establishment of a government marketing agency or through subsidizing private marketing firms. Distribution of benefits and costs between the government and the private sector differs for different administrative designs.

[4] The supply response in the Philippines has been primarily based on the response in the use of traditional inputs such as land and labor. Previous studies of rice supply by Mangahas, Recto, and Ruttan indicate that the price response of supply is largely an area response effect. It is reasonable to assume that area response accompanies a more or less parallel change in labor. Thus, in the case of the Philippines, the production cost represented by an area below SS consists primarily of the opportunity costs of land and labor.

[5] It is important to note that our standard of comparison is different from the free market equilibrium, which is usually used as a benchmark of price policy evaluations (e.g., Johnson, Wallace). Our benchmark assumes governmental intervention in the control of rice import in order to ensure a target rice price for consumers. Our benchmark coincides with the free market equilibrium when the target price is the same as the world price.

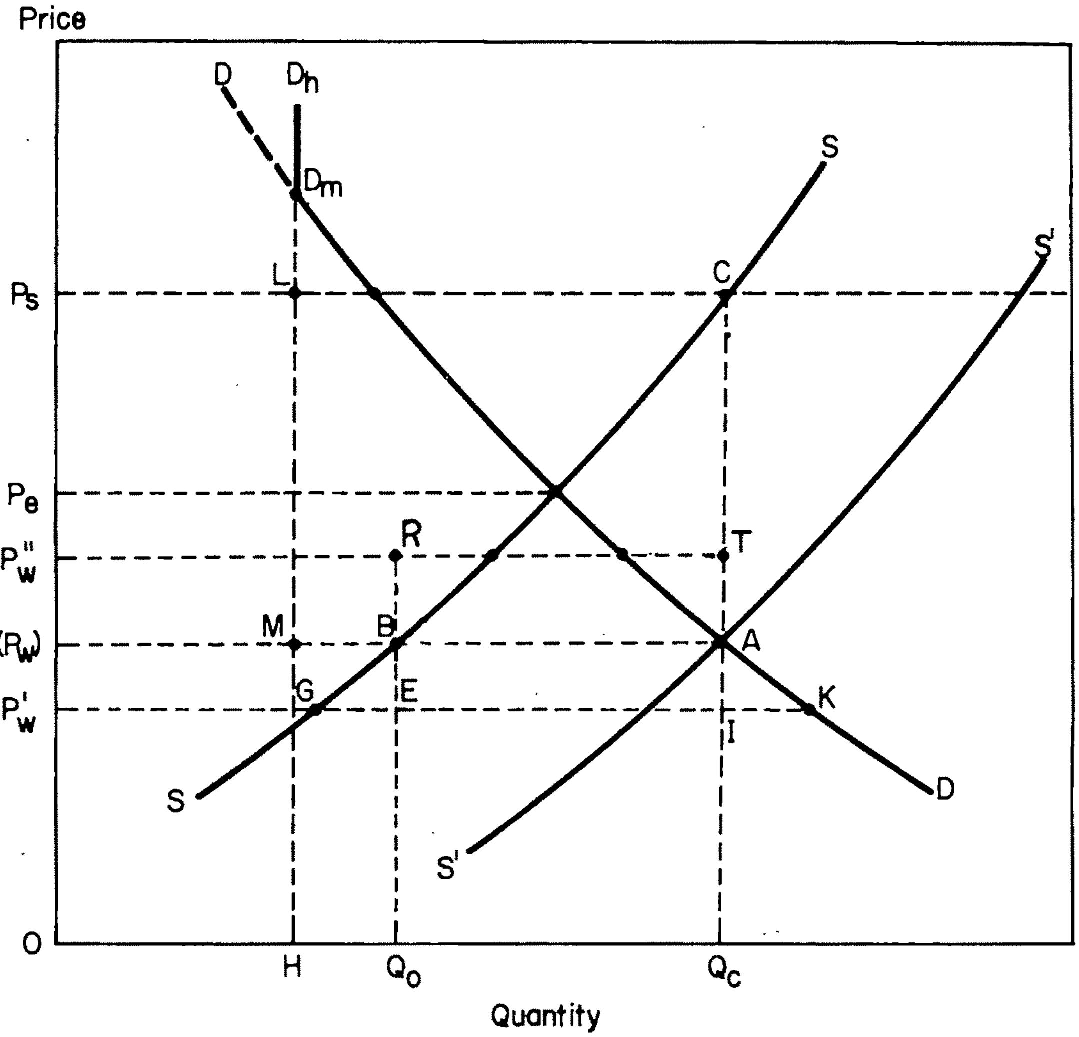

Figure 1. Model of price support and fertilizer subsidy for rice

profited in some years and lost money in others through its import transactions. On balance, the domestic Philippine price has remained fairly much in line with world rice prices.

Rice Price Support

Assuming a domestic supply schedule (*SS*) as fixed, the self-sufficiency of rice can be achieved by supporting the producer price at OP_s. Since the government has to maintain the consumer price at OP_d, the self-sufficiency of rice by means of price support would involve a cost to the government represented by area *ACLM* as a difference between the procurement cost and the sale.[6] In addition, compared with the check case of importing *AB*, the policy to achieve self-sufficiency by supporting the producer price at OP_s would result in a reduction in government revenues from the import of rice by area *ABEI* if the world price is OP'_w (or an increase by the area *ABRT* if the world price is OP''_w).

With the support price at OP_s, producers' revenue from the sale of rice would increase by area *ACLM*, but the cost of the rice to the producers would also increase by area *ABC*. The difference (area *BCLM*) represents an increase in the income of the rice producers at a cost to the government. The net loss of eco-

[6] If the gap between the producer price and the consumer price is not so large as to cover the marketing cost, producers may retain *OH* for home consumption. However, as the difference becomes larger, producers would sell all of this product and buy back a part for their own consumption. In this case the government cost will exceed area *ACLM* and may even approach to area ACP_sP_d.

nomic welfare to society is represented by the area ABC (aside from the consideration of possible benefits from foreign exchange savings discussed below).

A net savings of foreign exchange is area ABQ_oQ_c (IEQ_oQ_c if world price is lower than domestic price and TRQ_oQ_c if vice versa) minus the increase in fertilizer input due to increased fertilizer application stimulated by a more favorable ratio of fertilizer price to rice price.[7]

Fertilizer Subsidy for Rice

Self-sufficiency of rice can be achieved without supporting the producer price by shifting the supply curve from SS to $S'S'$ in figure 1. Since the supply curve represents a marginal cost curve, it can be shifted to the right by lowering the price of the input.

Given the production elasticity of fertilizer in the rice sector and the price elasticity of demand for fertilizer used for rice production, we can determine the quantity of fertilizer to obtain the increased output needed for self-sufficiency and the decline in price required to induce this additional fertilizer consumption needed.

A model of the fertilizer market is shown in figure 2. The demand curves for the rice (D_rD_r) and sugar (D_sD_s) sectors can be added horizontally to obtain the industry demand curves (DD). The domestic supply curve is SS and the world supply curve (S_w) is assumed to be completely elastic.

If the price of fertilizer applied to rice must be subsidized at OP_{fs} to achieve self-sufficiency, the government cost of fertilizer subsidy to rice is represented by the area $ABP_{fs}P_{fw}$ in figure 2. The reduction (increase) in government revenue due to a decrease in rice imports as a result of the achievement of self-sufficiency (as in the case of rice price support) is represented by the area $ABEI$ (or area $ABRT$) in figure 1.

The rice producers would receive a dual benefit from being able to buy all their fertilizer at a lower cost as represented by the area $CDP_{fs}P_{fw}$ in figure 2 and from the increased output value, area ABQ_oQ_c minus fertilizer cost from using additional amounts of fertilizer because of the more favorable price relationship, area BDX_oX_s in figure 2.

Net savings in foreign exchange can be shown as the net reduction in foreign exchange expenditures for rice imports, area ABQ_oQ_c in figure 1 minus the increase in foreign exchange requirement for increased fertilizer import, area ACX_oX_s in figure 2. As in the case of rice price support, the welfare of rice consumers does not change because they consume the same quantity of rice at the same price irrespective of the support on subsidy programs.

Fertilizer Subsidy for Sugar

We now move to analyze the impact of alternative subsidy plans on the sugar sector. Plan A (two-price system), which charges a market price for fertilizer to sugar growers, involves no additional cost to the government and no change in the income of the sugar sector. Under plans B and C (single-price system), the sugar sector benefits from the purchase of subsidized fertilizers and the government must bear the cost.

The impact of a fertilizer subsidy under plan B is illustrated in figure 3. SS and DD represent respectively domestic supply and demand schedules for sugar. $S'S'$ represents a shift in supply curve corresponding to a fertilizer subsidy for sugar at the same rate as for rice. OR_w is the export price of sugar, whereas OR'_w is the price that sugar producers receive for the export of their product, the difference representing a rate of export tax.

Without the fertilizer subsidy, an equilibrium of sugar production would be established at B with an output OY_o. In this case, if there is no government intervention, export and domestic consumption of sugar would be BJ and JR'_w, respectively. In fact, the Philippine government has been protecting consumers by setting a quota for producers to sell in a domestic market at a lower price (OR_d). Since the consumer price of sugar (OR_d) in figure 3 (similar to the rice price [OP_d] in figure 1) is determined by the government in consideration of social and political stability, it would be maintained irrespective of whether a fertilizer-subsidy program is introduced. Therefore, consumers' welfare with respect to sugar consumption would remain unchanged.

Again referring to figure 2, the government cost of the fertilizer subsidy on sugar as calcu-

[7] It is likely that this formula overestimates the contribution of price support to foreign exchange savings because not only fertilizer import but also the import of other inputs such as farm machineries that have foreign exchange components may be increased as a result of higher rice prices. Also, the export of cash crops such as sugar may be reduced because higher rice prices may result in a diversion of land area from the cash crops to rice.

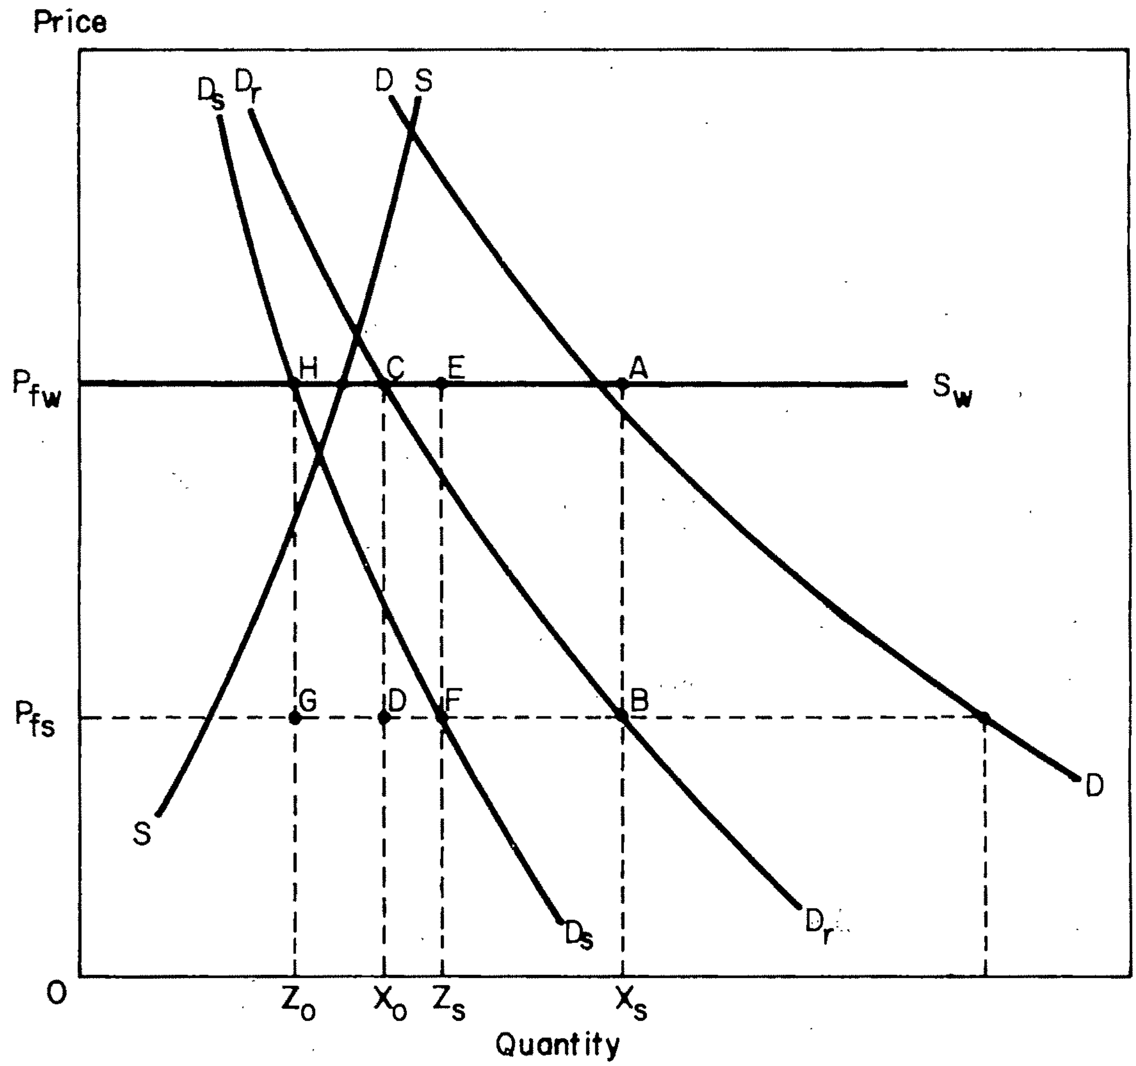

Figure 2. Model of fertilizer demand in relation with subsidy

lated is the area $EFP_{fs}P_{fw}$. Corresponding to the shift in the supply curve from SS to $S'S'$, sugar exports would increase from Y_cY_0 to Y_cY_s (figure 3). Government revenue from sugar export tax would increase by area $BCEH$.

The sugar producers would receive a dual benefit from being able to buy all their fertilizer at a lower cost as represented by the area $HGP_{fs}P_{fw}$ in figure 2 and from the increased output value (area BCY_sY_0 in figure 3) minus fertilizer cost from using an additional amount of fertilizer because of the more favorable price relationship (area FGZ_0Z_s in figure 2).

The net gain in foreign exchange earnings from sugar exports is the area EHY_0Y_s in figure 3 minus the increase in foreign exchange expenditures for fertilizer, area EHZ_0Z_s in figure 2.

If we adopt plan C, which raises the tax rate in sugar corresponding to the magnitude of the fertilizer subsidy, further modifications are necessary. An increase in the export tax rate results in a decrease in the price received by producers, which in turn depresses the level of fertilizer application and reduces output. The increase in tax, of course, reduces the net cost of the subsidy to the government at the expense of the sugar producers.

Parameters and Data

This model allows us to calculate private and public sector benefits and costs for achieving self-sufficiency in rice for any one of the four plans specified (mathematical approximation formula in appendix). In order to estimate the

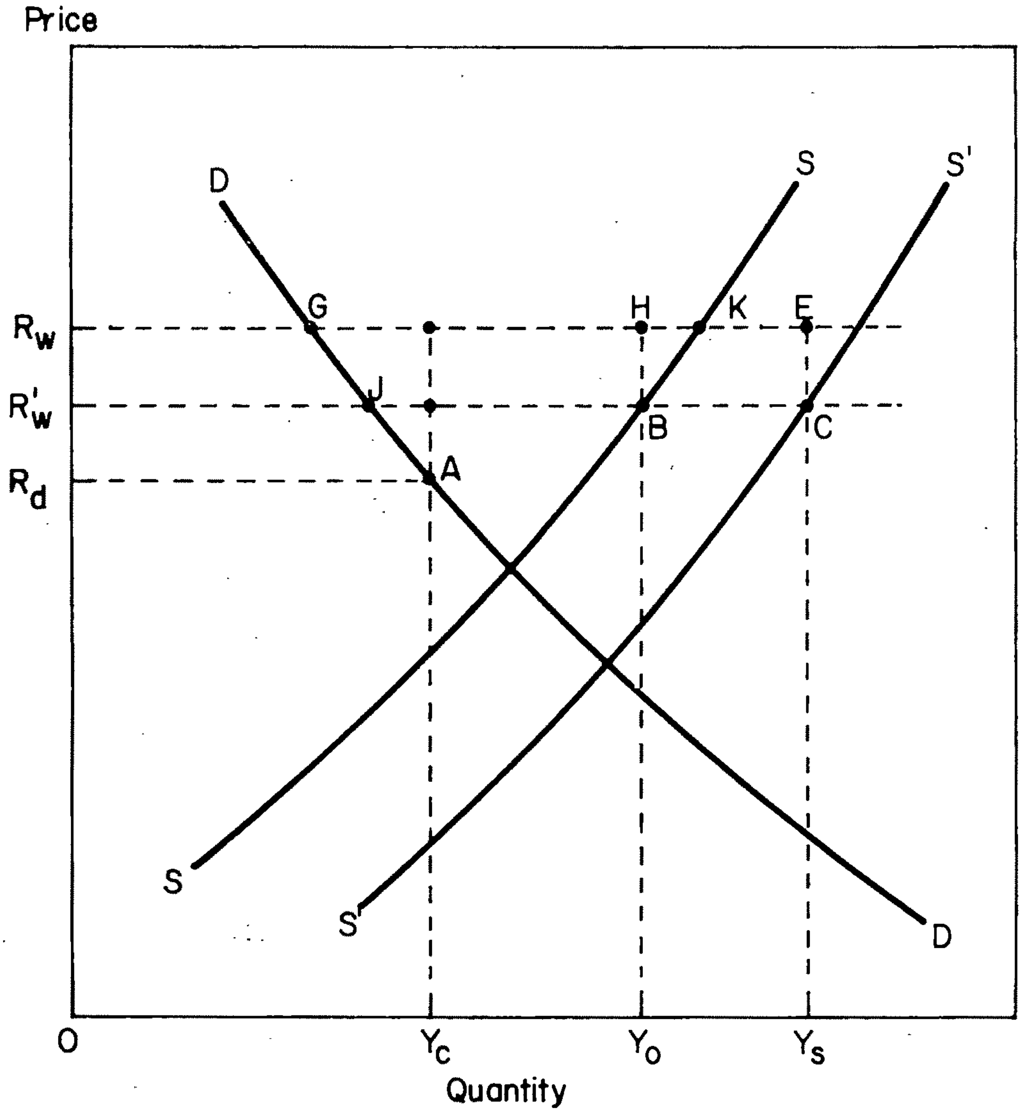

Figure 3. Model of fertilizer subsidy for sugar

benefits and costs, certain parameters and data must be specified. For the purpose of this analysis, we choose 1975 as the base year. Production and consumption relationships with respect to rice, sugar, and fertilizer are estimated for 1975 assuming no price-support or subsidy program. The assumptions made and analysis conducted here are based upon a "normal" relationship between sugar, rice, and fertilizer prices in both the international and domestic markets. Hence, it abstracts from the recent situation of abnormally high prices.

We define a self-sufficiency requirement as the percentage increase in output needed to avoid imports of rice in all but extreme situations such as occurred with the severe drop in domestic rice production due to the floods and droughts in 1972–73. Based upon the record of the past ten years, the added production requirement to achieve self-sufficiency appears to be about 5% of total production or currently around 220,000 metric tons of milled rice.[8]

Assumptions with respect to parameters and data are summarized in table 1. Taxation on sugar export consists of a regular tax (6% *ad valorem*) and a premium tax (20% on the difference between the current export price and the base export price of $182 per ton). For

[8] Throughout the analysis the quantity of rice is expressed in terms of milled rice equivalents and the exchange rate between the Philippine peso and U.S. dollar is assumed as seven to one.

Table 1. Assumptions for Analysis of Rice Price Support versus Input Subsidy, the Philippines Case

Item	Amount
Domestic consumption of milled rice (q_c)	4,400,000 tons
Domestic output of milled rice (q_o)	4,180,000 tons
Consumption in households of rice producers (60% of total)	2,640,000 tons
Domestic output of sugar (y_o)	2,300,000 tons
Export of sugar	1,500,000 tons
Domestic consumption of sugar (y_d)	800,000 tons
Fertilizer input for sugar (45% of total) (z_o)	330,000 tons
Fertilizer input for rice (41% of total) (x_o)	300,000 tons
Increase in output of milled rice to achieve self-sufficiency	220,000 tons
Export price for sugar (r_w)	\$440/ton
Domestic consumer and import price for rice (P_d and P_w)	\$300/ton
Domestic retail price for fertilizer (26N, $7P_2O_5$, $3K_2O$) (P_{fo})	\$160/ton
Ratio of a unit processing and marketing cost to the export price of sugar (m_s)	35%
Ratio of a unit processing and marketing cost to consumer price of rice (m_r)	30%
Ratio of a unit marketing cost to the retail price of fertilizer (m_f)	15%
Price elasticity of demand by fertilizer with respect to rice and sugarcane, absolute value (γ and ϵ)	0.5
Price elasticity of rice supply (β)	0.3
Production elasticity of fertilizer with respect to rice and sugarcane (α and δ)	0.1

plan C, the premium tax rate is increased to 23% and 26% for the subsidy rates that correspond to the 97.5% and 100% levels of rice self-sufficiency.

The estimate of the elasticity of rice supply is based upon the time-series analysis of Mangahas, Recto, and Ruttan. The production and demand elasticities for fertilizer with respect to rice are based on the recent analysis of David using survey data from Laguna Province and are further supported by the results of experiments conducted by Mandac in farmers' fields in Central Luzon.

Our judgement regarding the magnitude of the elasticities for sugar is based upon an examination of nitrogen response experiments conducted by the Philippine Sugar Institute and reported in a study of fertilizer demand by Rodriguez. The average per hectare input of nitrogen for sugarcane is much larger than for rice, and it is clear that the response functions differ in that the maximum yield level of nitrogen input for sugar is more than double that for rice. The magnitude of the elasticity estimates is sensitive to modest changes in the assumed shape of the typical production function. We have purposely been conservative in choosing elasticities of nitrogen for sugar equal to those for rice.[9]

The marginal value product (MVP) per ton of fertilizer in rice and in sugar production was estimated using the data and parameters specified in table 1: MVP for rice = $\alpha(q_o/x_o)\,(1 - m_r)p_d$ = \$293 per ton, and MVP for sugar = $\delta(y_o/z_o)\,(1 - m_s)\,r_w$ = \$200 per ton, which are both substantially higher than the domestic retail price of fertilizer (\$160 per ton).

Recent research on the constraints to increased rice production in the Philippines supports our general assumption that despite the rapid spread of modern varieties there are many regions of the Philippines where fertilizer use is still well below the optimum (International Rice Research Institute, p. 24). In the case of sugar there is a considerable gap in the level of fertilizer use between the more progressive large farmers in Negros and the small producers in Luzon and in some of the newer districts elsewhere in the Philippines.[10]

[9] In sugar, the actual nature of the output response is dictated not only by the farm level response to price but also by the milling capacity, which in the short run is reasonably fixed. In this analysis, the industry is assumed to be operating at a level where mill capacity is not acting as a constraint on output.

[10] Such disequilibria in the levels of modern inputs in agriculture

Evaluation of Policy Alternatives

The estimated benefits and costs of price-support and fertilizer-subsidy programs are summarized in tables 2–4. The choice among policy alternatives can be based on the valuation of a number of criteria. These include (*a*) the cost of the program to the government (or taxpayer), (*b*) the efficiency of the policy in terms of total benefits to the society relative to cost of the program, (*c*) the distribution of benefits and costs among various sectors of society, and (*d*) the savings in foreign exchange. These criteria are measured in terms of the differences from the check case of rice import at AB to maintain the consumer price at OP_d (figure 1).

The policy alternatives are compared in table 2 in terms of the first two criteria. Income distribution effects are shown in table 3, and the effect of alternative programs on foreign exchange in table 4. In aggregating the foreign exchange savings into social benefits in tables 2 and 3, we have tentatively assumed the foreign exchange premium to be 5% based on the difference between official and black market rates of exchange.

The calculations are made for two levels of rice self-sufficiency rate defined as the ratio of domestic output to domestic consumption (i.e., 97.5% and 100%). In order to attain those levels of self-sufficiency, domestic output of rice must be increased from 4,180 metric tons to 4,290 and 4,400 metric tons, implying that the rates of increase in output are 2.63% and 5.26%, respectively. Given output and price elasticity assumptions, these rates of increase can be achieved either by raising the rice price by 9% and 18.6%, respectively, or by lowering the fertilizer price by 40.6% and 64.1%, respectively.

The findings from the analysis can be summarized as follows.

(*a*) The total social benefit produced by the rice price-support program is quite large ($73 million), but since the direct cost of government for the support is even larger ($106 million), the net social benefit is negative (table 2).

(*b*) The substantial net social benefit produced from the subsidy on fertilizer may at first seem to be an anomaly because price distortions due to the government intervention in product or input markets usually result in inefficiency or net loss in social and economic welfare. It has to be remembered, however, that we are dealing with an economy characterized by suboptimality in farmers' application of inputs and that our benchmark is not free market equilibrium.

(*c*) Among the fertilizer price subsidy alternatives, the net social benefit for plan A ($16 million) is lower than for plans B and C ($20 million), but the direct government

have been found even in developed economies such as the United States (Griliches) and Japan (Hayami et al., pp. 96–99).

Table 2. Benefits and Costs Associated with Price-Support and Fertilizer-Subsidy Programs

	Self-Sufficiency Rate	
	97.5%	100%
	----Million $-----

Rice producers	34	65
Sugar producers	0	0
Government[a]	−24	−49
Fertilizer subsidy—plan B		
Rice producers	34	65
Sugar producers	26	50
Government[a]	−46	−95
Fertilizer subsidy—plan C		
Rice producers	34	65
Sugar producers	14	24
Government[a]	−35	−69

[a] Direct government cost of price support or subsidy program net of government tax revenue and foreign exchange premium (assumed as 5% of total foreign exchange savings-earnings).

cost for plan A ($51 million) is only about half that for the other alternatives (table 2). However, plan A, based on a two-price system in which only rice (and corn) producers are entitled to purchase subsidized fertilizer, has proved difficult to implement administratively especially when there is a fairly substantial gap between subsidized and nonsubsidized prices encouraging black market activities.

(*d*) Despite the high direct government cost for the single-price system of fertilizer price subsidy, the net government cost can be reduced by increasing the export tax on sugar ($72 million for plan C versus $98 million for plan B). Based on net government costs, the benefit-cost ratio for plan C (1.77) is higher than for any of the other alternatives (table 2).

(*e*) Rice producers gain considerably in terms of income benefits in each of the four alternatives being compared. Plans A, B, and C differ principally in the way costs and benefits are partitioned between the government and sugar sector (table 3). Under plan B, both rice and sugar producers gain in similar magnitude at a large cost to the government. Under plan C, the gain of rice producers is almost three times that of sugar producers. However, considering the fact that the area planted to rice is six times larger than the sugar area (3 million versus 500,000 hectares) and the proportion of the population engaged in rice production is even larger, plan C seems more equitable than plan B as a means of income transfer.

Table 4. Total Earnings-Savings in Foreign Exchange Due to Rice Price-Support and Fertilizer-Subsidy Programs

	Rate of Rice Self-Sufficiency	
	97.5%	100%
	------Million $-------	
Rice price support	31	62
Fertilizer subsidy		
A	21	39
B	34	62
C	33	61

(*f*) Rice price support gives a substantially larger contribution to foreign exchange savings than plan A of fertilizer subsidy, since the import expenditure for rice is eliminated with less additional expenditure for fertilizer import. However, there is no difference in savings between price support and plans B and C (table 4).

Conclusions

We have developed a model to compare in a fairly limited context the benefits and costs associated with alternative rice price-support and fertilizer-subsidy programs to achieve self-sufficiency. It should not be implied from this analysis that achieving self-sufficiency through any of these alternatives discussed is a desirable policy goal for the Philippines. There are not only alternative ways of achieving self-sufficiency but also alternative goals to self-sufficiency that may be more desirable.

What we do argue, however, is that in a period of highly volatile food grain and fertilizer prices, such as we have recently experienced, food staple self-sufficiency and the related price-policy objectives to achieve this goal have become a matter of major concern to many developing countries. The major constraint facing these governments is the budget.

Our results show that a subsidy on the price of fertilizer applied to the rice sector only requires less cost to the government for the achievement of self-sufficiency (plan A). It is more efficient than rice price support in terms of the benefit-cost ratio. However, past experience has shown that it is difficult to limit the fertilizer subsidy to the rice sector because the increase in the gap between the subsidized

and the unsubsidized prices promotes a large-scale diversion of fertilizer from the rice to the sugar sector through the black market. As the diversion becomes larger, the cost to the government will increase and approach the cost under a single-price system (plan B).

The increase in government cost due to an expansion of the fertilizer-subsidy program to cover both rice and sugar sectors can be compensated for by the increase in export tax revenue if the rate of sugar export tax is increased corresponding to an increase in the subsidy rate (plan C). Efficiency in the use of government funds in terms of total social benefit to net government cost is highest for this scheme. It also seems more equitable in terms of the subsidy per person engaged in rice and sugar production.

The fact that the government has been trying to maintain the two-price system for fertilizer seems to suggest a short-run focus of government policies. For the policy maker the direct government cost of the program, which can be budgeted initially, would probably be a more important consideration than the possible income that may be derived in the program in the future through the export tax on sugar or other tax gains that may result from higher farm incomes.

It has to be emphasized that our analysis in this paper is based on "normal" price relations in the Philippines. The benefits and costs of alternative programs change as price relations change. It seems more reasonable to hypothesize that policy makers make a policy choice in relation to specific price relations in specific periods rather than "normal" relations. In order to make more meaningful inference on the decision of policy makers, it would be necessary to extend our calculations for the different sets of price relationships that are specific to the history of the country.

Appendix

Formula to Estimate Benefits and Costs Associated with Alternative Policies

In order to estimate the benefits and costs of alternative policies shown in figures 1 through 3, a simple power function with a constant elasticity is assumed for production, demand, and supply functions. The following notation is used: price elasticity of rice supply = β, production elasticity of fertilizer with respect to rice = α and with respect to sugar = δ, and price elasticity of fertilizer demand with respect to rice = $-\gamma$ and with respect to sugar = $-\epsilon$.

Price support. The cost to the government or difference between procurement cost and sales revenue is

$$\text{(A.1)} \qquad \text{area } ACLM = (p_s - p_d)(q_c - h).$$

Reduced revenue from government imports is

$$\text{(A.2)} \qquad \text{area } ABEI = (p_d - p_w)(q_c - q_o),$$

where $p_d = OP_d$, $p_s = OP_s$, $p_w = OP'_w$, $q_o = OQ_o$, $q_c = OQ_c$, and $h = OH$ in figure 1.

The relation between p_d and p_s can be established as $p_s = p_d(1 + k)^{\frac{1}{\beta}}$, where $k = (q_c - q_o)/q_o$.

Since we assume a constant-elasticity supply function—$q = \Phi p^\beta$—where Φ is a scaler including supply shifters, an increase in rice producers' income due to government support is calculated as

$$\text{(A.3)}\quad \text{area } BCLM = \text{area } BCP_sP_d - \text{area } MLP_sP_d$$
$$= (1 - m_r)\left[\int_{p_d}^{p_s} \Phi p^{\beta} dp - h(p_s - p_d)\right]$$
$$= (1 - m_r)\left[\frac{1}{1+\beta}(p_sq_c - p_dq_o) - h(p_s - p_d)\right],$$

where p_d and p_s are measured at a retail level, and m_r is the rate of processing and marketing margin for rice (the margin assumed proportional to the retail price).

The net savings of foreign exchange is

$$\text{(A.4)}\quad \text{area } ABQ_oQ_c - \text{increase in fertilizer import} = p_w(q_c - q_o) - p_{fo}(1 - m_f)(x_c - x_o),$$

where p_{fo} is the domestic retail price of fertilizer, x_o and x_c are the fertilizer inputs corresponding to p_d and p_s, respectively, and m_f is the rate of marketing margin for fertilizer. The relation between x_o and x_c is established as $x_c = x_o(p_s/p_d)^{\gamma}$.

Fertilizer subsidy for rice. The fertilizer input required to produce a self-sufficiency level of rice output (q_c) while other factors remain constant is $x_s = x_o(q_c/q_o)^{\frac{1}{\alpha}} = x_o(1 + k)^{\frac{1}{\alpha}}$. The subsidized price of fertilizer that would induce farmers to apply more fertilizer at the level x_s is $p_{fs} = p_{fo}(x_s/x_o)^{-\frac{1}{\gamma}} = p_{fo}(1 + k)^{-\frac{1}{\gamma\alpha}}$, where p_{fo} and p_{fs} are unsubsidized and subsidized prices of fertilizer for farm producers, respectively. The government cost of fertilizer subsidy for rice to achieve self-sufficiency is

$$\text{(A.5)}\quad \text{area } ABP_{fs}P_{fo} = x_s(p_{fo} - p_{fs}).$$

A reduction (or increase) in government revenue due to a decrease in rice import as a result of achieving self-sufficiency is the same as for rice price support (see equation A.2).

The rice producers' benefit is

$$\text{(A.6)}\quad \text{area } CDP_{fs}P_{fo} + \text{area } ABQ_oQ_c - \text{area } BDX_oX_s = (p_{fo} - p_{fs})x_o + (1 - m_r)p_d(q_c - q_o) - p_{fs}(x_s - x_o).$$

The net savings in foreign exchange is

$$\text{(A.7)}\quad \text{area } ABQ_oQ_c - \text{area } ACX_oX_s = p_w(q_c - q_o) - p_{fo}(1 - m_f)(x_s - x_o).$$

Fertilizer subsidy for sugar. Fertilizer input for sugar corresponding to the subsidized price of fertilizer required for rice self-sufficiency is $z_s = z_o(p_{fo}/p_{fs})^{\epsilon} = z_o(1 + k)^{\frac{\epsilon}{\alpha\gamma}}$, where z_s and z_o are fertilizer inputs at subsidized and unsubsidized prices, p_{fs} and p_{fo}, respectively, while the rice price remains at p_d. The sugar output at the subsidized price of fertilizer is $y_s = y_o(z_s/z_o)^{\delta} = y_o(1 + k)^{\frac{\epsilon\delta}{\alpha\gamma}}$, where y_s and y_o are sugar outputs corresponding to fertilizer inputs z_s and z_o, respectively.

The government cost of fertilizer subsidy for sugar is

$$\text{(A.8)}\quad \text{area } EFP_{fs}P_{fo} = z_s(p_{fo} - p_{fs}),$$

The government revenue from the sugar export tax would increase by

$$\text{(A.9)}\quad \text{area } BCEH = tr_w(y_s - y_o),$$

where r_w ($= OR_w$) is the export price of sugar, and t ($= R_wR_w/OR_w$) is the rate of sugar export tax.

The sugar producers' benefit is

$$\text{(A.10)}\quad \text{area } HGP_{fs}P_{fo} + \text{area } BCY_sY_o - \text{area } FGZ_oZ_s = (p_{fo} - p_{fs})z_o + (1 - t)(1 - m_s)r_w(y_s - y_o) - p_{fs}(z_s - z_o),$$

where m_s is the rate of processing and marketing margin for sugar. The net gain in foreign exchange is

$$\text{(A.11)}\quad \text{area } EHY_oY_s - \text{area } EHZ_oZ_s = r_w(y_s - y_o) - (1 - m_f)p_{fo}(z_s - z_o).$$

By increasing the tax rate from t to t' in plan C, the fertilizer input and sugar output would change from z and y to $z'_s = z_s[(1 - t')/(1 - t)]^{\epsilon}$ and $y'_s = y_s[(1 - t')/(1 - t)]^{\epsilon\delta}$. Costs and benefits associated with fertilizer subsidy for the sugar sector under plan C can be calculated by substituting t', z', and y' for t, z, and y in equations (A.8) through (A.11) except for an additional export tax applied to export $(t' - t)r_w(y_o - y_d)$, where y_d is domestic consumption, which has to be added to equation (A.9) and subtracted from equation (A.10).

Peasant Risk Aversion and Allocative Behavior: A Quadratic Programming Experiment

Thomas B. Wiens

A quadratic risk programming model is used to examine the impact of yield uncertainty on peasant allocation of land among crops and use of hired factor services. The assumption of an exponential utility of income function permits sample estimation of the extent of risk aversion and interpretation of the dual solutions as shadow prices. Historical survey data on a Chinese village are used to show that optimization qualified by risk aversion proves superior to risk neutrality or credit constraints in explaining peasant allocative behavior.

Key words: China, farm planning, quadratic programming, risk aversion.

Quadratic risk programming is commonly considered a theoretically appealing technique for analyzing the impact of risk aversion on farm planning in terms of the trade-off between the first and second moments of stochastic outcomes of farm plans (Hazell, Rae, Freund). It is often recognized that use of the expected income-variance (E-V) criterion of optimality is equivalent to maximization of the expected value of an exponential utility-of-income function if income is normally distributed (Freund). However, it is rarely recognized that in this case the dual solution of the quadratic program has an interpretation analogous to the linear case, and a criterion emerges for measuring the extent of farmer risk aversion from readily accessible data.

In reaction to the limited success of programs in certain less developed countries intended to induce acceptance of technical changes among smallholders, a number of recent microstudies (Baker and Bhargava, Wolgin, Schluter, Roumasset) have examined the relative importance of subjective factors such as risk aversion or liquidity requirements and objective factors such as credit or input availability on peasant decision making, arriving at contradictory conclusions. This study utilizes historical Chinese sample survey data to demonstrate that the behavior of peasants facing market and technological choices comparable to those confronted elsewhere in Asia today exhibited substantial risk aversion, which tended to decrease with farm size. Neither risk neutrality nor liquidity constraints alone could explain both the cropping patterns and the factor employment observed among these farmers.

Thomas B. Wiens is a senior research analyst at Mathematica, Inc., Bethesda, Maryland.

This research was supported by a grant from the Social Science Research Council, Joint Committee on Contemporary China. Helpful advice was received from G. Bierwag and M. Grove.

The Method of Analysis

Use of the E-V criterion in risk analysis is frequently justified on the assumption that the decision maker's utility-of-income function is quadratic and concave (Hazell, Markowitz). This assumption is theoretically objectionable (Pratt) and eliminates the dual solutions to quadratic risk programming problems as a source of valuable information on both the optimality of resource allocation patterns and the extent of risk aversion of the decision maker. Moreover, the assumption is unnecessary if incomes are approximately normally distributed.

In the latter case, it is far more convenient to assume an exponential utility-of-income function:

$$(1)\quad U(R) = K - \theta \exp(-\lambda R), \qquad \text{for } K,\ \theta, \text{ and } \lambda > 0.$$

Let net income be defined by $R = b'X$ and vector $b \approx N(\mu,\Sigma)$, then

$$(2) \quad E(U(R)) = K - \theta \exp[-\lambda\mu'X + (\lambda^2/2)X'\Sigma X].$$

To maximize equation (2) with respect to vector X of activity levels is equivalent to maximizing

$$(3) \quad W = \mu'X - (\lambda/2)X'\Sigma X = E(R) - (\lambda/2)\,\sigma(R)^2,$$

that is, the exponential utility function yields a conventional E-V objective function in the case of normality (Freund). Moreover, it is apparent that equation (3), which is nonstochastic, represents the certainty-equivalent level of income defined as R^* such that $U(R^*) = E(U(R))$. This is seen by substituting R^* for R in equation (1), setting equation (1) equal to equation (2), and solving for R^*. Since the difference between the expected return and the certainty-equivalent return (CER) defines a risk premium, the latter has monetary value $(\lambda/2)X'\Sigma X$.

In conjunction with a set of linear constraints ($AX \leq C^*$), maximization of the E-V objective function, equation (3), defines a quadratic programming problem with optimal primal solution X^*. The corresponding dual problem evaluates $\emptyset = \partial W/\partial C^* = \partial R^*/\partial C^*$ at $X = X^*$ (Intriligator). Just as R^* can be interpreted as the maximum amount of (certain) income the decision maker would be willing to trade for the stochastic opportunity set described by $R = b'X$, so can $\emptyset = \partial R^*/\partial C^*$ be interpreted as the amount of (certain) income that would be willingly sacrificed for an increment in C^* at $X = X^*$; that is, the dual solutions $\emptyset$ represent true "shadow prices."

Suppose the decision makers are producers maximizing the expected utilities of net revenues according to the above utility function, subject to fixed market prices of the factors of production. Then observed allocative behavior should be optimal, and we may simulate the outcome of their decision problem by treating observed levels of resource use (C^*) as constraints in a quadratic program for which $R = b'X$ defines the gross revenues derived from activities X. If the primal solutions approximate observed choices of production activities and the dual solutions the market prices of factor services, we may be satisfied that the model has correctly described producer behavior. Should some factor markets be inactive or imperfect, the shadow-market price comparison will reveal it without vitiating the analysis (since the objective function ignores factor costs).

The major parameters (μ, Σ, and C^*) of such a simulation can be observed or estimated, but the parameter λ reflecting the risk aversion of the decision maker(s) is manifestly subjective. In previous articles (Anderson, Hazell, Rae) this has been stressed as a drawback of the E-V approach, and it has been presumed that either direct measurement of utility functions or the solution for the full range of E-V frontiers is required to avoid it. In our approach, it is possible to directly estimate the value(s) of λ that come closest to ensuring that primal solutions X are identical with actual activity levels X^* and dual solutions $\emptyset$ approach actual market prices r.

The Kuhn-Tucker conditions for an optimal solution to the quadratic programming problem defined above require

$$(4) \quad \mu_i - \lambda\Sigma_i X - A_i'\emptyset = 0$$

for all nonzero activities i in the solution, where μ_i is the ith element of μ, Σ_i is the ith row of Σ, and A_i is the ith column of A. Substituting X^* for X and r for $\emptyset$, we may estimate λ as

$$(5) \quad \lambda^* \approx (\mu_i - A_i'r)/\Sigma_i X^*.$$

While this should hold for each production activity if all assumptions are exactly fulfilled, in practice an average over all production activities will suffice. Note that λ^* will vary with scale of production, returns to scale, and activity mix.

Hence, the assumption of an exponential utility function permits a rigorous test of the applicability of the risk aversion model based on both primal and dual solutions and allows direct estimation of the elusive risk aversion parameter λ.

Data and Estimation Techniques

The model is here applied to data from a survey of resource allocations among alternative cropping patterns on twenty-one farms in North China over the years 1937–39.[1] The

[1] Sample data from the South Manchurian Railway (Minami Manshu etc., 1939, 1940a, and 1940b). A fuller description of the regional agrarian economy is found in Dittrich and Myers.

sample includes tenant, part-tenant, and fully-owned farms ranging in scale from small (under 0.6 hectares) to atypically large (3.2+ hectares) and representing a relatively commercialized district with good market access. The primary decision problem faced is to determine the amounts of owned and hired factor services to devote to each of three crops—cotton (high and stable yielding but with high cash outlay and intertemporally declining profitability), maize (higher but unstable in yield and profitability with low outlay), and kaoliang, a sorghum variety (low yielding but hardy with low outlay). These crops share a single growing season and are generally substitutable, although cotton requires well-drained land. The local market has ready access to imported supplies and a trivial middleman's margin, so "subsistence requirements" do not dictate a particular cropping pattern.

To capture substitutability of inputs, the unit of choice is assumed to be the "frontier technique," defined as any technically efficient method of producing a value-unit of each crop under optimal growing and harvest conditions. As increasing returns to scale are observable in the sample, separate technique sets are distinguished for seven large (over 2.75 hectares) and fourteen smaller farms, with large farms presumed to have access to small farm techniques. For all farms, years, and crops, thirty-four nondominated combinations of unit input requirements are distinguished as "frontier techniques."[2] The most important of these are shown in table 1.

The activity level X_i for each frontier technique is a nonstochastic choice variable related to realized gross revenues through the function $R = \sum_i b_i X_i$. The vector b is assumed decomposible into its expected value plus stochastic cross-sectional (u_i), intertemporal (v_t), and mixed deviations (w_{it}) due to variations in farm efficiency and natural conditions:

$$b_{it} = \mu + u_i + v_t + w_{it}, \tag{6}$$

where i is farm unit and t is crop year. Treating b_{it} as pertaining to a particular crop rather than a single technique, the expected values are estimated by regressing realized yields on frontier yields (suppressing the intercept), where frontier yields for each farm and crop year represented the maximum potential yield for each crop (as estimated using conventional linear programming techniques) given the frontier techniques and the input levels actually employed.

[2] "Frontier" estimation techniques, while required to distinguish efficient production processes, are sensitive to errors of observation (Timmer). A very few observations are rejected as containing probable errors. A fuller discussion of the methodology and data may be found in Wiens.

Table 1. Resource Requirements per Chinese Dollar of Expected Value of Product (1937 Prices)

	Land (ha./100)	Labor (days)	Animal Labor (days)	Fertilizer ($)	Other Capital ($)
Large farms					
Corn	0.473	0.299	0.030	0.055	0.055
	0.440	0.652	0.069	0	0.016
	0.347	0.444	0.045	0.116	0.029
Kaoliang	0.680	0.581	0.055	0.003	0.059
Cotton	0.300	0.596	0.005	0.140	0.038
	0.367	0.587	0.032	0.152	0.020
Small farms					
Corn	0.813	0.621	0.043	0.004	0.020
	1.000	0.900	0.005	0.096	0.040
	0.693	0.401	0.064	0	0.031
	0.300	1.437	0.045	0.036	0.019
	0.627	0.365	0.005	0.005	0.105
	0.453	0.615	0.051	0.050	0.078
Kaoliang	1.367	0.893	0.064	0	0.019
	0.733	0.758	0.015	0	0.041
	0.913	0.300	0.055	0	0.103
Cotton	0.313	0.683	0.019	0.153	0.020
	0.340	0.792	0.016	0.143	0.020
	0.253	0.699	0.017	0.097	0.022

Note: The above represent a sample of alternative "frontier" techniques for producing each crop. Only those appearing in optimal quadratic programming solutions for one or more farms are shown.

The residuals of these regressions could be used as a measure of the stochastic elements in the farmer's choice problem, if purged of the irrelevant cross-sectional components. A two-way balanced cross-classification analysis of variance technique (Graybill) is used to estimate Σ, with strictly cross-sectional components removed.

Constant prices are assumed in the estimation of μ and Σ, but the estimates are subsequently adjusted for intertemporal changes in price expectations based on a one-year lag model. While inadequate data existed to account for the variance of realized prices around expectations, it appears that the magnitudes involved are insignificant relative to intertemporal variance-covariance of yields (see table 2). Comparing similar findings for India (Schluter), this suggests that price risk can frequently be disregarded in studying production decisions in peasant agriculture.

The estimates of μ and Σ used as parameters in the quadratic objective function (at 1937 prices) are given in table 3. The estimated parameters confirm the assessment of risk return characteristics of each crop given above.

Estimates of the risk aversion parameter λ are separately derived for large and small farms (0.0085 and 0.091, respectively) using relation (5). While results could benefit from estimation of a separate value for each farm, for this exercise it is felt sufficient to show that the average behavior of a group of farms of similar size (or wealth) could be accounted for in terms of a single average extent of risk aversion. Not surprisingly, it is found that decreasing absolute risk aversion with increased wealth is required to explain the behavior of both groups, implying a tendency for the distribution of income to worsen over time (see Weeks).

Table 2. Proportional (Logarithmic) Variance-Covariance of Prices and Yields around Their Expected Values

	Variance			
	Corn	Cotton	Covariance	r_{xy}
Price	0.023	0.017	−0.002	−0.11
Yields	0.261	0.071	0.067	0.50

Note: Price (logs) variance-covariance computed from Nanking fourth quarter wholesale price series, 1920–36 (a long farm gate price series was unavailable), with expected prices assumed equal to lagged actual prices. Prices series for kaoliang were unavailable. Yield (logs) variance-covariance around estimated expected values from sample data, with cross-sectional variance-covariance removed. The simple correlation coefficient for the pair of crops is r_{xy}.

Table 3. Estimated Parameters of the Objective Function (1937 Prices, Chinese Dollars)

	Corn	Kaoliang	Cotton
$E(b)$	0.799	0.748	0.837
Σ_b			
Corn	0.048	0.017	0.025
Kaoliang	—	0.032	0.003
Cotton	—	—	0.025

Note: $E(b)$ estimated by regressing realized yields on frontier yields (suppressing the intercept). Σ estimated from the residuals of the regressions using two-way balanced cross-classification analysis of variance (Graybill).

Findings

Solutions of the quadratic programming problem, along with those of the comparable linear programming problem, are obtained for each farm and year in order to test the hypothesis of risk averse behavior against the alternative of risk neutrality.[3] To explore the relationship between credit availability and resource allocation, solutions to both problems are also obtained on the assumption that working capital (or "liquidity") is the only ultimate constraint.

The results of risk neutral linear programming solutions are distinctly contrafactual (average risk neutral solutions for a subgroup are given below). Given the levels of resources employed, the sample farms should with few exceptions be diversified between cotton and maize with no sorghum grown and with emphasis on cotton in 1937 shifting drastically to emphasis on corn by 1939. Dual solutions are on average significantly higher than market prices for all factors except fertilizer (which had too low a shadow price), indicating overall insufficient hiring of factor services. Because of increasing returns, shadow prices tend to be higher on large farms than on small.

When working capital is treated as the sole constraint, specialization in cotton or maize at various times appears optimal (with labor intensity lower than observed) and the rate of return to working capital exceeds 75% per crop season, sufficient to justify recourse to moneylenders (at a 24% annual interest cost). Nor does it appear that, in the context of this

[3] Computer processing is based on an efficient algorithm similar to one suggested by Shetty.

marketing and cropping system, a more complex model of liquidity requirements would improve the verisimilitude of solutions (see Baker and Bhargava).

By contrast, the risk aversion model accords quite well with the average behavior of the sampled peasants. Primal solutions in general call for full diversification among the three crops in proportions close to those observed (see table 4). Moreover, since in the course of general price inflation (which raises risks disproportionately to expected returns) risk and price effects work in opposite directions, the optimal crop proportions show greater stability over time than is found in risk neutral solutions, explaining an apparent anomaly in sample farm behavior.

Risk aversion also generally reduces the difference between dual solutions and market prices (see tables 5 and 6). Indeed, for those factor services with active markets, divisibility, and correct specification (in particular, labor and land), the average levels of use are close to optimal. For these factors, too, the variance of dual solutions for different farms is relatively low, indicating that individual deviations from optimality are rarely serious.

Dual solutions diverge in varying degrees from market prices of other factor services (cotton land, animal labor, fertilizer, and other capital), and display dispersed and bimodal distributions (either zero or high in value). Many farms appear to make wasteful use of their animal labor and fertilizer, while others seem starved for these services. These results probably indicate specification error and market imperfection rather than suboptimal or risk neutral peasant behavior.

The separate restriction on cotton land is added to account for the requirement of well-drained land for this crop. Most likely, such land is higher yielding in other uses as well (not accounted for in our technical coefficients), hence the persistence of high market rentals for such land even when not planted in cotton.

Although the average shadow prices for fertilizer are not far from market prices, the model does not account for the bifurcation of that input into two distinct types—slow-acting organic base fertilizers and fast-acting top dressings (bean cakes and animal byproducts), nor is it clear how the survey attributes prices to these different items (the first largely self-supplied at near-zero labor cost during the slack season). Such heterogeneity could account for high variance of dual solutions.

The high and varying shadow prices of animal labor and other capital (the latter primarily depreciation of tools and implements) originate largely in indivisibility and the absence of an active rental market. Because of tight cultivation schedules imposed by a short growing season, peasants cannot afford to depend upon their neighbors for use of animals or implements, although a few personalized transactions occur at prices tied to wage rates (for plowing, about 1.6% of potential animal labor days). Farms that opt to buy and maintain animals and implements could frequently have excess capacity and other farms apparent shortage as indicated by high shadow prices, yet the addition or removal of a discrete unit (e.g., one labor animal) need not be economically justified. Integer programming techniques must be used to account for such indivisibilities in farm planning models (Gotsch and Yusuf).

Table 4. Crop Production as a Percentage of Land, Actual and Optimal under Risk Aversion

Sample	Corn		Kaoliang		Cotton	
Farms	Actual	Optimal	Actual	Optimal	Actual	Optimal
Large						
1937	8.1	16.4	31.4	25.2	60.5	56.0
1938	11.9	22.5	31.2	23.8	56.9	53.7
1939	10.4	10.0	34.7	37.9	54.9	50.7
Small						
1937	12.0	19.1	24.8	22.9	63.2	56.1
1938	19.0	18.1	29.4	26.2	51.6	52.4
1939	15.4	17.6	33.4	32.0	51.2	45.1

Note: All figures above are based on means of actual or optimal solution values for the size-year class of farm. Optimal percentages do not necessarily add to 100, since solutions called for a small percentage of land left fallow. Both actual and optimal proportions reflect changes in relative prices expected, as implied by the following (based on farm gate prices). The indices of cotton-corn price relatives for 1936–39 are 121, 100, 90, and 51, respectively. The indices of kaoliang-corn price relatives for 1936–39 are 109, 100, 101, and 108, respectively.

Table 5. Mean Certainty-Equivalent Shadow Prices for Large and Small Farms and Market Prices of Factor Services

	1937	1938	1939
Land			
Large	16.79	14.24	13.58
Small	19.09	12.61	20.24
Market	24.61	21.64	24.18
Labor			
Large	0.49	0.58	0.70
Small	0.34	0.63	0.65
Market	0.45	0.55	0.70
Fertilizer			
Large	0	0.20	0.67
Small	0.51	0.34	0.52
Market	0.32	0.44	0.56
Cotton land			
Large	37.27	22.55	16.55
Small	39.76	13.39	23.45
Market	28.61	34.61	36.91
Animal labor			
Large	0.31	0.70	6.39
Small	10.10	5.41	5.67
Market	0.80	1.00	1.20
Other capital			
Large	3.61	4.70	5.36
Small	4.31	5.24	6.39
Market	1.00?	?	?

Note: Sources of Market Prices: land (ordinary) and cotton land (well-drained)—previous year's mean reported rental value (+10% where rent prepaid); land rentals contracted for one year in advance. Labor—modal daily labor payment (including value of commodities supplied). Animal labor—modal rate per day for animal plus plow or baskets if hired (based on a limited number of transactions). Fertilizer—based on values of fertilizer utilized as attributed by survey researchers; organic fertilizer nutrient content is absorbed over four years in roughly equal amounts (manure); the capital recovery rate on one dollar is $0.32, given an interest rate of 10%, hence is the level of return justifying the purchase of an additional $1 unit; values during 1938–39 were computed by adjusting this figure according to an estimated price index of fertilizer. Other capital—includes seeds, tools and implements, and storage facilities, evaluated at their rate of depreciation based on age and original cost; however, the latter may be well below replacement cost (unknown), hence the assigned 1937 unit cost of $1 may be too low.

An alternative explanation for the high shadow prices of some types of capital service could be the presence of a shortage of long-term credit (Wolgin, Baker and Bhargava). Such credit is available through a land mortgage market but at high effective rates of interest (20% to 30%). Some conclusions on the extent of shortage can be drawn by replacing the factor service constraints with a single working capital constraint (preserving the fiction that a rental market in capital services exists, making long-term capital unnecessary). It is found that peasants could reduce their working capital burden by substituting the services of land, animal labor, and tools and implements for hired labor and purchased fertilizer, while maintaining full diversification. In this case, the CER to working capital would be low or slightly negative, so that even short-term borrowing at subsidized rates of interest would not be attractive. Such low returns of course do not imply that peasants should employ more of their liquid assets in moneylending, for this alternative involves risks no less severe and need not appear attractive to risk averters.

Since the rental market in capital services is in fact underdeveloped, it can be presumed that actual CER's are lower still. Hence, while the fundamental constraints on farm resource allocation and expansion includes the farms' own stocks of liquid assets and the indivisible nature of certain capital inputs, it does not follow that improved credit availability, even at moderate rates of interest, would induce borrowing for productive purposes. Only substantial reductions in the peasants' subjective risk premia would induce such borrowing.

The sensitivity analysis for small farms (table 6) suggests that the effects of policies to reduce risk or risk aversion are technology-specific and sometimes ambiguous. For example, in this sample, a risk-reducing crop (cotton) also is fertilizer-intensive, hence risk aversion tends to increase peasant demand for fertilizer (and crop insurance might have decreased it). Nor is the acreage in cotton a monotonically increasing function of the extent of risk aversion as might be supposed, for at some point land-intensive cotton-producing techniques are optimally replaced by fertilizer-using techniques to free land for low risk sorghum production.

Conclusions

The historical age of the sample data used in this study might seem to limit the applicability of conclusions to current policy. Yet neither the attitudes nor the objective circumstances of the Chinese peasant circa 1930–40 can be shown to differ in substance from those of many peasants in Asia and elsewhere today. The one major difference in circumstance (ignoring institutional and other changes in the socialist countries) contributes to the relevance of this study. Whereas the Chinese peasants were familiar with the risks inherent

Table 6. Sensitivity Analysis, Risk Aversion Parameter; Small Farms, 1939

	Crop Proportions[a]			Shadow or Market Prices[b]					
	Corn	Kaoliang	Cotton	Land	Cotton Land	Labor	Animal Labor	Ferti-lizer	Other Capital
Optimal, $\lambda = 0$	0.51	0	0.42	34.30	36.42	0.81	7.22	0.35	10.55
Optimal, $\lambda = 0.0085$	0.34	0.16	0.44	26.24	28.18	0.73	6.52	0.41	8.48
Optimal, $\lambda = 0.0170$	0.21	0.29	0.46	20.97	22.24	0.68	5.78	0.43	6.47

[b] See notes to table 5 for explanation.

in their opportunity set, many peasants today face new technological choices involving incalculable risks and could well act with far more caution.

Nevertheless, since risk is shown to have had such an overwhelming role in determining peasant resource allocations in this sample (compare also Schluter, Wolgin), a firm conclusion is that policies to reduce risk or otherwise overcome risk aversion would be important instruments for inducing productive change in similar rural economies. Aside from their efficacy in inducing greater specialization and more extensive use of hired inputs, the exercise of such policies might well make peasants more responsive to other familiar instruments, including price and credit manipulation policies.

The Measurement of Economic Uncertainty in Public Water Resource Development

Bernard W. Taylor and Ronald M. North

The existing benefit-cost criteria for evaluating water resource projects are deterministic and therefore incomplete, since the uncertainty inherent in project outcomes is not considered. A Monte-Carlo simulation approach is used to generate a mean and standard deviation for the benefits, costs, benefit-cost ratio, and net present value for the controversial Spewrell Bluff Project. Subjective estimates defining probability distributions of project benefits and costs were obtained from the Corps of Engineers. A project selection process that includes probability considerations in the benefit-cost criteria is recommended and several approaches for including uncertainty as a variable are suggested.

Key words: benefit-cost analysis, simulation, Spewrell Bluff, uncertainty, water resource evaluation.

A serious limitation of benefit-cost analysis as practiced by federal agencies has always been the questionable assumption of economic certainty when estimating project benefits and costs. Attempts to include the element of uncertainty in the economic evaluation of water resource projects have been sporadic (Hufschmidt and Fiering, James and Lee, McKean, Turnovsky).

The computation of statistical parameters (i.e., a mean and standard deviation) that reflect the variability of project outcomes has been a perplexing problem. Since water resource projects are unique and singular in nature, historical data for the purpose of describing probability distributions are not available. The authors suggest an application of the Monte-Carlo simulation technique, which employs subjective probabilities in order to generate mean benefit-cost values and a standard deviation for improving project evaluation by measuring uncertainty. This methodology was tested on a limited basis via a case analysis of the Spewrell Bluff Dam Project in Southwest Georgia.

Bernard W. Taylor, III, is an assistant professor of management science at Virginia Polytechnic Institute and State University, Blacksburg, and Ronald M. North is an associate director of the Institute of Natural Resources, University of Georgia, Athens.

The authors acknowledge with thanks the financial support of the Georgia Department of Natural Resources and Office of Water Research and Technology (USDI/OWRT Project A-052), the cooperation of the U.S. Army Corps of Engineers, Mobile District, and the helpful contributions of Richard N. Boisvert, Cornell University.

Benefit-Cost Analysis and Uncertainty

In a world where imperfect knowledge is pervasive, taking account of uncertainty in the analysis of public investments should extend beyond purely theoretical discussions (Hirshleifer and Shapiro). The concept and treatment of uncertain expectations in water resource projects has remained somewhat nebulous to economists and decision makers (Haveman). The conceptual difficulties have been large and the "state of the art" in the fields of applied economics, finance, and water resources evaluation has yet to provide a solution. As a result of this lack of development, benefit-cost analysis has typically made the questionable assumption of certainty in the evaluation of water resource projects. Some have claimed that certain intuitive, ad hoc adjustments or subjective judgments were made for uncertainty factors (Hirshleifer and Shapiro). In fact, neither the federal agencies nor the major theoretical contributors in the field of water resource development alter the benefit-cost investment criteria because of uncertainty (Margolis).

However, McKean notes the exclusion of economic uncertainty in the evaluation processes employed by government water resource agencies as a significant deletion. He describes the costs and benefits arrived at through agency analyses as only estimates or expected outcomes. As a result two projects,

A and B, may offer identical average outcomes yet differ greatly with respect to other possible outcomes. These differences may be a matter of some importance if A's possible results are nearly the same as its average, but B's outcome possibilities range from "fabulous success to utter disaster" (McKean, p. 64).

The most common method suggested to incorporate uncertainty into the water resource investment decision is to add a risk premium to the discount rate in the present value algorithm. Eckstein (in discussing uncertainty related to time) concludes that a risk premium of ½% to 1% added to the interest rate appears to be the most appropriate adjustment for risk in project evaluation. However, he would still present to Congress only expected values based on this new interest rate with a risk premium. This method of recognizing project uncertainty is in essence the same as the certainty-equivalence approach presented by Hicks and Lange for the evaluation of private investment (Modigliani and Miller).

The inability to reliably determine risk premiums makes this method open to question. In addition, the ½% to 1% rate suggested by Eckstein seems to be a rather mild adjustment for projects with an expected life of between 50 and 100 years, especially since project planners may not be sensitive to small differences in discout rates. He attempts to justify the low risk premium and this method in general by viewing the government as a firm and projects as one of its investments and then observing whatever risk the government as a whole incurs because of a single project (Margolis).

While the argument for a risk premium results in an adjustment for uncertainty in the correct direction (which is the reduction of present value with project life), it "misses the major problem" (Margolis, p. 102). The responsible government agency and Congress must select the best possible projects and this choice should be "affected not only by the expected values of the projects but also by the probabilities of a range of benefits and costs, i.e., a measure of variability" (Margolis, p. 102). Each major water project can have a significant economic, social, and environmental impact on a particular municipality or region. Because of such impacts the project in question should be fully evaluated to include some measure of variability (a range of benefits and costs).

Alternative methods that might be employed to cope with the problems of uncertainty within the benefit-cost framework are suggested by Eckstein as shortening the period of analysis (the economic life of the project) or making safety (or contingency) allowances by arbitrarily raising some categories of costs by a flat percentage or by reducing benefits through price assumptions that are below expected prices. (These same approaches are suggested by the federal government in their guidelines for water resource project evaluation [U.S. Government 1950, 1971, and 1973].)

As noted by Margolis, these methods do not solve the problem of uncertainty any more than the use of a risk premium. Eckstein also notes the difficulty in applying these methods and the kinds of considerations necessary for deriving safety allowances. The question of uncertainty remains so unclear that Eckstein is forced to admit that judgment methods, whether verbal or formal, must be used to identify major contingencies and make some provision for the design of reasonable procedures in the face of uncertainty.

A Simulation Approach for the Determination of Project Variability

As Margolis points out, McKean was the first and primary contributor to recognize that public investment decisions should include the consideration of uncertainty. McKean views uncertainty "as an intangible . . . an especially ubiquitous and significant one" (p. 64). The estimates of costs and benefits that accrue from water resource development are only expected outcomes, which contain a significant amount of uncertainty. He notes that it is desirable to reduce uncertainty, but not enough is known about the frequency distribution of outcomes and the resulting probabilities to develop any type of certainty-equivalent as suggested by Eckstein and the federal government.

McKean suggests that some type of ". . . correct quantitative 'results' should usually be multi-valued to show various 'reasonable' outcomes . . ." to the decision maker (p. 68). Since in benefit-cost analysis a frequency distribution based on historical data is out of the question, other quantitative indicators that would include a range of possible project outcomes as a measure of project variability are required.

The difficulty in developing an alternative approach to the single-valued estimate lies in the measurement of the mean and standard deviation. Hertz offers a solution to this problem in his analysis of uncertainty in private capital investment. He notes that probability distributions can be based on probabilistic judgments made by the decision maker. In this approach the manager makes a subjective estimate of the probability of achieving a particular cash flow. This process is repeated for various expected cash flows until a probability distribution (with a mean and variance) is generated for an investment.

Swirles and Lusztig as well as Anthony and Watson offer a similar approach for developing probability distributions. In this instance three estimates for each project return are gathered: a most likely, an optimistic, and a pessimistic. These three subjective estimates form the limits of a triangular distribution. This method for building subjective probability distributions is similar to that employed in PERT (Project Evaluation and Review Technique) analysis. In PERT, three time estimates for each project activity are obtained from the project manager. For this application, instead of time estimates as used in PERT analysis, benefit and cost estimates for water resource projects are used (figure 1).

MacCrimmon and Ryavec and Van Slyke discuss the appropriateness of the triangular distribution (when using three subjective probability estimates) as opposed to the more traditional Beta distribution employed extensively in PERT analysis. MacCrimmon and Ryavec, performing an error analysis on PERT models, note that the incidence of error is less in the mean and standard deviation of the triangular distribution than in the Beta distribution (since the mean and standard deviation of a triangular distribution are given exactly as opposed to the approximations used in the Beta). These authors note that another advantage of the triangular distribution is that the possible range of its standard deviation is more centralized than the Beta assumed standard deviation.

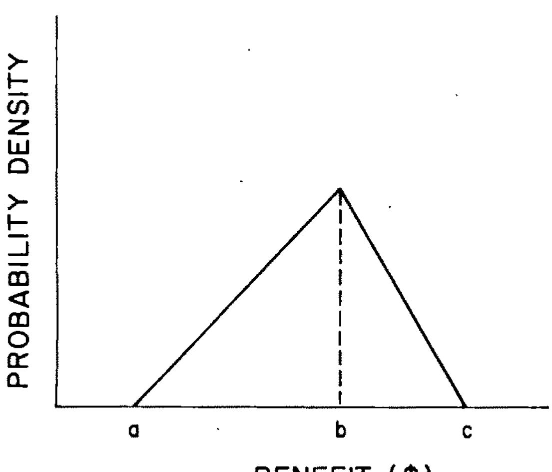

Figure 1. Benefit Density Function, where a = pessimistic, b = most likely, and c = optimistic

MacCrimmon and Ryavec conclude that "since there is no a priori justification (for) . . . a distribution . . . the fact that a mean and standard deviation can be given exactly for a triangular distribution make(s) it equally meaningful, and more manageable. . . . It would be more manageable . . . if it was necessary to use the whole distribution, say in an analysis or a Monte Carlo study" (p. 25). Van Slyke in a comparison of several distributions (e.g., normal, uniform, Beta, and triangular) also found the triangular to be equally acceptable. In addition to this evidence attesting to the validity of the triangular distribution, Swirles and Lusztig as well as Anthony and Watson found the triangular distribution easy to use, and this factor promotes the application and implementation of uncertainty analyses.

The triangular distributions are employed in a Monte-Carlo simulation model to generate the benefit-cost probability distributions. Each triangular benefit and cost distribution yields a process generator for the triangular variates. By successively selecting uniformly distributed random numbers (from a table, etc.), values are generated for each benefit and summed to yield a total benefit value for one simulation run. The same procedure is followed to generate the total cost figure. These two values for total benefits and total costs are then inserted into the appropriate benefit-cost algorithm to yield a benefit-cost ratio (or net present value). However, this is for one simulation only, which yields only one benefit-cost value. By repeating this process for multiple iterations a frequency distribution of benefit-cost values is developed. The frequency distribution resulting from these multiple, simulation iterations is then used to compute a mean and standard deviation.[1]

[1] The reader should not be confused by the Monte-Carlo process. Each simulation produces one value (e.g., a benefit-cost

Any or all of the following benefits may result from a particular water resource project (Howe, James and Lee, U.S. Government 1971): flood control, recreation, water supply, hydroelectric power, irrigation, shoreline development, water quality, navigation, area redevelopment, and others. Costs are of two basic types: project installation costs (capital and project operation) and maintenance and replacement costs (OMR). Government agencies performing benefit-cost analyses assume that the various dollar benefits that result from a project can be uniquely categorized in each of the benefit areas; that is, benefits in any given category (e.g., flood control) are assumed to be uncorrelated with other benefits (e.g., power) once the project has been scaled and designed. In fact, these benefits, once estimated, are fixed by law in the congressional authorization for implementation. Since this simulation experiment was conducted within the traditional (*Green Book* and Senate Document 97) benefit-cost framework and the data are ex ante, we are faced with the agency assumption of independence of benefits at this stage of analysis (U.S. Government 1950, 1962).[2]

The major thrust of this application of simulation to project evaluation is to demonstrate that for any given project there is a significant range of probable outcomes for each project purpose. Such ranges of expected outcomes should be considered in the project planning process to approximate the marginal conditions for efficiency among all purposes. The triangular distribution using Monte-Carlo simulation techniques begins with the assumption of independence of benefits for a project in the advanced stages of design and authorization such as the Spewrell Bluff Dam.

Case Analysis: The Spewrell Bluff Project

The Flint River, one of Georgia's major river systems, originates near Atlanta and flows in a southerly direction to Florida. The middle portion of the Flint River offers a unique, scenic river setting that is also an ideal site for hydropower generation. It is in this region where the U.S. Army Corps of Engineers has proposed and planned a major impoundment project, the Spewrell Bluff Dam.

The Spewrell Bluff project is planned to produce the following tangible benefits: the generation of hydroelectric power, flow regulation for downstream navigation, reservoir recreation, flood control, fishing, and area redevelopment. Power generation and recreation provide approximately 84% of the total benefits (table 1, column 2).

The Estimation Procedure

The subjective probability estimates (i.e., a most likely, an optimistic, and a pessimistic) were obtained by interviews in the authorized planning agency, the U.S. Army Corps of Engineers, Mobile District Office. The estimates were obtained from the various area chiefs for the socioeconomic section, recreation resources section, environmental and resources branch, and the project engineering and configuration section. In each instance the chief of the project development section assisted. Thus, for each project benefit and cost two experienced people made the estimates. A detailed explanation of the purpose of the experiment and the procedure to be followed in making the estimates was given to each participant. This included a thorough explanation of the meaning of the "end points" of the triangular distribution (i.e., points a and c in figure 1).[3]

The estimates were obtained during a several hour interview in which the individual would consult additional information to verify variations or uncertainties in the published figures. Once the procedure was described and all factors that should be taken into account were understood by the interviewee, no attempt was made to alter the individual's estimating procedure nor his estimates. This was done to avoid projecting any bias into the estimates through an unwarranted comment or suggestion. The resulting subjective benefit and cost estimates are believed to be realistic and the best available (table 1).

ratio). A mean and variance is not computed for every benefit distribution (as might be done for time activities in an analytical PERT analysis) and then summed to yield a total benefit-cost value (ratio) and variance. Thus, the possibility of covariances is eliminated.

[2] The existing economic evaluation process accepts certain gross assumptions about the independence of costs from benefits. We know intuitively that this assumption of independence is not necessarily made in the early stage of scaling and design where trade-offs among competing functions are made to optimize the project benefit-cost ratio. We in fact fix these assumptions during the planning process so that judgments may be exercised in the political process.

[3] It is necessary to explain the "end points" in detail so that the subject knows that the probability of a benefit being less than a or greater than b is zero. Moder and Rodgers report on the types of bias that might result from this type of estimating procedure.

Table 1. Subjective Estimates of Spewrell Bluff Project Annual Benefits and Costs

	Subjective Estimates ($)		
Benefit or Cost	Pessimistic	Most Likely[b]	Optimistic
Benefit			
Flood control	847,600	1,173,900	1,485,300
Hydroelectric power	5,034,125	5,922,500	5,922,500
Navigation	25,200	28,000	30,200
Recreation	4,202,000	5,372,000	7,783,000
Fish and wildlife	57,500	127,500	172,500
Area redevelopment	0	830,000	1,192,000
Total annual benefits	10,166,425	13,454,000	16,585,500
Cost			
Total capital cost	192,279,000	179,700,000	162,410,200
Annual cost[a]	7,038,460	6,578,000	5,945,837
Operation and maintenance	2,192,430	2,049,000	1,741,650
Total annual costs	9,230,890	8,627,000	7,687,487

Note: The Corps of Engineers computes all benefit-cost parameters on an annualized basis. That convention was followed in this research.

[a] Total capital cost annualized at a discount rate of 3.25% for a project life of 100 years.

[b] The "most likely" estimates coincide exactly with the initial project benefits and costs as reported in the U.S. Army Corps of Engineers planning document for the Spewrell Bluff Project. Since the project had not been officially authorized for construction, the original benefit and cost estimates remain unofficial.

Once the estimates (which defined triangular distributions) were obtained they were incorporated into a computerized simulation model employing the Monte-Carlo technique. The computer program was developed using the Fortran computer language with two subroutines, "DRAW" and "TABLE." The experiment was conducted for 400 iterations of the simulation model.

The output was divided into five economic parameters describing the benefits and costs of the Spewrell Bluff Project. These included total annual benefits, total annual costs, annualized benefit-cost ratio, total annual net benefits less costs, and total net present value. The statistical mean, standard deviation, and frequency distribution were generated for these parameters (table 2).

The mean (expected value) for each of the five benefit-cost parameters noted in table 2 coincide with the original benefit and cost estimates. This occurrence was expected since in all cases the subjective, most likely estimate coincided exactly with the original deterministic estimate made by the Corps of Engineers. This was a logical procedure on the part of the individual making the estimate, since he would naturally assume that his previous deterministic estimate would be the "most likely."

Table 2. Statistical Results of Spewrell Bluff Simulation Experiment

Economic Parameters	Mean Values ($)	Standard Deviation ($)
Total annual benefits	13,450,270	830,938
Total annual costs	8,516,762	240,281
Total annualized net benefits	4,933,831	858,609
Total net present value	145,717,100	25,362,030
Annualized benefit-cost ratio	1.58	0.11

Application of the Simulation Results

The simulation results are not significant within themselves. A mean outcome and standard deviation standing alone (without some basis for comparison) will not generally provide an answer to the question of the economic acceptability of a water resource project. However, statistical parameters are significant when numerous projects are compared with one another. One project may have a higher mean outcome than another but it also may have a higher standard deviation (indicating a greater amount of risk). The question then becomes one of policy. Which is more preferable—the higher expected outcome or the lower risk? As a result of this dilemma, specific decision rules must be formulated that reflect the taxpayers' preference for risk or risk avoidance.

There are several decision models available to compare alternative private investment projects. However, in order to demonstrate such models for use in the public sector it is necessary to evaluate more than one project. There-

fore, the following three hypothetical water resource projects will be used for demonstration purposes.

Let project 1 produce a mean (M) annual net benefit of \$3,000,000 with a standard deviation (σ) of \$400,000, project 2, which corresponds to the Spewrell Bluff example, produce a mean annual net benefit of \$4,933,831 (848,609), and project 3 produce mean benefits of \$2,500,000 (600,000).

The first decision model discussed is the familiar "coefficient of variation": $V = \sigma/\mu X 100$. This particular measure shows the standard deviation as a percentage of the mean. For the three projects, respectively, the coefficients of variation are $V_1 = 0.14$, $V_2 = 0.17$, and $V_3 = 0.24$.

Project 1 is the most desirable since it has the lowest value for the coefficient of variation (i.e., the least amount of uncertainty relative to the magnitude of the mean value).

The second method is the "safety first" criterion suggested by Roy (Boisvert). In this approach the decision maker (i.e., the public) specifies a minimum acceptable project outcome. Using this minimum level incorporated in Chebyshev's inequality we can determine the upper boundary for the probability of experiencing an undesired outcome:

$$P(\theta \leq \theta^*) \leq P\{|\theta - \mu| \geq \mu - \theta^*\} \leq \frac{\sigma^2}{(\mu - \theta^*)^2}.$$

To minimize the above probability we choose the project that yields the minimum value for $v = \sigma^2/(\mu - \theta^*)^2$. For our example, a minimum acceptable project outcome is established as \$2,000,000 in mean annual net benefits. For the three projects, the minimum values are $v_1 = 0.16$, $v_2 = 0.09$, and $v_3 = 1.44$.

Using this decision methodology, project 2 is the most desirable. As in the previous approach, this method is limited by the difficulty of determining the public's minimum acceptable outcome (θ^*).

A third approach is the use of a graphical investment frontier (as suggested by Markowitz 1959). In this method the mean net benefits of a number of projects are plotted on a graph against the standard deviations of net benefits. Under the assumption that decision makers (i.e., society in the public sector) are risk averters, Markowitz (1952) and Pyle and Turnovsky explain how one can limit consideration to only a portion of all expected value and standard deviation combinations. In their analysis only those values that maximize the mean for given values of the standard deviation are employed (figure 2).

Line AB represents the efficiency frontier for all government projects in the sense that it maps out all possible combinations for which the mean is maximized for each level of standard deviation. It is in a sense the production possibility frontier (all other feasible projects lie above and to the left of AB). Given that the decision makers or society are risk averse and wish to maximize expected utility, Pyle and Turnovsky demonstrate under rather general assumptions that the indifference curves, reflecting the willingness to trade off mean benefits and the standard deviation in benefits, are given by I_1, I_2, and I_3. Since the objective is to reach the highest indifference surface, alternatives that lie above the efficiency frontier line AB (such as point 3) can be eliminated from consideration. If one were to know the shape of the indifference curves, a single point could be selected, in this case, the point X. However, estimating the indifference surface would be a difficult, if not impossible, task. While this procedure is unlikely to lead to a single "best decision," it does provide a basis for substantially restricting the number of alternatives to be considered.

The decision models represented in figures 1 and 2 that might be used to apply the results of the simulation model include several significant assumptions. The first assumption is that decision models typically used by the investor in the private sector could be applied to the public sector. Second, it has been assumed

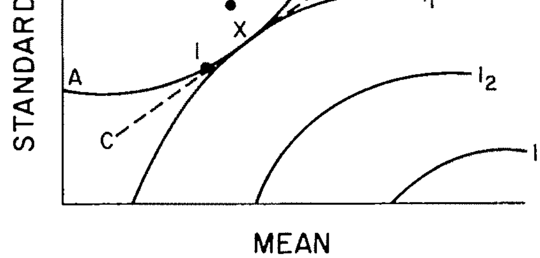

Figure 2. Expected utility maximization

that the public reflects a "risk-averse" attitude that justifies the "safety-first" criteria. It has already been noted in the first section of this paper that "pooling" of risk associated with water resource projects is inappropriate (Margolis). Each water resource project can have a significant impact (socially, economically, and environmentally) on a particular community or region. Thus, the recipients directly affected by the project are concerned with the risk involved.

However, whether the public should be classified as "risk takers" or "risk averters" is subject to some amount of speculation. The authors feel that if projects were evaluated solely on economic considerations the public would tolerate a certain amount of risk taking. But with the increasing emphasis on "multiple objective" planning an opposite trend seems to be developing; that is, the public is now concerned with both the social and environmental (as well as economic) consequences of water resource projects.

The public is becoming increasingly hesitant to accept projects that have an adverse environmental and social impact no matter what the economic gain.[4] Thus, it appears that the public is developing a risk-averse attitude. Given these assumptions and the premise that the public is concerned with risk, it seems appropriate to apply the decision models developed for investors in the private sector to similar situations in the public sector.

One final point should be made concerning the subject of risk in government financed projects. It might be necessary to separate the risks associated with the economic and environmental objectives of a project especially when the values are incommensurate. There may be a tendency in the future, within the multiple objective planning framework, to consider environmental and economic impacts separately. Within this framework an alternative approach to risk evaluation may be taken. Referring to figure 2, once projects are evaluated and found to be inefficient (i.e., project 3) or efficient (i.e., projects 1 and 2) some other values reflecting multiple objectives might be considered in selecting between the efficient projects. These other considerations could include subjective evaluations by the public since environmental and social impacts may be difficult to quantify.

[4] The Flint River/Spewrell Bluff project examined in this paper is an example of the public's concern for the environment. As a result of public pressure former Governor Jimmy Carter vetoed this project 1 October 1973. The Corps of Engineers is now "holding" the project for later consideration.

Summary

This research was undertaken to develop a more realistic alternative to the existing deterministic benefit-cost evaluation procedures. The methodology used to measure project uncertainty was a Monte-Carlo simulation model employing triangular, subjective probability distributions. The proposed Spewrell Bluff Project was used as a case analysis to demonstrate the simulation model and its application to water resources development projects. The simulation results were demonstrated and then compared via investment decision models in a hypothetical example. The authors note that the existing models are limited in application until acceptable methods of determining the public's aversion to risk in water resource projects are developed. Meanwhile, the authors' use of subjective estimates of experienced managers to develop estimates of uncertainty parameters has immediate possibilities of application internally within agencies to improve the project evaluation and selection process.

Optimum Effort and Rent Distribution in the Gulf of Mexico Shrimp Fishery

Wade L. Griffin, Ronald D. Lacewell, and John P. Nichols

Traditional methods used to estimate fishing effort that maximizes rent to an open access resource have almost universally assumed all costs are directly proportional to effort. When crews receive a fixed share of gross returns, labor costs are proportional to catch; hence, rent accrues to crews as well as vessel owners under limited entry. A model that allowed costs to be proportional to effort and catch was applied to the Gulf of Mexico shrimp fishery. This study indicates that traditional analysis would result in management schemes that overtax vessels and ignore rent accruing to crews.

Key words: common property, fisheries, rent distribution, shrimp.

During the past two decades the basic results of both theoretical and applied articles have shown that the common property nature of fisheries, accompanied with the free entry of labor and capital, results in overfishing (Gordon, Scott, Schaefer, Turvey, Van Meir, Quirk and Smith, Smith, O'Rourke, Bell, Gates and Norton). This crowding externality gives rise to the phenomenon of resource rent dissipation and implies some type of imposed management system if rent is to be maximized to the resource.

In what we term the "traditional" fishery economic literature, the assumption is almost universally made that all costs are directly proportional to effort, where effort is defined as the relative fishing power per day fished aggregated across days fished and vessels.[1] However, when crews are paid a share of gross or net returns instead of a wage, labor costs are proportional to catch rather than effort. Zoeteweij states that the share system is predominant in marine fisheries. Crutchfield and Zellner point out that the reason for the universal use of the share system is that it spreads the inevitable high risk of fishing and provides a direct incentive for teamwork and maximum effort during the season. Whether crew labor costs are proportional to effort or catch, Cheung has shown that in a common property fisheries rent will be dissipated.

Although the assumption that all costs are proportional to effort greatly simplifies an analysis, it can also distort the results. The purpose of this paper is to provide methodology and an empirical application for estimating the economic optimum in a fishery when some costs are proportional to catch. This analysis has implications relative to the economic optimum catch (catch where rent to the resource is maximized) and, even more important, to the distribution of rent from the resource.

To appropriately quantify the distribution of rent to various components of an open access fishery, a needed adjustment to the traditional analysis is inclusion of those costs that are proportional to catch rather than effort. A general conceptual framework of rent distribution in marine fisheries is developed and then applied to the Gulf of Mexico shrimp fishery. Optimum effort, catch, and rent distribution are compared under alternative assumptions regarding the nature of costs. Finally, policy implications are discussed.

Wade L. Griffin in an assistant professor and Ronald D. Lacewell and John P. Nichols are associate professors in agriculture economics at Texas A&M University, College Station.

Technical Article No. 12503 of the Texas Agricultural Experiment Station. The assistance of Bruce Beattie and Hovav Talpaz as well as two unidentified *Journal* reviewers in providing valuable suggestions is gratefully acknowledged. This research was partially funded by the Southeastern Region Office of the National Marine Fisheries Service and by Sea Grant at Texas A&M University.

[1] Turvey recognizes the share system but argues that this is not relevant to his case and assumes that total cost rises more than proportionally to effort. O'Rourke also recognizes the share system but assumes the two methods are similar and treats all costs as proportional to effort.

Nature of Fishery Production Costs

Traditional Concepts

Traditional fishery economics assumes all costs items to be a linear function of effort implying that

$$(1) \qquad \Pi = R - C = PY - rE,$$

where Π is rent to all vessel owners in the industry as calculated by the traditional method; R is total revenue to the industry calculated as price of fish—P, assumed to be constant—times total pounds landed by the industry—Y; and C is total cost incurred by the industry and calculated as the unit cost of effort—r, assumed to be constant—times effort exerted by the industry—E.

Applying marginal analysis to the production function between pounds landed and effort or $Y = f(E)$, rent is maximized by employing that amount of effort such that

$$(2) \qquad f'(E) = r/P.$$

Given C and R in figure 1, rent is maximized to all vessel owners in the industry at effort level E^*. As is well established in the literature, equilibrium with open access to the fishery is at E' units of effort, which dissipates all rent.

Proportional Concept

In most marine fisheries, vessel owners incur some costs that are proportional to catch and not effort, such as crew shares (typically the crew receives a share of the catch), packing and handling, social security, and other related items. When part of total cost is proportional to catch and part is proportional to effort, the rent equation becomes

$$(3) \qquad \Pi_v = R - C_e - C_y,$$

where Π_v is rent to all vessel owners in the industry when some cost components are proportional to catch; C_e is total cost proportional to effort incurred by the industry; and C_y is total cost proportional to catch incurred by the industry.

Using this modified conceptual framework, total cost to all vessel owners is $C_p = C_e + C_y$. In this case equilibrium with open access occurs where C_p equals R at effort level E', as shown in figure 1.[2]

[2] In figure 1, C, C_p, and R are drawn to intersect at E' for convenience of illustration only. In fact, C_p may not intersect C at the same point C intersects R.

Total cost proportional to catch (C_y) includes crew shares, packing charges, and other cost items that are proportional to catch. Therefore, C_y can be disaggregated to the following:

$$(4) \qquad C_y = R_c + C^*_y = sPY + r_1Y,$$

where R_c is total revenue going to all crew members in the industry and is calculated as a fixed percentage—s—of total value product —PY; C^*_y is total cost proportional to catch, incurred by all vessel owners in the industry, other than crew shares and is calculated as the unit cost—r_1—times the pounds landed—Y.

With the costs separated into these components, the total cost (C_p) increases proportionally less than effort rather than more. If the yield function exhibits the expected diminishing returns to effort, then C_y must increase at a decreasing rate requiring C_p to do so also.

Extending the analysis to distribution of rent from the resource, E' catch in figure 1 indicates equilibrium for the open access resource and is the point where rent to the resource is zero. It is arbitrarily assumed that members receive their opportunity cost or wage at catch level E'. This is done for comparison purposes since in reality their real opportunity cost is not known. Therefore, to the left of E', in figure 1, part of the difference between C_p and C is rent accruing to crew members. To maximize rent to the fishery, rent to both vessel owners and crew members must be considered.

As the industry reduces effort below E', fewer crew members are needed in the industry. In traditional fishery economics, it is implicitly assumed that excess labor competes for limited crew member positions causing rent to crew members to be reduced and hence accrue to vessel owners. This effect is a downward shift in C_p curve of figure 1. However, if crew members, through unions or by long historical precedent, consider a fixed percentage share as the minimum they would work for as fishermen,[3] and if the time horizon to reduce effort from E' to E^* is several years, then C_p shifts little or none (Crutchfield and Zellner). For this analysis it is assumed that

[3] For example, in the last two years the Gulf shrimp industry has been caught in a severe cost-price squeeze. Attempts have been made to reduce the share agreement by having crew members share in the fuel cost. Even with some vessels remaining in port because they cannot meet variable cost, vessel owners have not been able to change the share agreement.

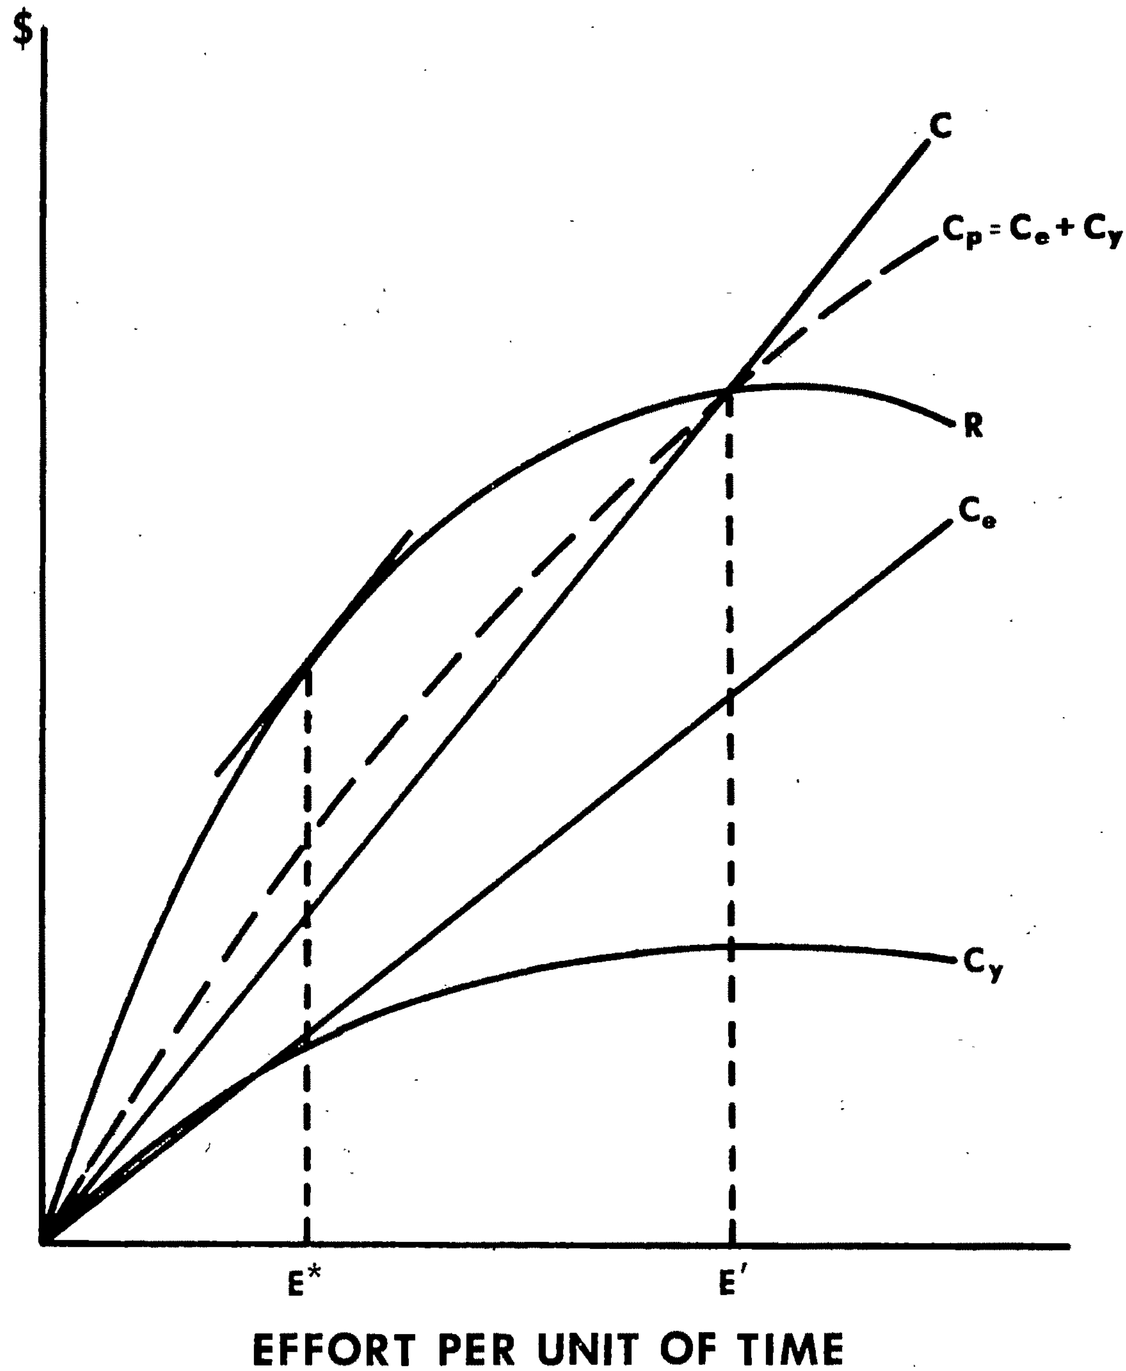

Figure 1. Hypothetical revenue curve (R) and cost curves when all cost items are proportional to effort (C) and when part of the cost items are proportional to effort (C_e) and part are proportional to catch (C_y)

crew share (as a percentage of catch) is fixed over time.

At equilibrium under open access fisheries (E'), the total revenue allocated to crew members (R_c) is equal to their opportunity cost (wage) plus production costs that are proportional to catch that crew members pay out of their share of catch, e.g., the crew may incur the cost of packing and handling of their share of the catch. However, as effort is reduced to

the left of E', it is expected that the number of crewmen is reduced proportionally to effort, while catch is reduced less than proportional to effort. This suggests crew members receive income above their opportunity cost and their part of production cost. This additional income to remaining crew members is rent from the resource. Thus, shares paid to crew members can be further disaggregated as follows:

$$(5)\ R_c = C_o + C_c + \Pi_c = r_2E + r_3sY + \Pi_c,$$

where C_o is opportunity cost of all crew members in the fishery and is calculated as the opportunity cost of the individual crew member association with each unit of effort—r_2—times total effort—E; C_c is production cost incurred by crew members that is proportional to catch and is calculated as the unit cost—r_3—times their share of catch—sY;[4] Π_c is rent accruing to crew members in the industry.

This provides the basic relationships needed to develop a model for estimating that level of effort that maximizes rent to the resource. To simplify to a single rent equation, equation (5) is substituted into equation (4) and then equation (4) into equation (3) to give the following relationship:

$$(6)\ \Pi_v + \Pi_c = R - C_e - C_o - C_c - C^*_v.$$

Since the objective is to estimate an optimum level of effort, it is necessary to express the right-hand side of equation (6) in terms of effort and catch. This gives

$$(7)\ \Pi_v + \Pi_c = PY - r_4E - r_2E - r_3sY - r_1Y,$$

where $C_e = r_4E$. Finally substituting the yield equation into equation (7), rent is maximized to the fishery by employing that amount of effort such that

$$(8)\qquad f'(E) = \frac{r_4 + r_2}{P - (r_3s - r_1)}.$$

This may be at an effort level less than, equal to, or greater than the effort level that maximizes rent to the resource using traditional analysis.[5]

[4] A more general model is one where crew members incur costs that are proportional to catch and effort; that is, instead of receiving a share of gross revenue, they receive a share of income above variable cost.

[5] Comparing equations (2) and (8), $r/P \gtreqless (r_4 + r_2)/(P - (r_3s - r_1))$ since $r_1 \gtreqless 0$, $r_2 > 0$, $r_3 > 0$, $r_4 > 0$, and $s > 0$. So $P > r_3s - r_1$, and $r = r_4 + sP\ Y_o/E_o + r_1\ Y_o/E_o$ and $r_2 \geq sP\ Y_o/E_o$ implies that $r > r_4 + r_2$, where E_o is actual effort exerted by the industry in a given year under open access, and Y_o is estimated catch based on the yield function associated with E_o. It can also be shown that rent is not necessarily maximized to vessel owners or crew members at the same effort level that maximizes rent for the resource.

Empirical Results

The methodology developed above was applied to the Gulf of Mexico shrimp industry. Optimum effort, catch, and rent are compared under traditional theory and under the proportional method as developed above.

The Yield Function

The topic of population dynamics is well documented in the literature cited earlier. However, the expected shape of the yield function needs to be discussed as it relates to this analysis. In most fisheries, the yield function is affected by both stock and crowding externalities. While the Gulf of Mexico shrimp fishery does experience crowding externalities, it does not experience the stock externalities since shrimp is an annual crop; that is, shrimp spawn offshore and the tide moves the larvae inshore to the estuaries. They grow into young shrimp and then move offshore to grow to maturity. Since laws protect the estuaries while the shrimp are young and since there is adequate natural protection offshore, fishing effort does not affect the recruitment stock relationship. Thus, assuming a constant population from year to year, as effort is increased, catch approaches some annual maximum yield (Schaefer).

However, the natural environment in the estuaries has a significant effect on annual shrimp production. Barrett and Gillespie have shown that temperature and salinities of bays and estuaries are important factors affecting the production of shrimp. High river discharge during the period that shrimp are in their nursery grounds reduces the temperature and salinity, causing population and, in turn, catch to be reduced. Therefore, the Mississippi River discharge (D), during the months that shrimp are in their nursery grounds, is included in the analysis.

With the existence of these conditions, the following yield relationship is used:

$$(11)\qquad Y = b_0D^{b_2}[1.0 - (b_1)^E],$$

where $b_0D^{b_2}$ is the maximum yield the function approaches for a given level of river discharge—D—(U.S. Army Corps of Engineers), and b_1 indicates the ratio by which marginal products of E decline. This Spillman-type function seems to be ideally suited to the physical relationship exemplified by Gulf shrimp fisheries (Heady and Dillon).

The catch-effort data used to estimate this relationship were developed from individual vessel records collected by the National Marine Fisheries Service for the period 1962–74 (U.S. Dep. of Commerce, 1962–74). Catch is total pounds (heads off) landed by all vessels in the Gulf of Mexico, and total effort is measured by days fished standardized by the relative fishing power of the individual vessels.[6]

Equation (11) was estimated using regression analysis and time-series data for the period 1962–74 as follows:[7]

$$(12) \quad Y = 3365D^{-0.5064}[1.0 - 0.994746^{E}],$$

where Y is in million pounds and E is in thousand units.[8]

Using average daily river discharge of 696 cubic feet per second, the maximum yield for vessels in the shrimp fishery is estimated to be 122.3 million pounds annually. Generally, effort has increased 50% (200,000 to 300,000 units) over the period 1962–74. Expected catch has increased 22% (79.7 million to 97.1 million pounds). The elasticity of production at 200,000 units of effort is 0.63% and at 300,000 units of effort is 0.40%. This implies that vessel owners are harvesting 37% less shrimp for each unit of effort exerted in the early 1970s than they were in the early 1960s. Furthermore, the production function suggests that if the vessel fleet were doubled so that it could exert 600,000 units of effort per year, expected catch would increase to only 117 million pounds or 20%.

Cost of Production

Cost data used in this study were collected for 115 vessels by personal interview of vessel owners and/or managers operating out of ports in Florida, Mississippi, and Texas for the calendar year 1973 (Wardlaw and Griffin). Costs proportional to catch are crew shares, payroll taxes, and packing charges.[9] Cost items proportional to effort are separated into the following categories: ice; fuel; nets, supplies, and groceries; repair and maintenance; insurance; depreciation; and opportunity costs on the vessel owner's capital investment.[10]

Since the Gulf shrimp fleet is comprised of a wide range in vessel size, construction, power, and capability, and there is a wide range of costs associated with the various vessel configurations, vessels are divided into nine different classifications based on construction, keel length, and effort index (table 1).

Total Cost for the Industry

Total cost proportional to effort (C_e) expended by all vessels in the Gulf is calculated from table 1 as follows:

$$(13) \qquad C_e = \sum_{i=1}^{n} N_i(C_{ei}),$$

where N_i is the number of vessels in class i operating in the Gulf in 1973 and C_{ei} is the total cost proportional to effort in class i.[11] In 1973 C_e was estimated to be \$122,383,000. Also, total effort exerted by all vessels in the Gulf in 1973 was estimated to be 304,431 units.[12] Therefore, from equation (8), r_4 = \$402,006 per thousand units of effort exerted in the Gulf in 1973.

Total costs proportional to catch incurred by all vessel owners in the industry, other than

---

[6] Effort (E) was calculated in the Gulf of Mexico shrimp fishery as

$$E = \sum_{i=1}^{N} (EI_i)(DF_i),$$

where DF_i is the total days fished of vessel i, and EI_i is the effort index of vessel i (or relative fishing power) and is defined as the ratio of the catch per unit of fishing time of a vessel to that of a standard vessel, fishing on the same density of fish on the same type of ground. The value for the effort index for each vessel was calculated as $EI_i = [(HP)_i^{0.1384}\ (LFR)_i^{0.4064}]/[(38)^{0.1383}\ (14.6)^{0.4064}]$, where HP is the horsepower of vessel i, and LFR is the sum of the lengths of the footrope measured in yards for vessel i. The smallest class of vessels operating in the Gulf from 1962–71 was used as a standard with average horsepower of 38 and average net size measured in yards of footrope was 14.6 yards (Griffin, Cross, and Nichols).

[7] Because of the regression technique used, the actual equation estimated was $Y = b_0D^{b_2}[1.0 - b_1^{E}]^{a}$. Theoretically, $a = 1$; therefore, b_1 was solved for through an iterative procedure such that a approaches one.

[8] The student t-value for the regression coefficients b_0 and b_2 are 2.48 and −3.90, respectively; R^2 = 0.66 and the Durbin-Watson coefficient was 2.22.

[9] Share agreements are based on 35% of gross revenue, payroll tax rate is 7%, and packing is \$0.08 per pound for owner share of catch.

[10] Depreciation is calculated using the declining balance method used by the U.S. Department of Agriculture, and opportunity cost is calculated using a 9% interest rate.

[11] Latest data available on vessel characteristics are for 1971 (U.S. Dep. of Commerce 1971). These also are used to establish the distribution of vessel by class. Vessel cost data are available for 1973; hence, it is assumed that the relative number of vessels in each class did not change from 1971 to 1973.

[12] Effort is calculated by multiplying the index of effort of each individual vessel by days fished for that vessel in each class and then aggregating all vessels.

Table 1. Gulf Shrimp Vessel Costs by Class, 1973

Class No.[a]	Construction	Keel Length (Feet)	Effort Index (Units)	Number of Vessels in Each Class[b]	Cost Proportional to Effort per Vessel—Ce_i ($)[c]
1	Wood	45–62[d]	1.64–1.89	1,648	23,987

[a] See footnote 11 in text.
[b] This is the total number of vessels in the Gulf shrimp fleet in 1973.
[c] Costs are based on a sample of 115 Gulf shrimp vessels.
[d] Keel length of 45 feet was the smallest vessel in the sample of 115 from which cost data were obtained. Actually two-thirds of the 1,648 vessels in this class were less than 45 feet in keel length causing $23,987 to be an upward bias for this class.[j]

crew shares, include packing and handling charges and payroll taxes on crew shares and are calculated as

$$C^*_y = k(1 - s)Y + tsPY = [k(1 - s) + tsP]Y = r_1 Y, \tag{14}$$

where s is the share received by the crew, t is the payroll tax, and k is the average packing charge in pounds landed. For the Gulf shrimp fishery, $s = 0.35$, $t = 0.07$, and $k = \$80{,}000$ per million pounds landed; therefore, $r_1 = \$52{,}000 + 0.0245P$ (where P is now in price per million pounds).

In the earlier theoretical section it was assumed that crew members received their opportunity cost at equilibrium under open access E' in figure 1. Although this analysis is based on 1973 data when the industry may not have been in equilibrium, crew members' opportunity cost is arbitrarily assumed to be equal to their 1973 expected share minus their costs that are proportional to catch. Opportunity costs of all crew members in the fishery are calculated as

$$C_o = \left[sP\frac{Y_o}{E_o} - ks\frac{Y_o}{E_o}\right]E = r_2 E, \tag{15}$$

where $E_o = 304{,}431$ units and is the total effort exerted by all shrimp vessels in the Gulf in 1973 and $Y_o = 97.7$ million pounds and is the estimated production using the yield function in equation (12). Thus, $r_2 = 0.1123P - 8{,}986$.

Costs proportional to catch that are incurred by crew members include packing and handling charges paid on their share of revenue above their opportunity cost and are calculated as

$$C_c = ksY = r_3 sY. \tag{16}$$

Thus, $r_3 = \$80{,}000$.

Rent equation (8), which allows part of the cost to be proportional to catch and assumes that crew shares are a fixed percentage of gross revenue, can now be written as

$$\Pi_v + \Pi_c = PY - 402{,}006E - (-0.1123P - 8986)E - 28{,}000Y - (52{,}000 + 0.0245P)Y = (0.9755P - 80{,}000)Y + (-0.1123P - 393{,}038)E. \tag{17}$$

With estimates of r_1, r_2, r_3, and r_4, the value of the unit cost of effort (r) is determined from equations (4) and (5) by applying the traditional method in equation (2) as

$$rE_o = r_4 E_o + sPY_o + r_1 Y_o. \tag{18}$$

Solving for r and substituting in known values, $r = 418{,}694 + 0.1202P$. The traditional rent equation (2) can be written as $\Pi_t = PY - (418{,}694 + 0.1202P)E$.

Equilibrium in the Fishery

Using the traditional methodology and the technique that allows some cost components to be proportional to catch, table 2 shows the economic optimum effort level in the Gulf shrimp fishery with associated catch, number of vessels, maximum rent, equilibrium effort

Table 2. Effort, Catch, Vessels, and Rent(s), Gulf of Mexico, 1973.

employed, and number of vessels assuming open access at three different price levels. The average exvessel price for shrimp received by vessel owners in 1973 was approximately $1.70 per pound.

Under open access, the estimated equilibrium amount of effort that vessel owners expend annually in harvesting shrimp from the Gulf of Mexico is 239,000 units using the traditional method and 201,000 units using the proportional method (table 2). Using the proportional method, equilibrium under open access is the same point where $R = C_p$ (or vessel owner's rent is zero) in figure 1. However, opportunity cost to crew members was calculated at the level of effort exerted in 1973 (304,431 units). Therefore, since equilibrium under open access using the proportional method is less than 304,431 units of effort, rents accrue to crew members in the amount of $8.7 million (table 2). Rent to crew members would be negative for the other case.

Equilibrium values for both the traditional and proportional method under open access are below the amount of effort actually expended in 1973 (304,431 units). One reason for this is the dramatic increase in the price of fuel and related products in the last quarter of 1973, which increased the cost of harvesting shrimp. Another reason is all vessels that landed shrimp in the Gulf in 1973 were assumed to be full-time shrimp vessels. Some vessels may have fished only part of the year because they were bought or sold some time during the year, or they may have been used in other fisheries part of the year.

Economic Optimum

With the continuing interest in maximizing rent to open access resources, these results are important, particularly with respect to distribution of rent between vessel owners and crew. Serious implications evolve relative to an appropriate policy for maximizing rent to the resource that is not included in previous analysis. The optimum effort that maximizes rent to the fishery is 107,100 units using the traditional method and 105,300 units using the proportional cost method.[13] Associated with the estimated optimum effort based on traditional theory are 1,213 vessels, assuming the same distribution among vessel classes, harvesting shrimp worth $22.9 million in rent to the resource. Using the proportional method, 1,192 vessels harvest shrimp returning a rent of $21.6 million of which $10.3 million accrues to the vessel owners and $11.3 million accrues to the crew members. Hence, the traditional method overestimates the optimum units of effort by only 1800 units (1.7%) but overestimates the rent accruing to the vessel owner by $12.6 million (122%). It is this discrepancy inherent in traditional analysis that is of special concern.

This distribution aspect of rent to vessel owners and crew members has important implications for fishery management schemes. If, for example, a government imposes a limited entry scheme taxing (through license or other means) vessel owners remaining in the industry at an amount equal to $22.9 million, vessel owners are overtaxed by $12.6 million. The actual tax rate should be $21.6 million and should be shared by vessel owners and crew members. Vessel owners in the shrimp industry should pay a total tax of $10.3 million, where crew members should pay a tax of $11.3 million. This is a tax on owners of $8,641 per vessel and $9,480 tax per crew.

This provides implications based on 1973.

[13] This optimum level of effort is beyond the range of the data used to estimate the yield function.

However, the analysis is sensitive to product price and fishing costs. Considering just price changes, they have a definite impact on the distribution of rent to vessel owners and crew members (holding unit cost constant). When prices increase from $1.70 to $2.00 per pound of shrimp landed, total rent to the resource increases to $34.3 million. Of this, vessel owners receive $20.5 million, which is a 100% increase in their total rent. However, since more vessels are employed, rent on a per vessel basis increases from $8,641 to $14,256 or an increase of 65%. Crew members receive $13.8 million, a 22% increase, while rent per crew increases only 1% from $9,480 to $9,564.

When prices decrease from $1.70 to $1.40 per pound of shrimp landed, as they did from 1973 to 1974, total rent decreases to $10.8 million to the resource. Of this, vessel owners receive only $2.6 million, which is a 75% decrease. This dropped 65% per vessel from $8,641 to $2,958. Crew members received $8.2 million, which is a 27% decrease. Per crew, there was only a slight decrease of less than 2% from $9,480 to $9,330.

Conclusions

This study emphasizes the distortions that exist in applying traditional methods to estimate fishing effort that maximizes rent to an open access resource when some of the costs are proportional to catch. This distortion, if used in developing fishing management schemes, could result in significantly misplaced controls, i.e., an overtaxing of vessels and ignoring rent accruing to crew members. The effect could result in a fishery being grossly mishandled and misused.

Application of the model developed shows that management schemes must be dynamic if they are going to be effective, since optimum effort rent to the resource is very sensitive to price changes. This means rent to vessel owners on a per vessel basis is very sensitive to product price changes. However, when crews receive a fixed share of gross revenue and do not share in the other cost proportional to effort, rent per crew member is affected only slightly at optimum effort due to price change. If crew members share in some of the cost proportional to effort, their rent per crew member is more sensitive.

A Spatial Equilibrium Analysis of Electrical Energy Pricing and Allocation

Noel D. Uri

Based upon a spatial equilibrium model, this study argues that society can gain with increased regional coordination of generation and transmission activities of the U.S. electrical energy industry. In 1973 society suffered a loss in welfare because of minimal regional coordination, reflecting that consumers in regions where relatively inexpensive electrical energy was available were permitted to consume more and pay less than what would have been optimal at the expense of consumers in less efficient producing regions. The policy implications suggest that regional coordination be more actively pursued, involving the use of legislated authority by the Federal Power Commission.

Key words: electrical energy, spatial equilibrium analysis, United States.

Historically, decisions on the pricing and allocation of electrical energy have been made according to legal and administrative criteria. When electrical energy was plentiful (in relation to price), few questions were raised concerning efficiency in the electrical energy industry. Recent years, however, have witnessed a growing realization of the need for improvements in the operational efficiency of the industry. This has challenged economists to investigate and develop methodologies that would allow normative recommendations to be made about pricing and allocation.

The purpose of this article is to demonstrate that the interregional equilibrium model developed by Samuelson and by Takayama and Judge (1964) may be adapted to determine the efficient pricing and allocation of electrical energy in the United States. In the present instance, it is assumed that the authority responsible for the pricing and allocation decisions does not act as a profit-maximizing monopolist but rather seeks a policy that will ensure that social welfare in relation to the available electrical energy is maximized.

The basis for this assumption is well grounded. The Federal Power Act of 1935 directed the Federal Power Commission to promote and encourage "the voluntary interconnection and coordination of facilities for generation, transmission and sale of electric energy" in order to "assure supply of electrical energy throughout the United States with the greatest possible economy with regard to proper utilization and conservation of natural resources" (Federal Power Commission 1970, pp. 33–34).

That this regional coordination is technically feasible has been adequately documented (National Electric Reliability Council 1975b). That it is economically attractive is also true. Among the economic arguments put forward to support regional coordination is that such coordination allows joint planning and operation of facilities, makes the exchange of economy energy easier,[1] prevents construction of unnecessary facilities by isolated systems, and increases reliability. More specifically, as a result of transmission interties, coordination offers distinct economies to participating systems. Because of time-of-day diversities (and the noncoincidental occurrence of the peaks of participating systems), it might be possible to reduce the total generating

---

The author would like to thank T. Takayama and the referees and associate editor of the *Journal* for helpful comments.

[1] Economy energy is defined as energy produced and supplied from a more economical source in one system, substituted for that being produced or capable of being produced by a less economical source in another system.

capacity requirements that otherwise would apply were each system charged with fully meeting its needs. By combining the existing capacity of many utilities, it is possible to reduce the needed reserve capacity.

Unfortunately, this coordination is still seriously inadequate (Breyer and MacAvoy). Why are not coordination arrangements actively pursued? There seems to be no straightforward answer. One of the problems seems to be that of dividing the potential gains from coordination among partially regulated companies. Another is that competition and regulation have combined to dampen the firms' desire to achieve coordination economies. The fact that a pool's method for apportioning operating costs is not likely to maximize incentive for its members to operate the whole system most efficiently presents another problem. Finally, if utilities coordinate their plans on a regional level, some generating plants might conceivably be constructed in areas that do not need electrical energy but are relatively inexpensive sites for large generating plants. The residents of areas subject to this risk justifiably may not want to have plants built to supply consumers in other areas.

No objective model can provide solutions to some of these problems. Conflicts among competing consumers and producers inevitably continue, and politics, rather than economics, is the final arbiter in the solution. The areas of conflict may be narrowed, however, and better choices may result if clear statements about equilibrium prices and the resulting allocation of electrical energy among competing consumers are available. This is the objective here.

Framework of Analysis

A spatial equilibrium model of production, consumption, prices, and transmission is constructed to represent the market for electrical energy in the United States. The basic model is that developed by Samuelson in 1952 and generalized by Takayama and Judge in 1964 and by Takayama and Woodland in 1970. The general model is adapted to accommodate the peculiarities of the market for electrical energy.

The objective of the study is to determine the optimal allocation and pricing of electrical energy for a given period for the contiguous United States. Consequently, the demand and supply equations and transmission costs are estimated and then used to determine the most efficient allocation for an arbitrarily (though not capriciously) chosen year—1973. The model is not cast in a general equilibrium framework. Other markets are considered to be outside of the investigation. Therefore, when discussing optimality it is in a partial equilibrium setting with the resultant qualifications necessary for the meaning of optimality.

The determination of the optimal allocation and pricing is accomplished by maximizing the net social payoff of the United States.[2] Before specifying the model, it is convenient to introduce the needed definitions and notation. Let $i, j = 1, 2, \ldots, R$ denote the regions, $\theta = 1, 2, \ldots, P$ denote the plant type for generating electrical energy (e.g., hydroelectric, nuclear), y_i is the quantity of electrical energy demanded by consumers in region i, x_{ij} is the quantity of electrical energy transmitted and distributed from region i to region j, x_i^θ is the net quantity of electrical energy generated in region i by plant type θ, K_i^θ is the generating capacity of plant type θ in region i, and t_{ij} is the unit cost of transmitting and distributing electrical energy from region i to region j.

Assuming that demand functions in each region are known with certainty or are available in the certainty equivalence sense, the demand functions are given as

$$(1) \qquad p_i = f_i(y_i),$$

where p_i is the price of electrical energy to all consumers in region i. A single demand function is used aggregated across all consumers in a region. The implications of this assumption are discussed by Mohring.[3]

Similarly, assume the cost functions are known with certainty or are available in the certainty sense. The marginal operation and

[2] Net social payoff in terms of the underlying demand and supply relations for all regions is defined as follows: the sum of the areas under the demand functions minus the sum of the areas under the supply functions at posttrade equilibrium prices, the sum of the areas under the supply functions at pretrade prices, and the total transmission and distribution costs incurred. Because the sum of the areas under the demand functions minus the sum of the areas under the supply functions at pretrade prices is constant, the sum may be omitted from the definition without altering the posttrade prices and allocation.

[3] Mohring argues that for the demand price of a commodity to depend only on its output level requires that a utility function u (perhaps after suitable transformation) can be written in the form $u = y_1 + \sum_{j=2}^{n} f^j(y_j)$, where f^j denotes the inverse demand function for commodity j and the y_j's are the units of the n commodities (p. 694).

maintenance cost functions (including fuel cost) are given by

(2) $$\Omega_i^\theta = \omega_i^\theta (x_i^\theta),$$

where Ω_i^θ is the marginal cost of generation per kilowatt-hour on plant type θ in region i. Marginal cost functions per unit capacity (capital cost) are given by

(3) $$\Gamma_i^\theta = \gamma_i^\theta (x_i^\theta),$$

where Γ_i^θ is the marginal capital cost per kilowatt-hour generated on plant type θ in region i.

The search for optimum demands, prices, and operating schedules is subject to a number of constraints. For a given region the quantity of electrical energy demanded must be less than or equal to the quantity supplied by that region plus the quantity transmitted from other regions:

(4) $$y_i \leq \sum_j x_{ji}.$$

For each region the total net transmission and distribution of electrical energy is less than or equal to the net generation from all plant types within that region:

(5) $$\sum_j x_{ij} \leq \sum_\theta x_i^\theta.$$

Transmission of electrical energy between regions is less than or equal to the maximum capacity of transmission lines available:

(6) $$x_{ij} \leq x^*_{ij},$$

where x^*_{ij} is the maximum technologically feasible interregional transmission. For each plant type in a region, net generation is less than or equal to the net generating capacity available for that plant type:

(7) $$x_i^\theta \leq K_i^\theta.$$

Pricing and Allocation Model of Electrical Energy

Before delineating the spatial equilibrium model, observe that in the formulation to follow it is desired to maximize the United States' welfare as a whole. Consequently, unrestricted transmission is optimal in the sense that it leads to the nation's welfare frontier conditional upon other factors being in equilibrium.

Using the notation and constraints as defined, the Hotelling type of net social welfare function that forms the objective function of the problem may be characterized as

(8) $$NSP = \sum_i \int f_i(y_i)\, dy_i - \sum_i \sum_\theta \int \omega_i^\theta (x_i^\theta)\, dx_i^\theta - \sum_i \sum_\theta \int \gamma_i^\theta (x_i^\theta)\, dx_i^\theta - \sum_i \sum_j t_{ij} x_{ij},$$

where NSP nominally refers to net social payoff.

Assuming the objective function is concave, the Kuhn-Tucker conditions give the necessary and sufficient conditions for the competitive solution (Takayama and Judge 1971). Associate the dual variables, ρ_{1i}, ρ_{2i}, ρ_{3ij}, and ρ_{4i}, with constraints (4) through (7), respectively.

The variable ρ_{4i} can be interpreted as the quasi-rent of plant type θ in region i and, if that plant type is utilized, is equal to the supply price ρ_{2i} minus the marginal operation and maintenance (here after operating) cost plus capital cost. Both operating cost and capital cost are used to determine the supply price. Unlike a peak-load pricing approach (Turvey), a utility is allowed to recover part of its capital cost (as well as a specified rate of return) on each kilowatt-hour of electrical energy generated (Jurewitz).

The Kuhn-Tucker conditions guarantee that to minimize total cost production will be scheduled on plant types in increasing order of supply and delivery costs. Therefore, the demand price to a consumer in a region equals the transmission and distribution costs plus the operating and capital costs on the least efficient plant type being used to generate electrical energy.

The quasi-rent of any plant type regardless of region in use is equal to the difference between its operating cost plus capital cost, distribution cost, and transmission cost and these costs accounted for by the least efficient plant type in all regions. Given this condition, it is possible to use a plant type to generate electrical energy that does not have the lowest combined operating and capital cost. If the transmission cost, say, is sufficiently large, then it might be optimal to use a plant with a higher operating or capital cost component while shutting down a plant type that is more efficient.

The model in the present formulation can answer the pricing and allocation questions that have tended to mitigate the desire for regional coordination among electric utilities. Specifically, the model indicates such things as how to apportion operating costs (by the

Table 1. Regional Classification

Region	State Composition
New England (NE)	Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut
Middle Atlantic (MA)	New York, New Jersey, Pennsylvania
East North Central (ENC)	Ohio, Indiana, Illinois, Michigan, Wisconsin

Mountain (M)	Montana, Idaho, Wyoming, Colorado, New Mexico, Arizona, Utah, Nevada
Pacific (P)	Washington, Oregon, California

region in which they occur). It cannot, and no model can, solve the problems concerning the institutional aspects that create the lack of desire for coordination. What this model can show is, by expanding the area of concern to encompass the country, the extent to which all of society will be better off even though some regions may be worse off.

The Setting

Before turning to the 1973 empirical implementation of the model, the various regions and plant types considered are discussed and the demand and supply estimates are presented. The regional classification used is the Bureau of the Census's nine-region division of the contiguous United States and can be found in table 1.

On the supply side, three alternative plant types for generating electrical energy are considered. They consist of hydroelectric plants, fossil-fueled steam electric plants (coal, oil, and natural gas), and nuclear steam plants. Internal combustion, a fourth method of generating electrical energy, is not considered. It accounted for only 0.33% of net generation in 1973.

Demand and Supply Estimates

Following Takayama and Judge (1964), it is assumed here that the demand and supply functions are known linear price-dependent relations. This reduces the general objective function (6) to a quadratic function, and hence one is confronted with a quadratic programming problem. This is done because of the availability of computer programs to handle very large quadratic programs. Some loss is incurred in making the linearity assumptions, as they are probably relevant in the short run but certainly not in the long run. Consequently, the analysis is confined to the short run exclusively.

Various econometric problems arise in estimating the demand curves for electrical energy (Uri 1975). Therefore, the linear demand curves are obtained first by estimating the price elasticity and then by converting these elasticities into point estimates of the aggregate demand functions. To estimate the demand elasticity for each region, a variable elasticity model analogous to the one used by Mount, Chapman, and Tyrrell is specified. Specifically, the quantity of electrical energy consumed in a region in a given year is assumed to be a function of the quantity of electrical energy consumed in the previous year, the average price of electrical energy for that year, per capita personal income for that year, and the average price of natural gas in the previous year. Upon pooling cross section and time series across all regions for the time period 1946–73, the price elasticities are estimated. Regionally, they range between −0.123 and −0.197 in the short run, which is within the range of the short-run elasticities obtained by Mount, Chapman, and Tyrrell as well as the values obtained by others (see Taylor).[4]

Other types of problems arise when trying to estimate the marginal operating and marginal capital cost. One such problem is that capital cost falls as capacity increases. This prob-

[4] Mount, Chapman, and Tyrrell get short-run elasticity estimates of about −0.14 for the residential sector, −0.20 for the commercial sector, and −0.20 for the industrial sector.

lem is suppressed by limiting the analysis to the short run. With the focus on the short run, and because of data problems, the assumption that marginal and average costs are equal is made.

Thus, average annual production expenses for the various plant types in the various regions are assumed to equal marginal operating costs. These production expenses are estimated for 1973 for a representative selection of plants in each region from the Forms Number 1 and 1-M filed by each utility with the Federal Power Commission.

Marginal capital costs are assumed to equal average capital costs. The average capital costs are estimated for a selection of plants in each region from Form 1159 filed by each utility with the Federal Power Commission. Given the kilowatt estimate, kilowatt-hour cost is calculated based on the service life of a particular plant type, the total net generation expected each year, the rate of equipment depreciation, and the annual rate of fixed charges that includes the cost of money, interim replacements, insurance and taxes, and a rate of return on investment.

Transmission cost is computed from average cost curve data found in the *1970 National Power Survey* by assuming a functional form of

$$T_{ij}/x_{ij} = a + b/x_{ij} + \epsilon_{ij}, \tag{9}$$

where a and b are coefficients, T_{ij} is the cost of transmitting a kilowatt-hour of electrical energy one mile, x_{ij} is as defined above, and ϵ_{ij} is the error term (Federal Power Commission 1971). The marginal cost of transmission (a) is estimated to be 0.00478 mills per mile.[5] A more complete description of the estimation process is contained in Uri (1976). Based on informal conversations with members of the electric utility industry, this figure is a realistic estimate of marginal transmission cost.

Nine demand points are used in the model for the purpose of measuring the distance between region i and region j. The resulting distance times the marginal cost of transmission will give the cost of transmitting one kilowatt-hour between region i and region j. The demand areas are large and it is difficult to select a single location as representative of an entire region. The method used to pick a representative location is to weigh each set of coordinates in a region by the consumption of electrical energy at that location, the average distance traveled by each kilowatt-hour through a region, and the maximum distance that electrical energy would have to travel.

Estimates of the maximum capacity of transmission lines between regions are obtained from the National Electric Reliability Council (NERC) (1975b). The NERC analysis included consideration of the effects of technical factors that are important. Such things as scheduled and nonscheduled maintenance, noncoincidence of peak load, the necessity of operating generating equipment for area protection and voltage control, and so on were included in the analysis.

Distribution cost is obtained from the *1970 National Power Survey* (inflated to account for price increases) and represents an average for all electric utilities in the contiguous United States. No attempt has been made to break the cost down by region, type of ownership, or other system of classification. Given the relatively low level of spatial resolution, regional averages closely approximate the national average and hence this value can be used without severe reservations. The figure used is 6.05 mills per kilowatt-hour.

Finally, the net generating capacity used reflects the actual net generation and hence consumption in 1973. It is obtained from the Edison Electric Institute.

As a final comment before turning to a solution for the model, all of the values of the primal variables in the problem are in net terms. Thus, for example, the quantity of electrical energy transmitted is in net terms and hence implicitly assumes that the same transmission loss is incurred for electrical energy transmitted interregionally as is transmitted intraregionally.

Empirical Results

In the current investigation, a policy is sought that will insure that net social payoff (social welfare) is maximized relative to the available supply of electrical energy. Economic theory indicates that such a situation is approached when a competitive market prevails. Under this condition, the market price of electrical energy should equal the marginal cost of supplying electrical energy to the market, which in turn is equal to the value in use of the last

[5] The marginal cost of transmitting a kilowatt-hour of electrical energy is

$$\frac{\partial T_{ij}}{\partial x_{ij}} = a.$$

Table 2. Optimal Flows of Electrical Energy Generated in 1973 by Region (Billion Kilowatt-Hours)

[a] The regional abbreviations denote the New England region, the Middle Atlantic region, and so on from table 1.

kilowatt-hour purchased by the consumer. This is exactly what the Kuhn-Tucker conditions for optimality guarantee.

Assuming that a competitive market prevails across plant types and regions, a solution to the spatial equilibrium model can be found. The optimal values are presented in tables 2 through 5. Not all of the values are presented. Specifically, supply prices are simply demand prices less distribution and transmission costs. In none of the cases where it is optimal to transmit electrical energy interregionally were the transmission constraints reached.

The solution gives overwhelming support to the argument that regional coordination of the generating activities of utilities results in significant interregional transfers of electrical energy with the bulk of the transmission activity taking place to the Middle Atlantic region from surrounding regions. This results because of the relatively older and consequently less efficient fossil fuel plants as well as, and most importantly, because of the high proportion of oil-fired plants that proved to be quite expensive to operate in 1973. In the short run it would have been optimal from the perspective of the whole society to let consumers in other regions bear some of the burden (through higher prices for electrical energy) of the high cost of electrical energy in the Middle Atlantic region. In the long run, it might be optimal to build new generating capacity. (The answer to such a question is outside the scope of the present study.)

A comparison of the competitive alternative with existing market behavior is apparent from table 4. The optimal prices differ by no more than transmission costs between regions where electrical energy interchange takes place. Predictably, the price to the consumer in the more efficient regions rises and in the less efficient regions falls.

The value of a particular plant type, measured by its quasi-rent, is presented in table 5. Hydroelectric plants are of greatest value to society with nuclear plants second in most regions. This suggests that if additional output could be obtained from existing plants by increasing the utilization factor through increased regional coordination, the gains to society in the aggregate would be even greater than those indicated here.[6] In this vein, the quasi-rents provide information about the types of plants on which it is most efficient to increase generation. By increasing the net generation by one kilowatt-hour on a fossil-fueled plant located in the South Atlantic region and transmitting it to the Middle Atlantic region and correspondingly decreasing the generation on a fossil-fueled plant in the Middle Atlantic region so that net additions to

[6] The utilization factor is the ratio of the actual output of a system to the maximum possible output. For the United States as a whole this is about 52%.

Table 3. Optimal Net Generation in 1973 (Billion Kilowatt-Hours)

Region	Hydroelectric Plants	Fossil Plants	Nuclear Plants
New England	4.93	50.19	13.24
	(4.93)	(50.19)	(13.24)
Middle Atlantic	27.81	66.36	10.29
	(27.81)	(185.21)	(10.29)
East North Central	3.55	301.67	26.56
	(3.55)	(301.67)	(26.56)
West North Central	11.36	77.56	3.56
	(11.36)	(93.99)	(3.56)
South Atlantic	17.79	272.00	16.31
	(17.79)	(260.00)	(16.31)
East South Central	24.92	143.72	0.25
	(24.92)	(143.72)	(0.25)
West South Central	9.02	186.60	0
	(9.02)	(186.60)	(0)
Mountain	25.74	51.44	0
	(25.74)	(51.44)	(0)
Pacific	124.25	91.79	6.51
	(124.25)	(91.79)	(6.51)

Note: Values when transmission is restricted are in parentheses. Actual net generation figures for 1973 are the same as the values when transmission was restricted with the exception that about 12 gigawatt-hours were generated in the South Atlantic region and transmitted to the Middle Atlantic region and about 8 gigawatt-hours were generated in the Mountain region and transmitted to the Pacific region in 1973. This additional generation occurred in all probability on fossil plants.

generation are zero, societal welfare would expand by 3.98 mills.

The implications of this are clear. Taking advantage of the noncoincidental occurrence of the peak demands of different utility systems across regions so that the more efficient plants are used to the exclusion of the less efficient plants is consistent with the social welfare maximization objective.

The optimal levels of generation are slightly different from actual levels on fossil plants in the Middle Atlantic and West North Central

Table 4. Price by Region for 1973 in Mills per Kilowatt-Hour

Region	Actual Price[a]	Optimal Price
New England	24.29	24.29
Middle Atlantic	25.10	23.94
East North Central	19.17	19.92
West North Central	21.01	20.15
South Atlantic	18.54	19.82
East South Central	12.55	19.27
West South Central	15.75	16.27
Mountain	16.96	17.25
Pacific	14.90	14.94

[a] Weighted average price by consumers according to the quantity of electrical energy demanded in 1973.

Table 5. Quasi-Rent of a Plant Type in Mills per Kilowatt-Hour in 1973

Region	Hydroelectric Plants	Fossil Plants	Nuclear Plants
New England	10.50	1.60	8.39
Middle Atlantic	11.98	0	6.79
East North Central	8.42	2.12	7.17
West North Central	5.50	3.08	4.85
South Atlantic	8.00	3.98	6.85
East South Central	8.69	5.41	5.76
West South Central	1.37	0.57	4.80
Mountain	2.62	0	4.82
Pacific	5.09	1.35	2.11

regions in 1973, arising due to higher operating costs of these plant types relative to costs in other regions from which electrical energy is transmitted. This change in the optimal level of generation in conjunction with the quasi-rents has significant implications since a great deal of public reaction to generating capacity additions results from the type of plant. By adding a nuclear plant comparable in cost respects to existing nuclear plants in, say, the West North Central region while at the same time retiring an "average" fossil plant, the net benefit to society would be 1.73 mills per kilowatt-hour. This excludes putting any pecuniary value on potential hazards from nuclear generation.

Incidentally, the positive nature of the quasi-rents on plant types within a region indicates a price in excess of recovering incurred costs plus a return on investment. In other words, the regulatory commissions set a price higher than warranted in 1973 in all regions except the Middle Atlantic and Mountain regions.

Restrictions on Interregional Transmission

As noted previously, regional coordination of electrical energy is not yet a normal part of the operation of the market for electrical energy.[7] In what follows, the costs to society arising from the lack of coordination are measured.

It has long been recognized that some trade (i.e., interregional transmission) is always potentially beneficial (Graaff). If one regards the

[7] The footnote on table 3 gives approximately the total interregional transmission. In the unrestricted model, electrical energy transmission into the Pacific region (specifically the Los Angeles area) from the Mountain region (the Four Corners power plant) does not show up because of the model structure.

entire United States as the group whose welfare it is desirable to maximize, unrestricted transmission leads to the nation's welfare frontier (subject to the aforementioned qualifications). If one is concerned with maximizing the welfare of a particular region, one would prefer movement along the frontier in a direction that favors the region with whom the concern rests. This is precisely what is done by restricting transmission by institutional means to and from a region. Thus, it is observed in what follows that the welfare of regions that have an economic advantage in the generation of electrical energy increases while the welfare of the less fortunate regions falls. In the aggregate society is worse off.

To quantitatively measure the impact of the lack of regional coordination, the constraint $x_{ij} = 0$ for $i \neq j$ is imposed on the spatial equilibrium model. Associated with this constraint will be a dual variable (ρ_{5ij}) that can be interpreted as the quasi-rent accruing to utilities in region i due to a restriction on the transmission of electrical energy to region j.

The results of imposing transmission restrictions can be found. These need not be enumerated because they can be obtained from a knowledge of the Kuhn-Tucker conditions and the solution for the unrestricted model. The equilibrium price of electrical energy, because of the way the demand curves are approximated, becomes the actual price observed in 1973. The quasi-rents arising from transmission restrictions are just the difference in the actual prices between regions. These quasi-rents are greater than estimated transmission costs between those regions where transmissions occurred, but in other regions a penalty due to the constraint is incurred, though this penalty does not indicate a strong enough desire on the part of consumers to have additional electrical energy. The quasi-rent for any plant type in a region is the difference between the actual price in 1973 and the operating and capital costs of that plant type.

The cost to society arising from the transmission restrictions is measured as the difference between the net social payoff in the restricted and unrestricted models. Quantitatively, this value is \$301 million. Thus, there is a real loss to society arising from uncoordinated generation by electric utilities in the United States.

The quantity of electrical energy generated does not change between solutions except in the Middle Atlantic region. The regions that have an economic advantage in the generation of electrical energy are able to supply the same quantity but at a lower price. This results in a larger intraregional consumption.

Obstacles to Coordination

As previously noted little electrical energy is transmitted interregionally. In 1973, only about 20 million kilowatt-hours (1% of total net generation) were transmitted interregionally. Given the significant gains that could have been made by transmitting electrical energy into the Middle Atlantic region in particular, a natural question is why was this not done. The general problems to coordination were alluded to above and basically revolve around the institutional structure.

With regard to the Middle Atlantic region, the specific arguments by utilities put forward against coordinated operation include (*a*) organizational complications, (*b*) larger area to be affected by system disturbances, and (*c*) complexity of operation (Federal Power Commission 1971). These problems are no different than those encountered by other regions. If only technological factors were to be considered, each of these problems could be mitigated. Unfortunately, it appears that the social climate is the militating force. One quote that typifies the industry attitude is "Interconnections cannot replace a long-term deficiency in installed generating plant or primary fuel supply. The purpose of interconnections is to permit the coordinated operation of generating capacity and for the transfer of power among systems at times of short-term emergencies" (NERC 1975a, p. 3).

Thus, it can be expected that without outside impetus the industry will continue to operate in the future as it has in the past—devoid of any active coordination efforts.

Sensitivity of the Results

While the model yields some interesting conclusions, the interpretations would be misleading if the results depended on the specific parameters used. The estimates of costs are by no means perfectly accurate. If slight changes in the estimates lead to major changes in conclusions, then the model is not at all interesting.

One of the estimates crucial to the empirical implementation of the model whose influence on the results is not immediately clear is the estimate of the price elasticity. It is well known that the omission of variables when specifying a demand equation will bias the estimates of ordinary least squares. Further, it should be apparent that some important variables have not been included in the demand equations used to estimate the price elasticities. Consequently, the model was solved both with and without transmission restrictions where it is assumed that the true price elasticity is both twice and one half of the estimated value. In both situations, the results do not change significantly.

The other estimates of great importance are transmission costs. These were varied in additional solutions to the unrestricted model. The interregional transmissions continued to obtain as long as it was assumed that actual transmission costs were less than the price differentials between regions.

A reduction of transmission cost estimates by 50% results in additional transmission from the East South Central region to the New England region. An increase in transmission cost estimates by 50% eliminates interregional transmission only between the East North Central and Middle Atlantic regions, the West South Central and Middle Atlantic regions, and the Mountain and West North Central regions. The gains to society from interregional coordination even in this latter case are still significant.

Conclusions and Their Policy Implications

The major conclusion that results from the foregoing analysis is that society can gain with increased regional coordination of the generation and transmission activities of the electrical energy industry in the United States. Using 1973 as a point of reference, the study indicates that society suffered a loss of $301 million in social welfare (i.e., net social payoff) because of minimal regional coordination. This reflected the fact that consumers in regions where relatively inexpensive electrical energy was available were permitted to consume more and pay less than what would have been optimal from a total societal perspective at the expense of consumers in less efficient producing regions.

Given the conclusions, the policy implications suggest that regional coordination be more actively pursued. The mechanism of this pursuit is suggested here. Coordination agreements, because of their nature, must be filed with the Federal Power Commission, which has authority to examine the propriety of the details and make appropriate modifications. The Federal Power Act of 1935 provides that no electric utility subject to the jurisdiction of the Commission shall, with respect to any transmission or sale, give undue advantage to any consumer or subject any consumer to an undue disadvantage or to maintain an unreasonable difference in rates, charges, service, or facilities either between locations or between classes of service (Federal Power Commission 1970).

This authority requires the Commission to test the provisions of a coordination agreement against the statutory provisions. Any discriminatory treatment among electrical utilities is unreasonable and too preferential unless the proponents can prove otherwise.

Under Section 202(b) of the Federal Power Act, the Commission is explicitly authorized to order the enlargement of transmission equipment (Federal Power Commission 1970). Upon complaint of a state commission or an electric utility, it can force a temporary connection of facilities and any generation, delivery, interchange, or transmission of electrical energy that will meet the emergency where emergency is defined to include a sudden increase in the demand for electrical energy or a shortage of electrical energy, of facilities for the generation or transmission of electrical energy, or of fuel or water for generating plants. Yet the Commission has not used this authority as a weapon to promote coordination. In view of the emergency created by environmental siting constraints, financing limitations, and the potential disappearance of smaller electric utilities, an analysis of the potential offered by Section 202 is needed.

The Commission has on occasion in the past required an electric utility to "wheel" electrical energy where "wheeling" involves the use of a third party's transmission lines to deliver electrical energy from a producer to a consumer. Consistent requirements of compulsory wheeling as seen above could increase efficiency. The consumer would be able to consider several generating sources to determine the arrangement of generation and transmission that will minimize his total electrical energy expenditures.

The Commission can exercise licensing and use leverage to encourage regional coordination and planning. For example, when a hydroelectric plant license issued by the Commission expires and the Commission is considering whether to issue a new license to the utility originally holding the license, it is reasonable to consider its behavior with regard to other utilities. One question that should be asked is whether the utility inhibited coordination.

Summarily, there exists a great deal of authority by which the Federal Power Commission could promote coordinated operation and planning in the electrical energy industry. That it should has been adequately demonstrated here.

Modeling and Simulation of the U.S. Economy with Alternative Energy Availabilities

J. B. Penn, Bruce A. McCarl, Lars Brink, and George D. Irwin

The acute energy shortages of 1973–74 accentuated the pervasiveness of energy utilization in the U.S. economy and underscored the complexity of the system interrelationships. It was also revealed that little is known about these interrelationships. This article reports on a systems analysis of the short-run economic effects of alternative situations involving reduced energy availability. The impacts of several different energy availabilities are analyzed. Specifically, the situations considered are a 2% quantity reduction in domestic coal supply, a 1.0 and a 1.5 million barrel per day reduction in crude petroleum imports, and a 10% quantity reduction in natural gas supply.

Key words: energy policy, energy shortage, input-output analysis, linear programming.

The acute energy shortages of 1973–74 accentuated the pervasiveness of energy utilization in the U.S. economy and underscored the complexity of the system interrelationships. They also revealed that little is known about these interrelationships. This article reports on a systems analysis of the short-run economic effects of alternative situations involving reduced energy availability.

Input-output (I-O) analysis has long been used for studies of the direct and indirect effects of certain system changes. However, I-O analysis generally assumes that primary resources are available to support any level of production. In a short-run energy shortage situation, primary inputs such as crude petroleum are fixed in their availability. To investigate these short-run impacts this study incorporates I-O data into a linear programming model with primary input constraints directly imposed.

The impacts of several different energy availabilities are analyzed. Specifically, the situations considered are a 2% quantity reduction in domestic coal supply, a 1.0 and a 1.5 million barrel per day (MBD) reduction in crude petroleum imports, and a 10% quantity reduction in natural gas supply.

Model Formulation

The objective is to

$$(1) \qquad \max LX,$$

which is the sum of gross dollar output within the modeled economy. Here, X is the n-element column vector of dollars of gross output by production sector and L is an n-element row vector of ones.

The constraints are specified in equations (2) through (11). The first constraint,

$$(2) \qquad (I - A)X - C_pH - IY = 0,$$

ensures that gross output (IX) equals demand, which consists of intermediate demand (AX) plus household personal consumption expenditures (C_pH) plus final demand (IY).[1] Household personal consumption expenditures are a linear function of household gross output (H) and are distributed among production sectors according to C_p. The second constraint,

$$(3) \qquad -WX + (1 - C_{ph})H - Y_h = 0,$$

[1] Final demand consists of gross private capital formation, exports, and government purchases.

is similar to equation (2) and requires that household gross output (H) equals employee compensation from the production sectors (WX) plus employee compensation for workers employed directly by households ($C_{ph}H$) plus final demand (Y_h). In order to limit deliveries to final demand,

(4) $$IY \leq D_f$$

represents n upper bounds (D_f) on maximum final demand accepted (Y) by the production sectors and

(5) $$Y_h \leq D_{fh}$$

is analogous to equation (4), giving a limit on maximum final demand accepted by households (D_{fh}). Equation (6),

(6) $$LY + Y_h - Y_{tot} = 0,$$

sums final demand accepted by the production sectors (LY) and households (Y_h) into a variable representing total final demand (Y_{tot}). Equation (7),

(7) $$E_1X + E_2H + E_3Y_{tot} - E_pP_d \leq Imp,$$

gives the quantity limitations of the five types of energy. Energy use by production sectors (E_1X) plus energy use by households (E_2H) plus energy used in meeting final demand (E_3Y_{tot}) is less than or equal to energy imports (Imp) plus domestic energy production (E_pP_d).[2] Domestic energy production is a linear function of gross output by the energy-producing sectors. Equation (8),

(8) $$-JX + IP_d = 0,$$

equates total gross output of energy-producing sectors (the element J_{ij} is 1 if sector i produces energy type j and is 0 otherwise) to the levels of the five energy production variables (P_d). To provide a physical upper limit (B_d) on domestic production of the five energy types,

(9) $$E_pP_d \leq B_d.$$

Equation (10),

(10) $$M_{tt}Y + M_{tth}Y_h = 0,$$

requires that trade and transportation final demand be proportional to the final demand for other sectors. The jth column of M_{tt} equals the trade and transportation margins required in selling and shipping final demand of production sector j. For the trade and transportation sectors these coefficients are -1. The nonnegativity specification on all variables is given by

(11) $$X, H, Y, Y_h, Y_{tot}, P_d \geq 0.$$

In addition, nonbinding accounting relationships are specified to yield information on employment, total value added, indirect business taxes, and property-type income.

The primal model described in equations (1) through (11) yields results on production activity, household activity, final demand, energy use, domestic energy production, and energy imports. In addition, dual variables (shadow prices) are generated. All shadow prices are in terms of contribution to the primal objective function—gross output. The dual model is presented in the appendix.

Empirical Specification of the Model

The model as stated above is developed consistent with theory and computational experience (McCarl et al.; Penn et al.; Penn, Irwin, and McCarl). The specification incorporates the U.S. Department of Commerce eighty-five sector published I-O data from 1967,[3] University of Illinois Center for Advanced Computation energy data (Simpson and Smith, Herendeen), and transportation and trade margins data synthesized from the published I-O data (U.S. Dep. of Commerce). The following sections describe particular aspects of the model formulation.

Closing Model with Respect to Households

The household sector is included as an endogenous sector along with the production sectors, due to the interest in economic interdependence including the induced effects of households. The activity of the household sector, as a supplier of labor services and recipient of wages, depends on the gross production level of the economy. To make the sector endogenous to the model, the personal consumption expenditure column (H) and employee compensation row of the I-O table are

[2] E_3 is energy used over and above the use in the production and household sectors.

[3] The problem was originally formulated using the more detailed 367 sector table but the solution of this problem was not feasible on any immediately available solver. This problem had 391 rows and 742 columns of which 368 were bounded. The density was 18.4%, which, when combined with the size of the problem, was the reason for the failure of the solving codes. The eighty-five sector problem had 109 rows and 178 columns (86 bounded) and a density of 44.3%.

made part of the Leontief matrix. This requires that the row and column totals are equal. However, in the 1967 table personal consumption expenditure exceeds employment compensation by almost $20 billion of nonwage personal income (U.S. Dep. of Commerce). This amount is entered as maximum final demand (D_{fh}), allowing up to this additional amount to be spent on consumption items. This formulation introduces a particular form of consumption function having an intercept equal to nonwage personal income and a constant marginal propensity to consume.

Choice of Objective Function

The I-O matrix and accompanying constraints define the eligible solution points, with the objective function directing the choice of a solution point. In order for the model to be meaningful, the solution and thus the objective function must be consistent with the behavior of the economy. The I-O matrix has been used previously in an optimizing framework by numerous authors (e.g., Chenery and Clark, Makower), and typical objective functions have maximized final demand accepted or consumption. Minimization of resource use has also been used but presents difficulties when there are multiple scarce resources, such as the five types of energy in this study. The objective of maximizing gross output (excluding households) is adopted because (*a*) in the unconstrained case this objective yields results consistent with Leontief I-O analysis (both in terms of activity levels and multipliers) and (*b*) it is assumed that the behavior of the economy can reasonably be represented by the production sectors maximizing their output, subject to the I-O matrix, which states that they only produce as much as demanded.

It could be argued that the behavior of the economy in an energy shortage situation cannot be represented by a single objective function. Here, consideration of individual producer behavior makes gross output maximization appear as the most reasonable single objective. In order to gain information on the response of the economy to an energy shortage under different behavioral assumptions, some alternative objectives are also used. These correspond to various policy considerations noted by Simon (1975a, b) and the *Economic Report of the President* and consist of maximization of (*a*) indirect business taxes (IBT), (*b*) property-type income (PTI), (*c*) total value added (TVA), which equals gross national product (GNP), and (*d*) employment (EMPL).

Transportation and Trade Margins

The U.S. Department of Commerce table is presented in terms of producers' prices, equivalent to values FOB. Such prices exclude distribution costs and wholesale and retail trade margins (but include excise taxes collected and paid by producers), which make up the differences between producers' and purchasers' prices. The trade margin on each item of the "bill of goods" is separately specified as a requirement from the trade sector. Similarly, transportation cost is separately specified as a requirement from the transportation sector. Without explicit treatment of the transportation, wholesale, and retail trade sectors, primary resource constraints may cause large reductions of activity in these sectors with only minor reductions in the other producing sectors. This means the margins could be greatly reduced while physical production is not, i.e., that produced goods are transported at no cost or with no trade margin. Thus, the relationship between production and margins must be specified and preserved. As the production level changes, so must the margins in accordance.

The matrix structure ensures correct accounting for domestic production, but a problem arises with respect to final demand. Generally, final demand of one sector is considered independent with regard to final demand of other sectors. However, this is not true in the case of transportation and trade margins, and in order to model this correctly, two rows linking final demand levels and margins are included in the model. The dollar requirements of transportation and trade of each sector for delivery of $1 to final demand are entered in these rows across the final demand columns. Thus, in a constrained solution where final demands are reduced, the margins will be reduced in proportion.

The Energy System

The energy data are usage of energy by each producing sector (Simpson and Smith). Energy is disaggregated into five basic types: coal, crude petroleum, refined petroleum, electricity, and natural gas. In order to model

accurately the energy system, both imported and domestically produced energy must be treated. Domestic production is attributed to the coal-mining sector for coal, the crude petroleum sector for crude petroleum, the petroleum-refining sector for refined petroleum, and the electric, gas, water, and sanitary services (utilities) sector for both electricity and natural gas.

Accounting for energy use to meet final demand is handled similarly to transportation and trade margins discussed above. Energy utilization (per dollar of final demand) coefficients are entered in the energy resources rows, and the model formulation is expanded to account for the energy required by final demand.

Results

Numerous simulations of alternative energy situations have been obtained with this model formulation. Space constraints permit only an abstraction of results from four situations to illustrate the model's capabilities. Solutions shown in table 1 are for: (*a*) a 2% quantity reduction in domestic coal supply, (*b*) a 1.0 and (*c*) a 1.5 million barrel per day reduction in crude petroleum imports, and (*d*) a 10% reduction in domestic natural gas supplies. The first is suggestive of the situation resulting from the coal miners' strike in 1974. The second and third situations are similar to the administration's energy strategy enunciated in January 1974 (Simon 1975a). The fourth is reflective of the situation suggested as possible for the East Coast and other areas in the winter of 1975–76, although it did not occur. The fourth simulation uses the alternative objective functions (noted above) to illustrate the effect of various assumptions regarding a single national economic goal. The reductions in energy availability are implemented as reductions in import availability or domestic production capacity for the pertinent energy type in constraints (7) and (9).

Coal

In 1967, before the acute energy shortages, the U.S. economy consumed 14.7 quadrillion

Table 1. Simulations of the Impact of Energy Reductions

	Base Gross Output (Mil. $)[a]	Reduction in: Coal 2% GO	Crude 1 MBD GO	Petroleum 1.5 MBD GO	Natural Gas of 10%, Alternative Objectives: GO	IBT	PTI	TVA	EMPL[c]

Final demand	304,728	99.7	96.6	95.5	92.9	91.5	93.0	92.9	92.4

Note: Categories included are defined by the U.S. Dep. of Commerce.

[a] 1967 I-O data without energy constraints.

[b] This figure indicates that agriculture, forestry, and fisheries produced 99.8% of the base production ($63,793 million) or $62,517 million worth of output.

[c] These indicate the objective function being maximized: GO = gross output, IBT = indirect business taxes, PTI = property-type income, TVA = total value added, and EMPL = employment.

British thermal units (BTU) of coal, practically all from domestic production. To simulate the impacts of the 1974 strike induced shortage, sometimes estimated at 2% of 1974 quantity, the domestic coal BTU availability (right-hand side on equation (9)) is reduced by that amount and the solution is obtained by maximizing gross output (*GO*). The results in table 1 indicate the short-run impacts of the relatively modest reduction to be small for most of the aggregated sector categories.[4] Individual sector impacts vary depending upon the coal-utilization intensity of the sector and its reliance on coal-intensive sectors for inputs. For the aggregate categories, levels are generally reduced by less than 1% with the exception of the mining sectors. The aggregate indicators reveal economic activity to be slowed only slightly, with GNP, personal consumption expenditure, employment, government tax revenues, and investment income reduced by 1% or less.

Crude Petroleum

Simulations of crude petroleum import reductions of 1.0 and 1.5 million barrels per day are obtained using maximization of gross output as the objective. These reductions are 65% and 100%, respectively, of the 1967 level of imports.[5] The impact on output levels of the aggregated real sector categories from the 1.0 million barrel per day reduction ranges from declines of 7% for mining to less than 3% for agriculture and related sectors. The "other" category, which includes dummy industries and imports, shows a slight increase as these sectors use little energy, and the negative trade balance of the base year solution is reduced due to the reduced level of energy importation. Aggregate economic activity is reduced by approximately 4% overall as shown by the indicators. Notably, unemployment increases 4% over the base year (1967) level, GNP declines 3.6%, and personal consumption expenditure and aggregate final demand are reduced slightly over 3%. The impacts of the 1.5 million barrel per day reduction are even more restrictive of economic activity but follow the pattern of the 1.0 million barrel per day reduction.

Natural Gas

A reduction in domestic natural gas supplies of 10% is simulated maximizing gross output and four alternative functions. First, considering the solution reflecting a maximization of gross output, the effects of a gas shortage are pronounced with real activity levels showing reductions of from almost 2% to 11%. The categories showing the largest decline are mining and manufacturing, especially the textile-related sectors. The aggregate activity level declines by 6% to 7%. Employment is reduced by 7.5%, and GNP declines by almost that amount with the other indicators being similarly affected.

An examination of this situation with the alternative objective functions show the difference in results to be slight. This is as might be expected since indirect business taxes and property-type income are components of total value added (the other component is employee compensation). Also, the similarity of these results to maximization of gross output is consistent since, generally, the correlation of total value added with gross output is high for most sectors.

The largest contrast in effects of objective function choice appears when results from these four criteria are compared to the results from maximizing employment. The relatively labor-intensive sectors are emphasized at the expense of those less labor intensive and a somewhat different pattern of production allocation emerges.

Natural Gas Shortage and Food and Fiber System

To further illustrate the type of information obtainable from the model, the impacts of the natural gas shortage (domestic capacity to produce is reduced by 10%) are examined for a representation of a food and fiber system.[6] This food and fiber system representation, composed of nineteen sectors from the eighty-five sector table, is shown in table 2. Gross income and employment totals shown exclude transportation and trade because food and fiber proportions of these sectors are small at this level of aggregation. The impacts on the component sectors of the system are generally consistent with the aggregate results presented

[4] While detail for individual sectors is available from the model, the sectors are grouped as in table 1 for space economy.

[5] BTU reductions are calculated using a conversion factor of 5.8 million BTU per 42 gallon barrel (Reardon, appendix, p. B-1).

[6] Actually, it is a shortage of both natural gas and electricity, since they are represented by the same utilities sector.

Table 2. Simulation of 10% Natural Gas Reduction in a U.S. Food and Fiber System

Sector	Gross Output		Final Demand	
	Base	Natural Gas Reduction 10%	Base	Natural Gas Reduction 10%
	(Mil. $)	(% of Base)	(Mil. $)	(% of Base Accepted)
Inputs				
Chemical and fertilizer mining	1,027	83.9	187	100.0
Chemicals and selected products	23,182	77.2	3,880	33.2
Petroleum refining and related industries	26,975	93.1	2,676	100.0

Transportation and warehousing	52,825	91.9	9,257	88.9
Wholesale and retail trade	163,365	93.2	11,448	88.9
Total final demand			22,890	84.2
Gross output[a]	315,445	92.3		
Employment (in thousands)[a]	10,630	93.1		

Note: Solution maximizing gross output. Categories as defined by U.S. Dep. of Commerce.
[a] The transportation and trade sectors are excluded.

in table 1, but the impacts may be seen more clearly with this level of detail.

For the natural gas shortage simulation, impacts vary considerably by sector. The five designated inputs sectors reduce output over a rather wide range. The chemicals and fertilizer sectors are affected most, being large direct users of natural gas. The farm-machinery-manufacturing sector is affected little by the reduction. Sales from the utilities sector, which contains gas utilities through which the 10% natural gas reduction is implemented, are reduced by approximately 10%.[7]

Three of the four agricultural-production-related sectors show output reductions. One sector, forestry and fishery products, shows an increase of 4%. The explanation for this apparently perverse result is the use of the gross-output-maximizing function, which favors sector production over use of the capital inflow.

Output impacts on the ten sectors designated as processing and distribution sectors are also varied. Eight sectors including the relatively large food and kindred product processing sector are reduced by from about 3% to 10%. The textile-related sectors are severely affected. For the fabric, yarn, and thread mills sector, the output reduction is 10% and for the other three textile-related sectors, it is 6% to 7%.

The transportation and warehousing sector is reduced by about 8% and trade about 7%. Gross income (sales) to the system is reduced

[7] This result is tempered by the fact that the utilities sector consists of both gas and electric utilities.

by almost 8% for this simulation. The system as defined has a base level employment of 10.6 million people, and the simulation of this fuel restriction indicates that a reduction of 7% would occur.

Final demands for the various sectors are also restricted differently under a fuel shortage. In any shortage, all equilibrium final demands cannot be accepted. The pattern of final demands accepted (shown in table 2) is seen to vary considerably across the sectors. It should be recalled that "final demand" in this model includes gross private capital formation, exports, and government purchases. Domestic consumption (personal consumption expenditure) is not included in final demand as it is treated as endogenous to the model (i.e., an intermediate product).

For the situation examined, the food and fiber system would be proportionately more severely affected than the economy as a whole. Employment declines indicated would be greater and output declines would show even greater disparity. These simulations reinforce the well-known overall conclusion that, given emergence of specific shortages, alternate schemes to alleviate their impact may produce similar results for the economy in the aggregate, but the impacts on individual sectors may be markedly different. For the selected sectors shown, the results further emphasize the direction and relative magnitudes of trade-offs that should be considered by policy makers in selecting one or more economic goals for emphasis over others.

Results presented and discussed have focused on sector gross output and aggregate activity levels. It is obvious that additional types of useful information can be gleaned from simulations with the model. Examples of this are the levels of sector final demands and sectoral and energy shadow prices.

In table 3, the total quantity of energy available is shown in terms of BTU and disaggregated into energy available through domestic production and imports. The figures reflect two situations: actual 1967 (base) and a 1 million barrel per day reduction in crude petroleum imports. Thus, table 3 corresponds to the simulation of the reduction in crude petroleum of 1 million barrels per day in table 1.

The simulation shows that the full domestic production capacity is used for crude petroleum and natural gas and for refined petroleum when crude petroleum imports are reduced. In addition, the crude petroleum imports are obviously at their limit. The creation of energy of other types is less than in the base situation. This reflects the general slow-down of the economy due to the petroleum shortage.

Interesting additional information generated by this simulation is the shadow price for available crude petroleum of $30 per million BTU.[8] Using the conversion factor 5.8 million BTU per barrel (Reardon, appendix, p. B-1), this translates to a gross output value of crude petroleum of $174 per barrel. This imputed value is much larger than the price paid for imported crude petroleum, which is in the

[8] For comparison, the shadow prices per million BTU of coal and natural gas from the 2% coal reduction and 10% natural gas reduction simulations are $50 and $70, respectively.

Table 3. Energy Balances for Base and for 1 Million Barrel per Day Reduction in Crude Petroleum Imports

		Domestic Production		Imports		Total	
Energy Type		Base	1 MBD	Base	1 MBD	Base	1 MBD
Coal	Base	14,715		6		14,721	
	1 MBD		13,961		6		13,967
Crude petroleum	Base	39,348		3,255		42,603	
and natural gas	1 MBD		39,348		1,138		40,486
Refined petroleum	Base	25,338		3,375		28,713	
	1 MBD		25,338		1,869		27,207
Electricity	Base	4,059		0		4,059	
	1 MBD		3,867		0		3,867
Natural gas	Base	18,018		456		18,474	
	1 MBD		17,626		0		17,626
Total	Base	101,478		7,092		108,570	
	1 MBD		100,140		3,013		103,153

Note: Figures are reported in 10^{12} BTU.

range of $10 to $15 per barrel. A decrease in the available quantity of crude petroleum imputes a very high value to petroleum and this in turn is likely to lead to extensive efforts to create substitutes. Certainly such a high imputed value should encourage exploration and/or technical substitution.

Conclusions

This paper has described and illustrated the use of a constrained I-O model for examination of primary resource constraints. A good example of the use to which this analysis can be put is given by the simulation of a natural gas shortage. The textile-related sectors of the economy (contained in the aggregate manufacturing category in table 1) are large users of natural gas. These sectors were severely affected by the simulated gas shortage. In other words, the model shows that, given the objective to maximize gross output, the rational action to take is to reduce activity in the textile industry. This conclusion may be compared with the actual policy followed by many natural gas suppliers in times of gas shortage. The accepted policy is to supply textile industries with gas on a "first interruptable" basis, which in effect means that activity in the textile industry is reduced. Thus, the appropriateness of that policy or other policies may be evaluated to some extent by this type of simulation.

Results available from the model must be viewed in the light of a combination of the separate assumptions employed both in linear programming and construction of the I-O table. Some of the more important assumptions present in the formulation described above are: (*a*) each commodity is produced by a single sector (industry); (*b*) the I-O formulation in general does not allow substitution; the formulation presented here permits "substitution" in the sense of underproducing for final demand, but the major component of final demand (personal consumption expenditure) is internalized in this formulation; (*c*) the inputs used by a sector are strictly proportional to output; (*d*) external economies and diseconomies are absent (additivity); (*e*) all relations are nonstochastic and continuous; (*f*) technology is fixed and dated—1967 I-O data are used;[9] and (*g*) electricity and natural gas are produced by the same sector.

An implication is that the economy is assumed not to have alternative production techniques, which might be less energy intensive. At best, this assumption is valid only in the short run. Also, the realism of the model relative to current conditions is lessened because of the changes in relative input (especially petroleum) and product prices since 1967. It is possible that problems related to the lack of substitution in I-O models could be dealt with more effectively if some of the information available to the U.S. Department of Commerce is not only aggregated into the I-O tables but also reported according to other technological classification.[10]

The approach of this study is to emphasize the short-run aspects of the problem. In the long run, it is likely that consumer demand adjustment and development of energy supplies will take place. These phenomena are not handled in this modeling effort. Likewise, no consideration has been made of balance of payments problems and price adjustments.[11] The longer run aspects of modeling energy constraints have been discussed by a number of authors in the proceedings of the 1975 Summer Computer Simulation Conference (American Institute of Chemical Engineers et al.).

[9] Nelson has conducted some investigations using the 1967 I-O model and suggests that the 1967 data are applicable to at least 1974. The U.S. Department of Commerce now prepares an I-O table following each quinquennial Census of Business. The most recently available table for 1967 was released on computer tape in late summer 1974.

[10] In order to prevent duplication in information gathering, in this case by the Center for Advanced Computation, it may be desirable that data on resource usage are reported along with the I-O tables. A step in this direction has been reported by Just, Borko, and Morris. The same argument obviously follows from difficulties encountered in this study when attempts were made to handle the relation between final demand and trade and transportation margins discussed above. This can be seen as a simple extension of Bonnen's arguments on data. The use of the data needs to be considered along with its creation. The authors suggest that a wider conceptual base should be considered for the U.S. Department of Commerce data.

[11] A possible extension of the model presented here is the adoption of a price-quantity response system. Harrington has shown how a model similar to the one above can be structured to portray price responsive primary resources and final demands. The above model could be formulated in such a manner incorporating price-responsive energy supply and final demand and solved by separable programming, for example.

Appendix

Dual Formulation

The dual of the programming model given in equations (1) through (11) is to

(A.1) $\min D'_f\gamma + D_{fh}\delta + Imp'\zeta + B'_d\theta$

(A.2) subject to $(I - A)'\alpha - W'\beta + E'_1\zeta - J'\eta \geq L'$,

(A.3) $-C'_p\alpha + (1 - C_{ph})\beta + E'_2\zeta \geq 0$,

(A.4) $-I\alpha + I\gamma + L\epsilon + M'_{tt}\kappa \geq 0$,

(A.5) $-\beta + \delta + \epsilon + M'_{th}\kappa \geq 0$,

(A.6) $-\epsilon + E'_3\zeta \geq 0$,

(A.7) $-E'_p\zeta + I\eta + E'_p\theta \geq 0$,

(A.8) γ, δ, ζ, and $\theta \geq 0$,

and

(A.9) α, β, ϵ, η, and $\kappa \gtreqless 0$.

The variables are defined as follows.

α is a vector indicating the value to the economy's gross output of accepting one additional dollar of demand (intermediate or final) by each production sector. The value can be either negative or positive depending on whether energy cost exceeds the value of production. α corresponds to equation (2).

β is a scalar, analogous to α but for the household sector, β corresponds to equation (3).

γ is a vector indicating the value to the economy of accepting one additional dollar of final demand by each production sector. These values are somewhat analogous to the output multiplier used in I-O analysis. γ corresponds to equation (4).

δ is a scalar, analogous to γ but for the household sector. δ corresponds to equation (5).

ϵ is a scalar, indicating the value of one additional dollar of final demand not requiring energy. This can be interpreted as the energy cost of meeting final demand. ϵ corresponds to equation (6).

ζ is a vector indicating the value of one additional unit of available energy either imported or domestically produced by energy type. ζ corresponds to equation (7).

η is a vector indicating the value of one additional dollar's worth of output from the domestic energy producing sectors by energy type. η corresponds to equation (8).

θ is a vector indicating the value of one additional unit of domestic energy capacity by energy type. θ corresponds to equation (9).

κ is a vector of values of one additional dollar of trade or transportation margin forced into final demand. κ corresponds to equation (10).

The Productive Value of Human Time in U.S. Agriculture

Wallace E. Huffman

The quantity and marginal productivity of farm husband and wife labor services allocated to their own farm work are assessed. A behavioral model of the farm firm is developed and implemented empirically by fitting a production function to county average per farm data for 1964 for Iowa, North Carolina, and Oklahoma counties. A comparison of marginal products of husband's and wife's labor inputs with opportunity costs yields the implication that net rural-to-urban human migration and reallocation of working time between own-farm and off-farm work by the remaining farm population had succeeded in getting rid of excess labor services in U.S. agricultural production in 1964.

Key words: education, extension, farm husbands, farm labor, farm wives, human time, production function.

This paper focuses on assessing the quantity and productivity of farm husband and wife labor services allocated to their own farm work. The assessment is possible because the 1964 Census of Agriculture records for the first and only time the actual hours of work on "own farm" and educational attainment of farm operators and other household members (U.S. Dep. of Commerce 1967). A behavioral model of the farm firm is developed to provide a framework for assessing the actual value of human time and other inputs, including education and agricultural extension, in agricultural production. The model is implemented empirically by fitting a production function to county average per farm data for 1964 for Iowa, North Carolina, and Oklahoma counties.

A comparison of implied marginal products of the inputs for representative farms of the three states yields the implication that the rural-to-urban migration of farm people and the reallocation of working time of the remaining farm husbands and wives between own-farm and nonfarm work have succeeded in getting rid of the excess labor services in agricultural production. However, only the marginal product of education for Iowa farm husbands and wives compares favorably with its marginal value at nonfarm work. The results also show a huge marginal product in agricultural production of agricultural extension agent time (in excess of $1,000 annually per day).

This article is organized as follows. First, a behavioral model of the farm firm is developed. The next section describes the data, discusses the empirical specification of the model, and reports the results. The final two sections present the implied marginal products and conclusions, respectively.

The Conceptual Model

The farm firm is assumed to take farm firm and household-supplied inputs and (other) purchased inputs and transform them into useful output. For farm firm and household-supplied inputs, the resource allocation should be largely unaffected by the payment or nonpayment of a wage or rental rate on household-owned resources because of the opportunity cost associated with alternative uses. For farm-family labor, hours allocated to farm work have a cost of the foregone alternative uses at nonfarm work and/or household production.

Wallace E. Huffman is an assistant professor of economics at Iowa State University, Ames.

Journal Paper No. J-8422 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa. Project 2078. Marshall, John Miranowski, Gordon Rausser, Luther Tweeten, and Ronald Moomaw provided helpful comments and suggestions on earlier drafts of the paper. The Manpower Administration (Grant No. 91-19-75-18) and the Iowa Agriculture and Home Economics Experiment Station provided financial assistance.

Agriculture is a multiproduct industry, and most firms in agriculture are multiproduct firms that produce at least two broad classes of final products—crop products and livestock products. The production of these final products requires many of the same inputs, but the technical relationship between inputs and outputs seems likely to differ. For example, when livestock products dominate output, the livestock input to output ratio is likely to be higher than when crop products dominate output. In an attempt to capture differences of input parameters due to major product mix differences, the technical relationship between outputs and inputs is specified as

$$(1)\quad Y = Y_l + Y_c = A \prod_{i=1}^{n} X_i^{\alpha_i+\beta_i\rho},\ Y > 0,$$
$$Y_l \geq 0,\ Y_c \geq 0,\ X_i > 0,\ 0 \leq \rho \leq 1,$$
$$A > 0,\ 0 \leq \alpha_i + \beta_i\rho < 1,$$

where Y_l is the value of final livestock output, Y_c is the value of final crop output, ρ is the share of final livestock products in total final output, and A, α_i, and β_i are unknown parameters.[1]

Some properties of the production function (1) are the following. (*a*) Additivity of final products Y_l and Y_c, weighted by market prices for an output index, has the desirable property (for this study) of equaling total value of output.[2] (*b*) The index of output is homogeneous of degree 1 in the two products, i.e., doubling each product doubles the output index. (*c*) The elasticity of product transformation between Y_l and Y_c is infinitely large in the region of an optimal product mix. Inside this region, the marginal rate of product transformation is constant and equals the ratio of output prices (in quantity units) or unity (in value units). Thus, a dollar of crop products is locally a perfect substitute for a dollar of livestock products in the aggregate output index.[3] (*d*) The input index permits the weight of a particular input in the aggregate input index to change as the composition of aggregate output changes. For example, if crop products dominate aggregate output, the weight given to the livestock input in the input index can be small, but if the livestock products dominate output, the weight given to the livestock input in the input index can be large. Stated another way, the partial elasticity of aggregate output with respect to an input (or assuming competition, factors of production are paid their marginal product and decreasing returns to scale, the factor minimum cost shares of output) is permitted to vary with the product mix. (*e*) The elasticity of scale and degree of homogeneity of the input index

$$h(\rho) = \sum_{i=1}^{n} (\alpha_i + \beta_i\rho)$$

varies with the product mix of output. (*f*) The marginal rate of substitution in production between pairs of inputs at given factor ratios varies with the product mix of output:

$$MRS_{ij} = \frac{\partial Y/\partial X_i}{\partial Y/\partial X_j} = \frac{(\alpha_i + \beta_i\rho)}{(\alpha_j + \beta_j\rho)} (X_j/X_i).$$

Thus, holding relative factor prices and aggregate output constant, the optimal factor ratios for cost minimization vary with the output mix. (*g*) The elasticity of substitution between any two pairs of inputs is unity.

As an objective, the farm firm is assumed to maximize expected profit subject to anticipated production. This objective is appealing for agriculture. First, the actual prices are unknown at the time that production decisions are made so the assumption is that farmers base scale decisions on the expected prices of outputs. This implies that farmers are risk neutral. Second, because random weather conditions introduce disturbances into the input-output relationship, the quantities of actual outputs are unknown at the time that resource allocation and scale decisions are made. Consequently, farmers are assumed to make farm production decisions based upon anticipated output and not on actual output. Thus, the disturbance in the production equation affects only output and is not transmitted to the other variables of the system.

The Empirical Analysis

The data, empirical specification of the model, and the empirical results are presented and discussed in this section.

---

[1] Separate production functions for the two final products are not implied. Production is joint. Furthermore, it is a useful simplifying assumption that the true coefficients in the production function depend on the share of livestock products in the total output (or on the type of farm).

[2] A transformation function of the Cobb-Douglas, CET, or translog type in the outputs does not have this property. Furthermore, a Cobb-Douglas form has the wrong curvature, convex to the origin (Mundlak).

[3] A straight-line segment of the transformation curve will imply specialization in production only if the infinite elasticity of product transformation holds for all combinations of Y_l and Y_c. But for all possible combinations of Y_c and Y_l, the transformation function is assumed to be (quasi) concave. For a discussion of properties of production possibility frontiers, see Christensen; Christensen, Jorgenson, and Lau.

The Data

The observations are average per farm aggregates for all 276 counties of Iowa, North Carolina, and Oklahoma. Observations from these three states were chosen because their agricultural sectors continue to be important industries, they provide a mixture of farming activities (with the predominant type of farm ranging from tobacco and cotton to dairy and livestock ranch), and they represent different geographic regions of the United States—Midwest, Southwest, and Southeast. (See table 1 for a summary description of the data and variables used in the analysis.)

The data base provided by combining data from the 1964 Census of Agriculture (U.S. Dep. of Commerce 1967) and from U.S. Department of Agriculture publications of the same period (Ibach and Adams; Sellers 1969, 1970; Strickler) is a rich source of raw data for deriving the empirical measures of the variables required in this study. In particular, it is a richer data base than the 1969 Census of Agriculture (U.S. Dep. of Commerce 1972). Farm outputs and inputs are measured as flows. Output by final product type is gross product and is measured as value of sales, home consumption, rental of farm dwellings, government farm program payments, and net increase in farm inventories.[4] The inputs of

[4] When the objective is to obtain unbiased estimates of the parameters of the average per farm production function, the

Table 1. Summary Statistics of Total Sample and Subsamples, 1964

	Arithmetic Means (Standard Deviation)			
Variables	Whole Sample (n = 276)	Iowa Counties (n_1 = 99)	N. Carolina Counties (n_2 = 100)	Oklahoma Counties (n_3 = 77)
Aggregate output ($/year)	11,987.0 (6,676.0)	17,772.2	8,466.6	8,884.7
Crop output	5,659.7 (3,659.1)	6,041.1	6,049.6	4,663.0
Livestock output	6,327.7 (5,170.8)	11,915.0	2,417.0	4,221.7
Land and buildings ($/year)	2,568.5 (2,565.3)	5,510.5	926.9	906.9
Fertilizer ($/year)	369.7 (248.4)	438.3	413.5	224.9
Machinery ($/year)	1,754.6 (779.9)	2,513.2	1,188.0	1,515.2
Livestock and seed ($/year)	3,811.1 (3,071.4)	6,744.2	1,566.7	2,955.1
Hired labor (days/year)	59.7 (53.6)	34.4	97.0	43.7
Farm husband (days/year)				
Days own-farm work	194.0 (68.2)	275.9	142.4	155.7
Days off-farm work	66.2	43.2	68.9	101.6
Total days worked	260.2	319.1	211.3	257.3
Farm wife (days/year)				
Days own-farm work	70.1 (28.3)	104.9	40.4	63.8
Days off-farm work	44.6	31.4	60.5	40.9
Total days worked	114.7	136.3	100.9	108.7
Education (years)				
Farm husband	9.2 (1.25)	10.2	7.8	9.7
Farm wife	10.0 (1.13)	10.9	8.8	10.3
Extension (one-tenth day/year)	1.85 (2.01)	0.64	3.18	1.69
ρ	0.506 (0.220)	0.66	0.33	0.53

Note: See the appendix for the derivation of labor and education variables and Huffman (1976, pp. C1–C10) for derivation of other variables.

three different labor services are derived from flow data on actual (not available) number of man-days worked per year on farms. Man- (woman-) days of farm work per year are derived from adjusted weekly hours of farm work during the census week by farm operators (nonoperator household members) and from annual expenditures on hired labor. Measuring the labor input, especially farm family, as the quantity of actual services used corrects conceptual and measurement errors that exist in other studies of agricultural production. The conceptual error is that the stock of labor contributes to production rather than the flow of labor services (Doll). The measurement error is the use of the stock of workers as a proxy for labor services actually used in production. The cross-sectional rates of conversion of the stock of workers to labor services used in agricultural production differ because of systematic variation in (the variables that determine) both the total supply of working time of individuals and the relative allocation of total working time between farm and off-farm work.[5]

Education of farm husbands (wives) is an index derived as an income weighted average of the number of farm operators (wives of farm operators) in seven different schooling completion classes. Agricultural extension is derived from unpublished Federal Extension Service flow data for 1960 as the annual average number of one-tenth man-days allocated to crops and livestock activities by agricultural extension agents (doing primarily agricultural work) per farm (USDA 1961). The use of 1960 rather than 1964 data was necessitated by data availability. One can argue, however, that there is a time lag between the expenditure of extension agent time assisting farmers and the observed effect on agricultural production. The length of this lag is unknown, but a one- to four-year lag for the primary impact seems plausible (Evenson).

proper definition of output is gross output and intermediate inputs are to be included as inputs (Christensen, Domar, Star).

[5] Kislev used the number of workers as a proxy for man-years of available labor services. Heady and Timmer in their separate studies used available man-months and man-days, respectively, as the quantity of farm supplied and hired labor input. Griliches works from an assumption of a given number of available man-days or annual man-years per worker, but he adjusted this number downward to account for days of off-farm work (1963, 1964). Thus, even in better approaches, measurement errors arise in the hours-of-farm-work variable because of incorrect allocation of total available time among nonearnings activities (consumption) and time at farm and off-farm earnings activities. An exception is Fane's study, which uses available hours from the 1964 Census of Agriculture (1972, 1975).

The fertilizer input is measured as price-weighted primary plant nutrients, and land-and-building services are measured as the rental on the value of farm land and buildings valued at 1954 prices, adjusted to the 1964 mix of land-and-building characteristics and to remove the implied value per acre of being close to standard metropolitan statistical areas. Machinery services are measured as the rental on an inventory of a selected group of machines on farms in 1964 plus expenditures on petroleum products. The livestock and seed inputs are lumped together and measured as the rental on the inventory of breeding stock plus expenditures on purchased livestock, feed, and seed.[6]

The Empirical Specification

The productivity analysis is to be pursued through direct estimation of the natural logarithmic transformation of the production function. The empirical specification of the production function contains three separate labor inputs: hired, farm husband, and farm wife. Furthermore, the elasticity of substitution between all pairs of inputs in equation (1) is restricted to unity. This assumption may not be too objectionable for pairs of inputs not containing two labor inputs, but one can reasonably ask whether there is empirical evidence to support a unitary elasticity of substitution between pairs of labor inputs.

Direct empirical evidence shows that the restriction to unitary elasticity of substitution between pairs of labor inputs is not too severe. By assuming a more general constant elasticity of substitution (CES) technical relationship between inputs and aggregate output and profit maximization (or cost minimization), the elasticity of substitution between pairs of labor inputs can be estimated from wage and input-quantity data. Taking the wage rates as exogenous, the relationship between relative factor quantities and relative factor prices is

$$(2)\quad \ln(X_i/X_j) = \ln(\gamma_i/\gamma_j) - \sigma_{ij}\ln(W_i/W_j),\ i \neq j,$$

where γ_i and γ_j are distribution parameters, $\sigma_{ij} = d(\ln(X_i/X_j))/d(\ln(W_i/W_j))$ is the elasticity

[6] Given that production function parameters vary by product mix of output and that seed input contributes primarily to crop output and livestock input primarily to livestock output, one might question the inclusion of the seed input with the livestock input. Combining the seed input with the fertilizer input, however, contaminates a relatively good fertilizer variable. There is not much "information" in the seed-expenditure data.

of substitution between inputs X_i and X_j, and W_i and W_j are wage rates for X_i and X_j.

USDA data are available on state average daily wage rates paid hired farm labor (USDA 1965), and by making an assumption that the wage rate for off-farm work by farm husbands and wives is the opportunity cost of their time at own-farm work, county average daily wage rate data are available for farm husbands and wives (U.S. Dep. of Commerce 1967). Farm husband (wife) farm labor is measured in efficiency units as man- (woman-) days times the education index (Griliches 1970). To permit the labor input ratios to vary by product mix, the equation to be fitted is

$$(3)\ \ln (X_i/X_j) = a + b_{ij} \ln (W_i/W_j) + c\rho + \epsilon,$$

where $\sigma_{ij} = -b_{ij}$, and ϵ is a random disturbance.

The results from fitting equation (3) by classical least squares estimation method to the 276 observations on county aggregate data are reported in table 2. Two striking implications from these results are that the elasticity of substitution between pairs of farm labor inputs, hired farm wife, hired farm husband, and farm wife–farm husband, is "low" and that the labor input ratios vary by product mix, holding relative wage rates constant. The results imply that the highest degree of substitutability is between hired and farm wife labor services ($\sigma_{ij} = 1.2$) and that the lowest degree of substitutability is between farm wife and farm husband ($\sigma_{ij} = 0.12$) labor services. An intermediate degree of substitutability exists between hired and farm husband labor services ($\sigma_{ij} = 0.68$). Thus, hired and farm wife labor services are a poor substitute for farm husband labor services. One explanation is that the labor services of farm husbands are a different type of input than farm wife labor and hired labor services because of the relatively large share of farm husband's time that is allocated to allocative decision making (Huffman 1974). Farm wife labor and hired labor services are allocated primarily to physical work.[7]

The results also imply that there is a very definite impact of product mix on labor input ratios, holding relative wages constant. Livestock production, as opposed to crop production, is intensive in farm husband and wife labor services relative to hired labor services and is intensive in farm wife labor services relative to farm husband labor services. Furthermore, the failure to take into account product mix differences in estimating the elasticity of substitution between pairs of labor inputs (when product mix differences matter) biases upward the size of the estimated elasticity of substitution.

The conclusion, based on the results in table 2, is that the assumption of unitary elasticity of substitution between pairs of labor inputs in this study can be accepted at a small cost relative to a more general input specification that is much more difficult to estimate, e.g., a nested CES function or CES nested in a

[7] However, if there are random errors of measurement in both the labor input and wage rate ratios that are uncorrelated, the estimate of the elasticity of substitution will be biased toward zero (Johnston).

Table 2. Estimates of the Elasticity of Substitution between Pairs of Farm Labor Inputs, 1964

	a	b_{ij}	c	R^2	σ_{ij}
Hired/farm wife	−7.342	−1.152	−2.853	0.583	1.152
	(−43.53)[a]	(−5.06)	(−13.79)		(5.06)
	−9.332	−2.581		0.259	2.581
	(−82.02)	(−9.787)			(9.787)
Hired/farm husband	−9.057	−0.682	−2.652	0.512	0.682
	(−59.45)	(−4.20)	(−14.62)		(4.20)
	10.768	−1.326		0.129	1.326
	(−82.79)	(−6.37)			(6.37)
Farm wife/farm husband	−1.915	−0.115	0.458	0.153	0.115
	(−48.75)	(−1.96)	(6.54)		(1.96)
	−1.690	−0.151		0.021	0.151
	(−82.70)	(−2.40)			(2.40)

Note: These least squares estimates of the parameters in equation (3) are averages for 276 counties of Iowa, North Carolina, and Oklahoma. See the appendix and Huffman (1976, pp. C1–C10) for sources and derivation of variables.
[a] t-ratios are in parentheses.

Cobb-Douglas function. Furthermore, the specification of the production function (1) permits pairs of labor input ratios to vary by product mix (as implied in table 1), holding the marginal rate of substitution in production constant.

The parameters of the production function are to be estimated directly from aggregate average data. The specification is

$$(4)\quad \ln Y = \alpha_0 + \sum_{i=1}^{n} \alpha_i \ln X_i + \sum_{i=1}^{n} \rho\beta_i \ln X_i + \delta\rho + \mu,$$

where α_i, β_i, and δ are unknown and estimable parameters. The specification of the disturbance term in the production function ($\ln e^{\delta\rho+\mu} = \delta\rho + \mu$) is an attempt to take account of heteroscedasticity of the disturbances that may be due to differences in the product mix of output. A discussion can be found elsewhere of potential problems with statistical identification of the production function (Griliches and Ringstad) and simultaneous equation bias (Hoch; Zellner, Kmenta, and Dréze) when the production function is estimated directly by the method of classical least squares.

Furthermore, estimates of parameters of equation (4) from aggregate average data may compare favorably with estimates from microdata. Given the comparative advantage of economic models for explaining the behavior of averages rather than individual decision units, the aggregation bias from fitting an empirical model to aggregate average data may be less serious than the specification errors from fitting it to individual farm data (Grunfeld and Griliches), where at best the model captures the effect of the most important variables on individual output. Furthermore, even if individual farm data from the census were available, it is plausible that measurement errors in output, the dependent variable, are smaller, perhaps zero, for aggregate average data than for individual farm data. In this case, estimates of the parameters of the production function from aggregate average data may be better estimates than estimates from microdata (Aigner and Goldfeld).[8]

The Empirical Results

The results from fitting equation (4) to 276 county average per farm aggregates are reported in table 3. The performance of the variables is remarkable.[9] All the estimated α_i's are positive and significantly different from 0, except for the coefficient of fertilizer.

Coefficients of all variable inputs except for fertilizer and machinery inputs differ significantly by product mix of output. All variations seem plausible. As the share of final livestock products in total final output (i.e., ρ) increases, the size of $\alpha_i + \rho\beta_i$ declines for land-and-building services and the labor inputs and increases for the livestock and seed input. Furthermore, the five nonzero β_i's imply that all cost-minimizing factor ratios except one vary by product mix of output, holding relative factor prices constant (see table 4). One might be surprised that the ratio of land to all the other variable inputs declines as the share of livestock products in total output increases, but land-and-building services are measured as a rental value on constant-quality land and buildings for current agricultural production. Clearly a land-and-buildings input measured as acres would increase as ρ increases, but acres evidently do not rise as fast as the price per acre falls when ρ increases. As ρ increases, the other factor ratios move as expected. The ratio of the livestock and seed input to all other inputs increases, the ratio of hired to farm husband and farm wife labor services declines, and the ratio of farm husband to farm wife labor services increases. The latter is a contradiction of a result reported in table 2. There, the ratio of farm wife to farm husband labor services increases as the share of livestock products in total output increased.

The coefficients of the variable inputs in

[8] The outputs and inputs are measured as arithmetic averages of aggregate data, but correct aggregation of outputs and inputs requires geometric averaging of microdata. The seriousness of the aggregation error is unknown, but it is unlikely to be very large in a relatively narrowly defined industry such as agriculture (Walters). When a variable is log, normally distributed, use of the arithmetic mean rather than geometric mean results in the size of the variable being generally biased because a factor of proportionality that depends on its variance is ignored. Aggregation bias is discussed in Theil and Green.

[9] Unrestricted estimates of the coefficients of equation (4) were first obtained, but high intercorrelation between the variables led to generally small t-values for estimates of some β_i's and δ. Experiments were performed on equation (4) by constraining different plausible sets of β_i's to being equal, being zero, and/or δ to being zero. The reported regression performed the best in the sense of having small residual variance and having estimated coefficients significantly different from zero. A test of the null hypothesis that the linear restrictions on the coefficients of the production function are fulfilled (i.e., $\beta_2 = \beta_3 = \beta_9 = \delta = 0, \beta_6 = \beta_7$) against the unconstrained version of the production function led to a calculated F-value of 1.571. Since the critical F-value at the 5% level with 4 and 256 degrees of freedom is 2.41, the null hypothesis cannot be rejected at the 5% significance level.

Table 3. Estimate of the Joint Product Aggregate Agricultural Production Function, 1964

	(−3.951)			
$R^2 = 0.976$	$s^2 = 0.01071$	$h = 1.513$	1.503	1.494

[a] Variables are in natural logarithms, except for extension, ρ, and state dummy variables (D_2 and D_3), which are in level form. The regression was estimated subject to linear constraints: (*a*) β_i's being 0 for Fertilizer, Machinery, Extension, and δ being 0 for ρ and (*b*) β_i's being equal for farm husband and wife labor. The "intercept" of the regression equation estimates the constant term of the log linear production function for Iowa counties. The coefficients of D_2 and D_3 estimate the change in the constant term of the log linear production function for North Carolina and Oklahoma counties, respectively. For more details of variable definitions, see table 1 and appendix.

table 3 imply sizable economies of scale for the aggregate input index (agricultural production). The size of the scale parameter evaluated at the sample's arithmetic mean for ρ (0.506) is 1.503, at the minimum observed value of ρ (0.051) is 1.513, and at the maximum observed value of ρ (0.904) is 1.494. Thus, scale economies are slightly larger for a mix of output concentrated with final crop products than concentrated with final livestock products.

The size of the agricultural extension input is largely outside the direct control of farmers. The Cooperative Extension Service is part of a mammoth publicly supported information system that supplies at a zero direct cost to farmers the decoded results and implications from basic and applied research conducted at or through the state agricultural experiment stations and the USDA. In addition, the extension agents serve as consultants to farmers on technical production problems. Thus, time spent by extension agents assisting farmers should and does contribute significantly to explaining output.

No economic significance should be placed on the signs of the estimated dummy variables. Procedures used in deriving measures of the inputs that are common to all counties within a state but that differ across states can lead to differences in the intercept of the regression.

Table 4. Change in Relative Factor Intensities as Share of Livestock Products in Total Output Increase, 1964

	Change: Column Input/Row Input[a]					
Variable Inputs	Land and Buildings	Fertilizer	Machinery	Livestock and Seed	Hired Labor	Husband Labor
Fertilizer	−					
Machinery	−	0				
Livestock and seed	−	−	−			
Hired labor	−	+	+	+		
Husband labor	−	+	+	+	−	
Wife labor	−	+	+	+	−	+

[a] Assuming cost minimization $\frac{\partial Y/\partial X_i}{\partial Y/\partial X_j} = \frac{(\alpha_i + \beta_i \rho)}{(\alpha_j + \beta_j \rho)} (X_j/X_i) = W_i/W_j$, where W_i and W_j are prices of X_i and X_j, determine the sign of $\frac{\partial(X_i/X_j)}{\partial \rho} = \frac{(\beta_i \alpha_j - \alpha_i \beta_j)}{(\alpha_j + \beta_j \rho)^2} (W_j/W_i)$. Estimates of β's and α's are taken from table 3.

The Implied Marginal Products

Implied marginal products for representative farms of each of the three states are derived from the estimated production function and sample information (see table 5). A representative farm of a state is defined as a farm in which values of variables equal subsample mean values calculated over all counties of the state. Output and the inputs land and buildings, fertilizer, machinery, livestock and seed, and education are measured in units of dollars per year, so the units on the marginal products of these inputs are dollars of output per dollar of input per year or return per year. The labor and extension inputs are measured in units of days (one-tenth for extension) per year, so the units on the marginal products of these inputs are dollars of output per (one-tenth) day of input per year. Given that the scale parameter exceeds unity (about 1.5) and assuming that marginal products are proportional to marginal factor cost for the variable inputs, the marginal factor costs (products) should be inflated (deflated) by 1.5 before comparing with marginal products (factor costs) for the variable inputs.

The implied marginal products of both the land-and-buildings input and fertilizer input for representative farms indicate that the marginal products are (significantly, except for fertilizer for the Iowa farm) less than marginal factor costs, i.e., \$1 of input produces less than \$1 of output.[10] Two possible explanations for the unusually low marginal products for the land-and-buildings input are first, that government farm programs (prior to 1964) created economic incentives (payments) to permanently retire farmland from production and to divert farmland to alternative uses. These programs could cause measurement errors in the land-and-buildings input and a small estimated coefficient on the input. Second, an overestimate of the inflation factor on prices of farmland and buildings between 1954 and 1964 (or of the interest rate) for each state would overestimate the denominator used in calculating the marginal product of land and buildings (although it would not affect estimates of the coefficient) and thereby cause a smaller marginal product than otherwise. For the fertilizer input, the marginal products are less than marginal factor costs for all three representative farms, but the difference is statistically significant (at the 5% level) only in North Carolina.

For machinery services, the implied marginal products indicate that the marginal products are significantly larger than marginal factor costs for all three representative farms. This finding is not surprising. There has been a fall in the relative price of machinery services during the 1950s and 1960s and there have been large increases in their rate of usage

[10] The implied marginal products are derived as $(\hat{\alpha}_i + \hat{\beta}_i\bar{p})\hat{Y}/\bar{X}_i$ except for extension, which is derived as $\hat{\alpha}_i\hat{Y}$, where the $\bar{X}_i$'s are geometric means of the inputs, except for extension and $\bar{p}$, which are arithmetic means, and $\hat{Y} = \exp[\hat{\alpha}_0 + \sum_{i=1}^{n} (\hat{\alpha}_i + \hat{\beta}_i\bar{p})\ln \bar{X}_i]$. These are (biased) conditional median values of the marginal products (Goldberger). To test the hypothesis that marginal products equal marginal factor costs, a test statistic was calculated as the marginal product less marginal factor cost (multiplied by 1.5 for all the variable inputs) and all divided by the approximate standard errors of the marginal products, $(\hat{Y}/\bar{X}_i)[\mathrm{var}(\hat{\alpha}_i + \hat{\beta}_i\bar{p})]^{\frac{1}{2}}$. Properties of these standard errors are discussed by Carter and Hartley and by Fisk. The test statistic is distributed approximately as the t-statistic with 260 degrees of freedom.

Table 5. Implied Average Marginal Products for Representative Farms, 1964

	Geometric Means (Subsamples)			Marginal Products[a] (Standard Errors)		
Variable	Iowa	N. Carolina	Oklahoma	Iowa	N. Carolina	Oklahoma
Aggregate output predicted (1964$/year)	20,206.3	6,693.3	7,289.3	—	—	—

[a] Regression coefficients were taken from table 3. See footnote 10 for definitions of marginal products.
[b] The numbers in brackets are cost per day in 1964 of respective type of labor. For hired labor the cost is the state average daily wage rate (USDA 1965). For husbands and wives, the cost is the geometric average daily wage rate for off-farm work by farm husbands and wives, respectively (see appendix).

(Hayami and Ruttan). However, the increase has been too small. For livestock and seed services, the marginal product is significantly larger than marginal factor cost for the Iowa and North Carolina farms, but it is significantly below marginal factor cost for the Oklahoma farm.

Turning to the farm-labor inputs, the marginal product of hired labor is larger than marginal factor cost for all three farms, and it is significantly different from marginal factor cost (at the 5% level) for the North Carolina farm (see table 5). Thus, these results imply that it would have been profitable in 1964 for North Carolina farmers to have used larger quantities of hired labor in agricultural production. For farm husband labor, the marginal product of own-farm work is larger than the marginal (opportunity) factor cost (the wage rate for off-farm work) for the Iowa and North Carolina farms, but it is less than marginal factor cost for the Oklahoma farm. The differences between marginal products and marginal factor costs, however, are not statistically significant at the 5% level for any of the farms. For farm wives, marginal (opportunity) factor cost of farm work is larger than the marginal product (but not significantly) for the Iowa and Oklahoma farms. For the North Carolina farm, the marginal product of farm wife labor is larger than marginal factor cost, but the difference is not significant here either. Thus, hired labor is the only farm-labor input in 1964 farm production that shows significant nonoptimal factor usage.

The education indexes give the income that the average education mix of farm husbands (wives) of a county would generate in the nonfarm labor market in 1959. Thus, the marginal products of education are measured as 1964 dollars of farm output per 1959 dollar of nonfarm wage input. If the increase in nonfarm

wages between 1959 and 1964 was equal to the difference between the farm and nonfarm cost of living, then the marginal products of education should be unity. For farm husbands, the marginal product of education is larger than marginal (opportunity) cost on the Iowa farm (significantly different at 8% level), but it is smaller than marginal factor cost (significant at 5% level) for the North Carolina and Oklahoma farms. For farm wives, the marginal product of education is below marginal (opportunity) cost for all three farms, but it is not significantly different from marginal cost for the Iowa farm, although differences are significant for the North Carolina and Oklahoma farms. Thus, these results imply that only on Iowa farms was it an economically wise decision in 1964 for households to have acquired additional education for husbands and wives and to have employed these skills on their own farm rather than at nonfarm work.[11]

The implied marginal product of agricultural extension is huge for all three representative farms, but it is largest for the Iowa farm. The marginal product is $303 annually (per farm) for each one-tenth day of extension time (per year) and is $100 and $109 annually per one-tenth day of extension time for the North Carolina and Oklahoma farms, respectively.[12] The size of the extension input is not under the direct control of farmers; it is determined at the aggregate level by the government sector. Thus, the relevant question is what is the social rate of return to allocation of resources to extension? Answering this question requires information on the marginal social value of added output and data on the marginal social opportunity cost of resources allocated to added units of extension. The latter data are not readily available. A conjecture, however, is that the estimated social return would roughly support Griliches's estimate of the social rate of return to agricultural research and extension (1964).

[11] Farm husband and wife labor were measured in efficiency units as the product of days of farm work per year times the education index. Thus, the estimated coefficients of education and days of farm work were constrained to being equal. Also, national average levels of income by education were used in deriving the education indexes. Locally, levels of income by education may be lower than the national average.

[12] The specification of the production function results in the marginal product of extension being a linear function of predicted output. Given the differences in the size of predicted output for the representative counties, differences in the marginal product of extension per farm could be overstated. Also, the quality of agricultural extension time may be affected by quality of research in the associated agricultural experiment station.

Conclusion

This paper focused on assessing the quantity and marginal productivity of farm husband and wife labor services allocated to their own farm work. A behavioral model of the farm firm provided a framework for assessing the actual value of human time and other inputs, including education and agricultural extension, in agricultural production. The model was implemented empirically by fitting a production function to county average per farm data for 1964 for Iowa, North Carolina, and Oklahoma counties. The estimated coefficients of the production function implied that all cost-minimizing factor ratios except one vary by product mix of output, holding relative factor prices constant.

The implied marginal products of inputs were compared with marginal factor costs for representative farms in each state. The finding of a marginal product of hired labor that was larger than marginal factor cost for representative farms for all three states (significant for North Carolina) implies underuse of the hired-labor input. Farmers could have increased their farm profits by using a larger quantity of hired labor. Although the marginal product of farm husband labor was larger than marginal (opportunity) cost for the Iowa and North Carolina farms and less than marginal factor cost for the Oklahoma farm, none of the differences was statistically significant. Similarly, the marginal product of farm wife labor was less than marginal (opportunity) cost (at nonfarm work) for Iowa and Oklahoma farms and was larger than marginal factor cost for the North Carolina farm, but again none of the differences was statistically significant. Thus, farm households seem to be allocating husband's and wife's working time between own-farm and off-farm work in a fashion that maximizes farm household income. Furthermore, these results suggest that the rural-to-urban migration of farm people and reallocation of working time of the remaining farm husbands and wives between own-farm and nonfarm work prior to 1964 have succeeded in getting rid of the excess labor services in agricultural production.

The finding for the Iowa farm that the marginal product of farm husband's education was larger than marginal opportunity cost and of farm wife's education was less than marginal opportunity cost (not significantly) implies that acquiring education with the anticipation

of employing its services in own-farm work is an economically sound decision in Iowa. However, for the North Carolina and Oklahoma farms, the marginal product of husband's and wife's education was significantly below marginal opportunity cost. Thus, the services of additional education of husbands and wives in these two states should be allocated to nonfarm work. In the future, as size of the North Carolina and Oklahoma farms increases and technology of farm production becomes more complex, the marginal productivity of education relative to marginal opportunity cost can be expected to increase.

Agricultural extension agent time is one component of the human time input in U.S. agricultural production, and the results showed that the marginal products of extension were huge (in excess of $1,000 annually per day). The size of these marginal products suggests that the rate of return on investment of federal and state funds in agricultural extension manpower compares favorably with alternative uses of these funds. Thus, perhaps we should proceed more slowly in reducing in real and absolute terms federal and state appropriations for agricultural extension. Furthermore, as extension data on time allocation become available that are equal in quality to the pre-1960 data, future research on the productivity of agricultural extension will be facilitated.

Appendix

Sources and Derivation of Labor and Education Variables

The number of days worked by hired labor per farm is derived as annual expenditures on hired labor (U.S. Dep. of Commerce 1967, table 9) deflated by the average daily wage rate for hired farm labor without board and room in 1964 (USDA 1965).

Farm husband's (wife's) man- (woman-) days per year of own-farm work are derived from weekly hours worked on farms by farm operators (nonoperator farm household members) (U.S. Dep. of Commerce 1967, county table 7). Several adjustments were made to convert the reported hours to equivalent annual days of work. First, the reported hours were adjusted to a common enumeration data; second, regression analysis followed by prediction was used to separate weekly hours of farm work by wives from hours of farm work by other nonoperator household members; and third, weekly hours were inflated by a state specific factor to make adjusted reported hours equal to average weekly hours on an annual basis. Finally, average weekly hours were converted to annual man- (woman-) days by multiplying by fifty-two weeks per year and dividing by 7.8 (6.9) hours per day. The adjustments factors for enumeration date and mean weekly hours per year were derived from unpublished USDA regional data based upon the 1966 Pesticide and General Farm Survey (USDA 1968). The factor for converting annual hours to annual days is the national average number of hours per day that farm operators (farm wives) worked at nonfarm jobs in 1965 for those who worked at nonfarm jobs (U.S. Dep. of Commerce 1968, table 16).

Farm husband's man-days of off-farm work per year equals the aggregate number of days that farm operators worked off own-farm on another farm or at nonfarm work during the census year (U.S. Dep. of Commerce 1967, county table 7) deflated by the census number of farm operators.

Wife's woman-days of off-farm work per year equal the aggregate number of days that nonoperator household members worked off the farm at nonfarm work deflated by the census number of farms (U.S. Dep. of Commerce 1967, county table 7).

The expected wage rate per day for off-farm work by farm husband (wife) is the estimated aggregate wage and salary income of farm operators (nonoperator household members) divided by the aggregate number of days of off-(non) farm work by farm operators (nonoperator household members) (U.S. Dep. of Commerce 1967, county table 7). Estimated aggregate wage and salary income of nonoperator household members is derived as total income of nonoperator members from sources other than farm operated (U.S. Dep. of Commerce 1967, county table 7) multiplied by the share that wage and salary income is of the total income from sources other than farm operated for this group at the state level (U.S. Dep. of Commerce 1967, state table 17). Estimated aggregate wage and salary income of farm operators is total wage and salary income of all farm household members minus estimated wage and salary income of nonoperator household members.

The level of education of farm husband (wife) is the income weighted average number of years of schooling completed for farm operators (nonoperator persons $\geq$ 25 years of age). The number of farm operators (nonoperator persons $\geq$ 25 years of age) in seven schooling completion classes (U.S. Dep. of Commerce 1967, county table 7) were weighted by 1959 mean incomes by schooling completion classes (Denison, table I-4, p. 223).

The Productivity and Allocation of Research: U.S. Agricultural Experiment Stations

Maury Bredahl and Willis Peterson

In this paper are presented estimates of the marginal products and internal rates of return to investment in agricultural research by commodity groups (cash grains, poultry, dairy, and livestock). The results are reported both in terms of national aggregates and on a state-by-state basis. Internal rates of return for the country as a whole range from 36% to 46%. At the state level the evidence suggests that the payoff to research is greatest for the commodities with the largest absolute value of output.

Key words: agricultural research expenditures, allocation, productivity.

The evidence forthcoming from a number of studies supports the hypothesis that investment in agricultural research in the United States has paid off with relatively high rates of return (Schultz; Griliches 1958, 1964; Peterson 1967; Evenson; Schmitz and Seckler). However, relatively little is known about the efficiency of the allocation of agricultural research. If there are differences in the rates of return to the various kinds of research, then the overall rate of return (for a given level of investment) could be increased by reallocating some research resources from the low to the relatively high return activities.

The main purpose of this article is to present estimates of the marginal products and rates of return to the four major categories of agricultural research conducted by U.S. agricultural experiment stations: cash grains, poultry, dairy, and livestock. Because research expenditures in time t will affect current and future output, estimation methods and interpretation of results must consider the lagged effect of research on output. This paper attempts to measure the long-run effect of research on output and corresponding rates of return.

The Model

We utilize aggregate agricultural production functions with research as a separate independent variable to estimate the marginal products of research. The production function approach affords an estimate of the effect of research on agricultural output and enables one to compute marginal (as opposed to average) rates of return.

The relationship of output, conventional inputs, and research is expressed in the standard Cobb-Douglas production function format.[1] The hypothesized relationship is written as

$$(1) \qquad Y_{hit} = A_i \prod_{j=1}^{p} X_{hijt}{}^{\beta_{ij}} \prod_{l=0}^{T} R_{hit-l}{}^{\gamma_l} e^{\epsilon_{hit}} ,$$

where Y_{hit} = hth observation output of ith commodity in year t, X_{hijt} = hth observation jth input in the production of ith commodity in year t, and $R_{hi,t-l}$ = hth observation research applicable to the ith commodity in the $t - l$th time period. The coefficient on research (γ_l) varies according to the date of the research input. Moving forward from year t, γ would first increase because of a lag in utilization of research but then decrease as current research becomes less related to future technology and also because of the depreciation of knowledge.

The model implies that the marginal pro-

Maury Bredahl is a former graduate student and Willis Peterson is a professor of agricultural and applied economics at the University of Minnesota, St. Paul.

The authors are indebted to Finis Welch for helpful comments on a previous draft of this paper.

[1] The use of a Cobb-Douglas production function implies unitary elasticity of substitution between inputs. Shatava reports an estimated elasticity of substitution of 1.126 from the regression of the log of the value added per unit of labor and log of the wage for hired farm labor (U.S. Dep. of Commerce 1972). The estimate is not significantly different from one. However, agricultural production functions are probably not homothetic, much less homogeneous. In practice, nonhomothetic production functions are difficult to estimate; the assumed Cobb-Douglas form is for simplicity and hopefully the marginal products of research are not affected.

ductivity of research should be differentiated with respect to time. Hence, the following definitions are in order. The short-run marginal product (*SMPR*) of research is the effect of current research on current output: $SMPR_{hit} = \partial Y_{hit}/\partial R_{it} \equiv \gamma_o Y_{hit}/R_{hit}$. The long-run marginal product of research (*LMPR*) measures the effect of current research on current and future output:

$$LMPR_{hit} = \sum_{l=0}^{T} \partial Y_{hi,t+l}/\partial R_{it} \equiv \sum_{l=0}^{T} \gamma_l \; Y_{hi,t+l}/R_{hi,t+l}.$$

The hypothesized production relationship could be estimated with time-series cross-section data. Unfortunately, such data are not available; we are limited to a single-year—1969—cross section. Thus, the estimation model is specified as

$$(2) \qquad Y_{hi} = A'_i \prod_{j=1}^{p} X_{hij}^{b_{ij}} \, R_{hi} \, e^{u_{hi}}.$$

Because a single-year cross section is utilized to estimate the parameters of the time-series cross-sectional model, the consequence of omitting lagged research expenditures should be determined. If we assume that research has been increasing at a constant rate over time such that $R_{t-1} = kR_t$, where $0 < k < 1$, the model can be simplified to[2]

$$\ln Y_{hit} = \ln A_i + \sum_{j=1}^{p} \beta_{ij} \ln X_{hij} + \ln R_{hit}\Big(\sum_{l=0}^{T} \gamma_l\Big) + \ln K\Big(\sum_{l=0}^{T} l\gamma_l\Big).$$

The expected values of the coefficients of the estimation model are $E(\ln \hat{A}'_i) = \ln A_i + C$, $E(\hat{b}_{ij}) = \beta_{ij}$, and $E(\hat{\delta}) = \sum_{l=0}^{T} \gamma_l$. Therefore, utilizing current year research as the research variable biases the expected value of the estimated constant term ($\hat{A}'$) of the production function upward but does not bias the expected value of the estimated coefficients of the conventional inputs (X_{ij}). More important, what effect does the misspecification of the model have on the expected value of the estimated marginal production of research?

The expected value of the estimated marginal product of research (evaluated at geometric means) is $E(\partial Y_t/\partial R_t) = E(\hat{\delta}) \cdot (\bar{Y}_t/R_t)$. Substituting and expanding, $E(\partial Y_t/\partial R_t) = \gamma_o(\bar{Y}_t/\bar{R}_t) + \ldots + \gamma_l(\bar{Y}_t/\bar{R}_t)$. This measure is clearly larger than the defined short-run marginal product of research.

The relationship to the long-run marginal product of research may be determined. Recalling $R_{t-1} = kR_t$, $k < 1$,

$$LMPR = \gamma_o \left(\frac{\bar{Y}_t}{\bar{R}_t}\right) + \gamma_1 \left(\frac{\bar{Y}_t}{k\bar{R}_t}\right) + \ldots + \gamma_l\left(\frac{\bar{Y}_t}{k^l\bar{R}_t}\right).$$

The expected value of the estimated marginal product of research is clearly less than the long-run marginal product of research because each $\bar{R}_t$ after the first term in the *LMPR* definition is multiplied by a constant which is less than one. The marginal product of research (*MPR*) in time t is indicated by

$$LMPR = \gamma_o \left(\frac{\bar{Y}_t}{\bar{R}_t}\right) + \gamma_1 \left(\frac{\bar{Y}_{t+1}}{\bar{R}_t}\right) + \ldots + \gamma_l \left(\frac{\bar{Y}_{t+l}}{\bar{R}_t}\right).$$

The relationship of the expected value of the estimated *MPR* and the "true" *MPR* is dependent on the level of future research and conventional input use. To the extent that these figures increase in a manner that increases the average product of research, the estimated value of *MPR* underestimates its "true" value. If so, then the estimated marginal products of research obtained in this study can be regarded as lower bound estimates of the *LMPR*.[4]

[2] The assumption of an identically constant rate of increase in research for each state is somewhat unrealistic. However, essentially similar results are obtained if k is randomly distributed with some mean $\bar{k}$ and variance σ_k. The mean might be interpreted as the national average rate of growth in research expenditures with the growth rate of the states distributed about the national average rate of growth (see Bredahl).

[3] The geometric mean values of output and research are $\bar{Y}_t$ and $\bar{R}_t$, respectively.

[4] The functional form of the research branch determines the interpretation of the estimated results. The ith production function may be written as

$$Y_{it} = A_i \prod_{j=1}^{p} X_{ijt}^{\beta_{ij}} R'^{\gamma}_{it},$$

where R'_{it} is interpreted as the "stock of research" at time t. If the research measure is a linear function of past research $R'_{it} = \delta_o R_t + \delta_1 R_{t-1} + \ldots + \delta_l R_{t-l}$ and if $R_t = kR_{t-1}$, substituting and expanding yields $R'_{it} = \delta_o R_t + \delta_1 kR_t + \ldots + \delta_l k^l R_t$. This model also implies that $\hat{\gamma}$ is an unbiased estimate of the marginal product of the stock of research. The specification of the research branch in this manner may lead to different methods of calculating rates of return and interpretation of the estimated marginal product of research.

The Variables and Data

Output is measured as average value of output per farm for each of four types of farms (cash grains, dairy, poultry, and livestock) as reported by the *1969 Census of Agriculture* (U.S. Dep. of Commerce 1972, 1973a, b). A farm is included in a "type of farm" classification if over 50% of its sales are of a given commodity type. These four farm types account for over 80% of all farms and sales of agricultural products in the United States. A more accurate measure of the relationship between output and its related research may be obtained if the dependent variable in each production function includes only that output that corresponds to the farm classification. For example, any livestock production that may have taken place on cash grain farms is not included in the dependent variable of the cash grains production function and vice versa. Also, constant prices are used to aggregate output in order to remove the effect of interstate price differences. More specific definitions of the four variables are presented in the appendix.

To the extent allowed by the data, the conventional inputs are selected and measured to reflect as closely as possible the output included in the dependent variables. For example, the land input in the cash grains function includes only the harvested acreage of the crops included in the output. Of course, for certain inputs it is not possible to apportion their use exactly to the output included. For example, tractors and equipment on cash grain farms no doubt are utilized in the production of other crops such as cotton in the South and West and sugar beets in the Midwest and West. In order to obtain asymptotically unbiased estimates of slope coefficients, an instrumental variable (IV) estimation technique is utilized in addition to ordinary least squares (OLS).[5] Again, interstate price differences that are not considered to reflect quality differences are removed. Specific definitions of the independent variables and data sources are presented in the appendix.

Because production decisions are made at the farm level, the farm is the proper unit of observation for the dependent and conventional independent variables. However, it is not clear that a per farm average is the correct specification for the research variable. Previous studies have utilized both per farm averages (Griliches 1964, Evenson) and state totals (Peterson 1967). Dividing total state research by number of farms obtaining a per farm average implies that the number of farms is a proxy for the number of problems faced by scientists, the greater the number of farms the greater the diversity of problems. On the other hand, the use of the state total as the research variable treats research as a public good. In this case, the research variable, which can be viewed as a proxy for the output of the experiment station, is not altered by the number of farms in the state. For example, halving the number of farms in a state should not double the measured research output of the experiment station. Certainly both specifications of the research variable have some justification. Perhaps the "true" specification lies somewhere between the two. An empirical test can be made to determine which specification comes closest to the truth.

Each of the aggregate production functions estimated in this study may be written as $\Sigma Y/n = A \prod_i (\Sigma X_i/n)^{\beta_i}(R/n^{\alpha})^{\beta_r}$, where ΣY is the sum of the appropriate output of the particular class of farms in the state, ΣX_i is the sum of the appropriate conventional inputs, R is the total appropriate research, and n is the number of farms in the particular class. If α equals one, then research per farm is the correct specification, whereas total state research is correct if α is estimated to be zero. Estimates of α are obtained from the following equation: $\ln(\Sigma Y/n) = \ln A' + \Sigma b_i \ln(\Sigma X_i/n) + b_r \ln R - c \ln(n)$. The estimated coefficient ($\hat{c}$) of the number of farms is an estimate of the product $\alpha\beta_r$. Because $\hat{b}_r$ is an estimate of β_r, $\hat{\alpha}$ is easily estimated by dividing $\hat{c}$ by $-\hat{b}_r$ and can be statistically tested for equality to one or zero. Estimates of α for each of the four production functions are cash grains, −0.123, dairy, 0.301, poultry, 0.073, and livestock, −3.720. The estimated value of α is significantly different from one in all four equations and is not significantly different from zero in the first three.[6] (The relatively large negative value for

[5] This technique is of the general form $\hat{b} = (Z'X)^{-1} Z'Y$, where Z is the matrix of instrumental variables, X is the matrix of independent variables, and Y is the column vector of the dependent variable. For each independent variable, the deviations from the mean are calculated and then rank ordered from smallest to largest. The deviates compose the X matrix and the rank ordering the Z matrix. It can be shown that b is a consistent estimator of each slope coefficient (see Durbin).

[6] The test is conducted by comparing the error sum of squares from the regressions where it is restricted to one and to zero with the error sum of squares, which is obtained when it is unrestricted.

α in the livestock equation is something of a puzzle.) The results suggest that the research per state is closer to the "true" specification than research per farm. Thus, the former is utilized in all four production functions.

State experiment station research expenditures are obtained from the *Inventory of Agricultural Research, F.Y. 1969 and 1970* (USDA 1970d). The composition of each research variable is explained in the appendix.

Regression Results

As mentioned, the possibility of errors in variables due to the inability to exactly apportion all inputs to the output measure prompted the use of the instrumental variable (IV) estimation technique to supplement ordinary least squares (OLS). The regression results obtained from the OLS and IV techniques for the four production functions are presented in tables 1 through 4.

By and large, the regression coefficients have reasonably large t-values. One exception is fertilizer in the cash grains function when the coefficient is restricted to a single value for all observations. This is somewhat unexpected in view of the importance of fertilizer in crop production. However, soybeans and wheat do not receive heavy applications of commercial fertilizer. In cash grains production, corn is by far the major fertilizer user. In order to take account of the diversity of fertilizer use stemming from differences in crops grown, the country is divided into three regions, as shown in table 1, with slope dummies on the fertilizer variable allowing the coefficient to take on different values for different regions.

Of most interest are the research coefficients. Ranging from 0.04 for cash grains to 0.10 for livestock, they bracket the 0.059 coefficient on all agricultural research obtained by Griliches from 1949–54–59 data (Griliches 1964). The 0.061 poultry research coefficient obtained here is virtually identical to the 0.062 coefficient reported by Peterson from 1959 data (Peterson 1967).

Table 1. Estimates of the Cash Grains Production Function

Inputs	OLS	IV
Fertilizer[a]		
Southeast	0.011 (0.2)	0.038 (0.8)
Corn Belt	0.111 (2.3)	0.137 (2.8)
Other	0.071 (1.9)	0.102 (2.3)
Labor	0.234 (3.5)	0.251 (3.2)
Land	0.207 (2.7)	0.192 (2.0)
Chemicals	0.074 (2.1)	0.081 (1.9)
Seed	0.164 (2.3)	0.132 (1.5)
Machinery	0.455 (3.2)	0.447 (2.4)
Research	0.038 (1.5)	0.041 (1.6)
$\bar{R}^2$	0.95	
Sum of coefficients[b]	1.18	1.14

Note: Figures in parentheses are t-values. 41 observations.
[a] The reference dummy is the group of states not included in the southeast and corn belt. The OLS t-values on the fertilizer slope dummies are: southeast, −3.0; corn belt, 1.9; and the IV t-values are: southeast, −3.1; corn belt, 1.6.
[b] For cash grains the sum of coefficients is computed from the regression where fertilizer is restricted to a single coefficient for all observations. In all cases the sum of coefficients excludes the research variable.

Table 2. Estimates of the Dairy Production Function

Inputs	OLS	IV
Dairy cattle	0.204 (3.3)	0.177 (2.5)
Labor	0.548 (8.4)	0.632 (7.9)
Land and buildings	0.062 (2.8)	0.077 (2.8)
Pasture	0.055 (2.3)	0.046 (1.8)
Feed	0.209 (4.2)	0.151 (2.3)
Research	0.042 (2.7)	0.054 (2.9)
$\bar{R}^2$	0.99	
Sum of coefficients	1.08	1.08

Note: Figures in parentheses are t-values. 48 observations

Marginal Products and Rates of Return

The estimated coefficients of the IV estimates are utilized to compute the marginal products of experiment station research. The research variable is measured as research per state while output is measured as output per farm. Thus, the estimated marginal product of research is measured on a "per farm" basis. To obtain an estimate of "per state" marginal

Table 3. Estimates of the Poultry Production Function

Inputs	OLS	IV
Feed	0.591 (5.4)	0.530 (4.1)
Poultry purchased	0.261 (2.6)	0.282 (2.5)
Land and buildings	0.145 (4.0)	0.123 (2.9)
Labor	0.163 (2.4)	0.185 (2.3)
Research	0.071 (1.8)	0.061 (1.5)
$\bar{R}^2$	0.93	
Sum of coefficients	1.16	1.12

Note: Figures in parentheses are t-values. 48 observations.

Table 4. Estimates of the Livestock Production Function

Inputs	OLS	IV
Feed	0.470 (4.6)	0.547 (4.6)
Land and buildings	0.290 (4.0)	0.261 (3.3)
Labor	0.147 (1.2)	0.067 (0.7)
Livestock	0.137 (1.4)	0.137 (1.2)
Research	0.109 (4.2)	0.099 (3.7)
$\bar{R}^2$	0.92	
Sum of coefficients	1.04	1.01

Note: Figures in parentheses are t-values. 46 observations.

products, the "per farm" estimate is multiplied by the number of farms.

Estimates of national "average" marginal products of research are obtained by using the geometric mean levels of inputs and outputs and the arithmetic average number of farms. The computed marginal product is $M\hat{P}R_i = \hat{b}_{ri}\bar{n}_i(\bar{Y}_i/\bar{R}_i)$. These estimates are given in table 5.

The estimated marginal product of research approximates the long-run marginal product of research, that is, the expected total returns from $1 invested in 1969. Evenson's work suggests the lag structure of agricultural research resembles that of an inverted "V." The estimated marginal products are approximations of the total area under the inverted "V" lag structure. The calculation of internal rates of return requires that the future returns be discounted. The internal rate of return is approximated by the following:[7]

$$\sum_{t=0}^{T}(\partial Y_{t+i}/\partial R_t)/(1 + IRR)^t - 1 = 0.$$

The calculated internal rates of return are dependent on the mean lag of the lag structure.

According to Evenson's results, the mean lag (high point of the inverted "V") for all agricultural experiment station research is in the neighborhood of six to seven years. However, estimates of the mean lag of research of the commodity groups of interest in this paper are not available. One might reasonably expect that the lag is somewhat shorter for crops where the possibility exists for large numbers of research trials to be carried on simultaneously than for livestock where biological processes probably constrain the pace of research more severely. For lack of better information, we assume the mean lag to be a bit shorter than average for cash grains, about average for poultry and dairy, and a shade above average for livestock, as shown in column two of table 5.[8]

In order to arrive at conservative estimates of rates of return, the marginal product figures in table 5 are divided by a factor of three to take account of public extension and private research.[9] This procedure is likely to bias the estimated rates of return downward for two reasons. First, it is unlikely that research results would go unnoticed in the absence of public extension or that the extension lags are this long. The rate of return to extension should be computed separately on the basis of how much it speeds up the adoption of the new technology (see Huffman). Second, the cost of private research must already be included in the prices of purchased inputs. Thus, we are in effect double-counting the cost of private research. However, it is still necessary to take account of private research because the coefficients on public research probably are picking up the excess of social over private returns to private research (see Peterson 1976).

If the lags that are specified in table 5 are reasonably accurate, at least in relative terms, the internal rates of return (IRR) of these four major categories of research are not grossly different. On the basis of this evidence, one might conclude that from a national standpoint agricultural experiment station research is being allocated fairly efficiently, at least across these four major categories.[10] Of course, if

Table 5. Marginal Products and Marginal Internal Rates of Return to Experiment Station Research

	Marginal Products ($)	Assumed Lag (years)	IRR (%)
Cash grains	14.09	5	36
Poultry	19.58	6	37
Dairy	25.93	6	43
Livestock	41.76	7	46

[7] The internal rate of return in this case is that rate of interest that makes the discounted returns of $1 of research invested in year t equal to the $1.

[8] One might argue that dairy and livestock should have about the same mean lag. However, the beef, hog, and sheep research that make up the livestock category is somewhat more oriented towards breeding work than is dairy research. Breeding research would seem to have a longer lag than research, which bears upon management, such as feeding and health practices.

[9] In recent years extension expenditures have been about equal to research. The magnitude of private research also is believed to be about equal to public research.

[10] Further support of the seemingly efficient allocation of research expenditures may be found by comparing the estimated marginal products of research assuming identical lag structures. In this case

evidence should come to light that suggests that the cash grains lag is really longer than that specified and/or the livestock lag shorter, then the estimated rates of return would diverge even more. Also, it is evident that the marginal social rates of return to investment in these four categories of research are relatively high, especially in view of the downward biases mentioned above.

In the context of a Cobb-Douglas production function, the marginal product of research depends upon two factors: the coefficient on the research variable (the production elasticity) and the average product of research, i.e., dollars of output per dollar of research.[11] Experiment stations that exhibit above average production elasticities on research, say, because of more competent and productive research workers and/or because of more dollars of output per dollar of research, will in turn enjoy higher marginal products and rates of return to research than their less productive or smaller average product counterparts.

In order to test for possible differences in the production elasticities of research across states, the sample for each research category is divided into three groups according to the size of their average products of research, with each group having about equal numbers of observations. The same production functions are then run with slope dummies on the research variables allowing the research variable to take on a different value for each group. (The smallest average product states constitute the reference dummy.) The coefficients and t-ratios on the slope dummies are presented in table 6. As shown, none of the slope dummies are significantly different from zero.

These results are consistent with the hypothesis that the coefficients on the research variables are not significantly different between comparable departments or between experiment stations. This does not mean that research workers are equally productive across departments or experiment stations. What it may imply is that the market for research workers is functioning rather efficiently. Workers with above average productivity receive above average compensation, and vice versa.

Table 6. Research Slope Dummies by Average Product Groups (IV Estimates)

	Middle Third	Highest Third
Cash grains	0.004 (0.6)	−0.010 (−0.8)
Poultry	−0.008 (−0.7)	−0.009 (−0.7)
Dairy	0.001 (0.1)	0.001 (0.3)
Livestock	0.018 (0.3)	0.021 (0.9)

Note: Figures in parentheses are t-ratios.

The results presented in table 6 also are consistent with the hypothesis of constant returns to scale of departments or research areas as denoted by the four categories of research. Except for dairy, the absolute size of the research establishment is positively correlated with the average product of research.[12] If there are economies of scale, then the larger departments or research areas should exhibit larger production elasticities, which they do not.

If the production elasticities of the departments corresponding to the four commodity groups do not differ by size of average product, then differences in average products between states should reflect differences in marginal products and rates of return. Using the research coefficients shown in table 5 (IV estimates), the marginal products of the four research categories for each state are presented in table 7. (These figures are not adjusted for extension and private research.)

It is evident from the marginal product figures in table 7 that substantial differences exist between states in the rates of return to investment in each of the four areas. By and large, the rates of return are highest in those states where the product makes up a large share of the agricultural output of the state and is large relative to the research input. For example, Illinois leads in the marginal product

equality of marginal products is a sufficient condition for equality of internal rates of return. The variance of the MPR's is approximated by $\mathrm{var}(n_i b_i \hat{Y}_i/\hat{R}_i) \simeq n_i^2(\bar{Y}_i/\bar{R}_i)^2 \ \mathrm{var}(\hat{b}_i)$. These estimated variances may be used to construct confidence intervals of the difference of the difference of any two marginal products (see Miller): $MPR_i - MPR_j \pm t_{(n-k/1-\alpha/2)} [\hat{S}^2_{MPR_i} + \hat{S}^2_{MPR_j}]^{\frac{1}{2}}$. For all pairwise comparisons, the confidence interval contained zero; therefore, the marginal products cannot be judged to be significantly different.

[11] The same holds true for the so-called "index number" approach of evaluating research. In this case, the "k" is comparable to the production elasticity of research and the absolute value of output is comparable to the average product (see Griliches 1958 and Peterson 1967).

[12] The average research expenditure per station for each of the four research categories by the three average product groups follow (thousands of dollars):

	Low	Middle	High
Cash grains	258	413	823
Poultry	202	312	409
Dairy	462	417	438
Livestock	514	616	1,061

Table 7. Marginal Products of Research, the Several Production Functions, by State

	Production Function			
State	Dairy	Cash Grains	Poultry	Livestock
Maine	$ 7.21[a]	n.a.[b]	$26.97	$ 3.72
New Hampshire	9.80	n.a.	3.40	17.15

Colorado	41.45	16.73	9.73	61.97
New Mexico	15.26	6.52	3.81	29.37
Arizona	7.38	2.14	5.23	11.01
Utah	7.38	2.12	9.70	13.80
Nevada	3.93	n.a.	1.43	10.18
Washington	11.52	9.88	4.42	9.10
Oregon	7.29	4.60	9.28	8.94
California	20.48	6.17	19.32	18.22

[a] The marginal products of research are not adjusted for private research and extension expenditures. To accomplish this correction, each marginal production is divided by 3. Average products may be calculated if the partial production elasticity is known. The partial production elasticities are: dairy, 0.054; cash grains, 0.041; poultry, 0.061; and livestock, 0.099. The average product is derived by dividing the marginal product by the partial production elasticity.

[b] All states with marginal products indicated by the not applicable (n.a.) notation are not included in the sample, i.e., did not have farms classified as cash grain farms, etc.; therefore, estimates of marginal products may not be calculated.

of cash grains research, Arkansas in poultry, Wisconsin in dairy, and Minnesota in livestock.

Also, it appears that some differences exist in the rates of return within states between the four commodity groups, although in this case one should be mindful of possible differences in lags. But when marginal product differences reach the magnitude of ten to twenty times, it is unlikely that differences in lags can equalize rates of return. Also, there are a number of states where the marginal products are higher for cash grains and poultry, which are likely to have the shortest lags. Again within states, the marginal products (and rates of return) for the most part turn out to be the highest for the large and important product categories in each state. For example, livestock research in Kansas appears to have a substantially higher payoff than poultry research, whereas the opposite is true in Arkansas.

In viewing these results, one should be mindful of possible spillover effects of research between states. It seems reasonable to believe that states having the largest departments or research areas are net exporters of research results. If so, this would have the effect of biasing the estimated marginal products of the small stations upward, while the marginal products of the large stations would be biased downward. (This could explain the apparent equality of coefficients between large and small departments.) The possibility of such a bias suggests that the measured differences between the large and small marginal products may be even greater than the results indicate because the highest marginal products tend to be associated with the largest departments.

The general conclusion that the absolute value of the related output has an important bearing on the rate of return to research is, of course, not new. Griliches demonstrated the importance of the value of related output in his hybrid corn study by comparing the rate of return of hybrid corn research to that of sorghum research (Griliches 1958). The figures in table 7 provide a more comprehensive and detailed picture of the payoff matrix.

Of course, the figures in table 7 should be viewed as general orders of magnitude rather than exact, accurate-to-the-penny marginal products. Because the production elasticities are averages over groups of departments or research areas, it certainly would be possible for a given department staffed by very compe-

tent and productive people to exhibit an above average production elasticity. Even if such a department was associated with a below average output per dollar of research (average product), its marginal product may equal or exceed a less productive department that enjoys a higher average product. Certainly good judgment and common sense still must be used in research allocation; the figures in table 7 are intended to complement rather than serve as a substitute for good judgment.

Appendix

Measuring Output and Inputs

This appendix does not detail the construction of each variable for each production function. Rather, the discussion is intended to present the general point of view adopted for variable construction and to illustrate the techniques utilized. Because the estimated functional relationships are advertised to be aggregate production functions, variables are constructed to reflect variation in physical quantities (free of price variation) rather than total sales or cost measures. Although considerable effort was made to obtain accurate measures of the variables, one should be mindful of possible measurement errors in the data itself.

Output. Output measures are constructed to reflect variation in physical quantities produced. The constructed output measures of cash grains and dairy reflect the two general approaches to measure output. Cash grains = $\Sigma_i Y_i \bar{P}_i$, where Y_i is bushels of each type of cash grain produced (U.S. Dep. of Commerce 1972), and $\bar{P}_i$ is national average price of each type of cash grain (USDA 1970a).

The first step in measuring dairy output was the construction of an index reflecting price variation: $Index_k = \Sigma_i (S_{ik}/\Sigma_i S_{ik})(\bar{P}_i/P_{ik})$, where S_{ik} is sales of ith dairy product in kth state (USDA 1970b), $\bar{P}_i$ is national price of ith dairy product (USDA 1970a), and P_{ik} is state average price of ith dairy product in kth state (USDA 1970a). The measured dairy output was constructed via $Dairy\ Output_k = (Sales_k)(Index_k)$, where $Sales_k$ is sales of dairy products in kth state (U.S. Dep. of Commerce 1972).

The poultry output variable is formed in the same manner as the dairy output variable.

Livestock output is computed from $Output_k = \Sigma_i Value_{ik}(No.\ Sold_{ik})$, where $Value_{ik}$ is average value of production per animal of ith livestock type in kth state (USDA 1970b), and $No.\ Sold_{ik}$ is number of animals sold of each livestock type in kth state (U.S. Dep. of Commerce 1972).

Inputs. The labor variable for all production functions was constructed in the following manner: $L_1 = P_o L_o + P_u L_u + P_h H/W$, where L_1 is calculated man-days of labor used in production of products agreeing with type of farm classification (U.S. Dep. of Commerce 1973b), P_o, P_u, and P_h are reported proportion of total operator, unpaid (family), and hired labor used in production of products agreeing with the type of farm classification (U.S. Dep. of

Commerce 1973b), L_o and L_u are total man-days of operator and family labor (U.S. Dep. of Commerce 1972), H is dollars expended for hired and contract labor (U.S. Dep. of Commerce 1972), and W is composite wage rate (USDA 1969). The variation of wage rates was believed to reflect differences in the quality of labor. Hence, the final labor variable was measured by $L_2 = (W_k/\overline{W})\ L_1$, where W_k is the kth state average composite wage (USDA 1969), and $\overline{W}$ is national average composite wage (USDA 1969).

The land variable is very difficult to measure. For crop production, harvested acres (U.S. Dep. of Commerce 1972) was chosen as the appropriate variable. This variable does not reflect variation in land quality. However, the bias of this omitted variable may be determined; the bias resulting from the use of an inappropriate quality adjustment is not known.

Pasture is a direct input into the dairy and livestock production function measured as pastured acres (U.S. Dep. of Commerce 1972). For poultry production land serves only as a site of production. The livestock, dairy, and poultry functions must include some measure of capital in the form of buildings. The measure used is *Buildings and Capital*$_k$ = $(Value_k)(\overline{L}/L_k)$, where $Value_k$ is market value of land and buildings in kth state (U.S. Dep. of Commerce 1972), $\overline{L}$ is national average per acre value of land (USDA 1970b), and L_k is the kth state average per acre value of land (USDA 1970b).

The research variable is the sum of expenditures for products agreeing with this type of farm classification. For example, the livestock research variable includes research for sheep, beef, swine, and pasture; dairy includes dairy and pasture research (USDA 1970d).

The other variables are too numerous to detail. Therefore, a very brief description of the other variables in each production function follows. For cash grains, fertilizer is the tons of fertilizer applied adjusted by an index expressing the variation in nutrient content of the fertilizer (U.S. Dep. of Commerce 1973b). Chemicals is measured as the dollars of agricultural pesticides applied deflated by prices of major pesticides (U.S. Dep. of Commerce 1972 USDA 1970c). Seed is the dollars of seed purchased (U.S. Dep. of Commerce 1972). Machinery is the service flow of machinery plus the deflated expenditures for energy sources plus hired machinery and customwork (U.S. Dep. of Commerce 1972). For dairy, dairy cattle is number of lactating dairy cows adjusted by an index of dairy cow prices (U.S. Dep. of Commerce 1972, USDA 1970b). Feed is the dollars of feed purchased and produced on the farm adjusted for regional price differences (U.S. Dep. of Commerce 1972, USDA 1970a). For poultry, feed is measured by dollars expended for feed adjusted for regional price differences. (U.S. Dep. of Commerce 1972, USDA 1970a). Poultry purchased is the purchases of poults and chicks adjusted for regional price differences (U.S. Dep. of Commerce 1972, USDA 1970a). For livestock, feed is the dollars of feed purchased and produced on the farm adjusted for regional price differences (U.S. Dep. of Commerce 1972, USDA 1970a). Livestock is the service flow of breeding stock weighted by on-farm price of each type plus the value of purchased livestock (U.S. Dep. of Commerce 1972, USDA 1970a).

Impacts of Market-Share Patterns on Marketing Firm Costs

Ronald Raikes and Arnold Heubrock

Uniform market-share patterns have been assumed in specifying cost functions for assembly or delivery operations. A more realistic assumption is that market share decreases with distance from the plant. Procedures for specifying assembly or delivery-cost functions for alternative linear market-share patterns and for determining impacts of changes in market-share patterns on costs and related results are developed and applied in an analysis of anhydrous ammonia retailing. These procedures permit more accurate estimates of cost-volume relationships and make it possible to address questions about how firms should attempt to achieve volume increases.

Key words: assembly, cost functions, delivery, fertilizer retailing, market share.

Many marketing firms have in addition to their in-plant operations assembly or delivery operations that require trips from the plant to each supply or demand point. A common procedure for measuring cost-output relationships for these firms is to estimate cost functions for the in-plant operation and for the assembly operation or the delivery operation or both and then to sum these functions to obtain a cost function for the combined operations. To specify a cost function for the assembly or delivery operation, an assumption is needed about the firm's market-share pattern. The market-share pattern defines the firm's trade area (i.e., the area in which the firm has a positive market share) and shows the firm's percentage market share at each point within its trade area. In earlier studies, it has been assumed that the firm's percentage market share is the same at each point within its trade area (e.g., studies by Anderson, Jorgensen, and Nelson; Araji and Walsh; and Mikes, Fletcher, and Futrell). This assumption has been popular not because it has been verified in empirical studies but because a procedure for incorporating other and perhaps more realistic assumptions about the market-share pattern into the specification of assembly and delivery-cost functions has not been developed. The development of a procedure for incorporating other market-share assumptions would make it possible to obtain more accurate estimates of cost-output relationships and to determine the impacts of changes in market-share patterns on firm costs.

In this article, a procedure for incorporating alternative assumptions about the firm's market-share pattern into the specification of assembly and delivery-cost functions is developed, qualitative impacts of changes in the market-share pattern on firm costs and other related results are shown, and results of an empirical study of impacts of changes in market-share patterns on costs of retailing anhydrous ammonia fertilizer are presented. Although the discussion focuses on impacts of market-share patterns on delivery costs, the application of the analysis to impacts of market-share patterns on assembly costs requires only a reinterpretation of some of the variables and parameters.

Delivery Cost Functions for Alternative Market-Share Patterns

To begin the analysis, some assumptions about a firm's delivery operation are introduced and a delivery-cost identity is specified. Next, a delivery-cost function is derived for a uniform market-share pattern. Then, a more general assumption about the market-share pattern is introduced, and a delivery-cost function for this market-share pattern is derived.

Ronald Raikes is an assistant professor of economics at Iowa State University, Ames, and Arnold Heubrock is a commodity broker at ACLI Inc., Minneapolis, Minnesota.

Journal Paper No. J-8138 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa. Project No. 1874.

Delivery-Cost Identity

To develop a delivery-cost identity, consider a firm that manufactures or processes a product and delivers the product from its plant to customers. Assume that the length of the delivery season is fixed, that a single delivery technology exists, that i different types of equipment are required for each delivery, and that the volume per delivery, number of stops per delivery, and average travel speed are constant. Then total annual delivery costs (TDC) for the firm may be expressed as

$$(1) \qquad TDC = (b_0 + b_1\bar{D})Q + \sum_i F_i N_i,$$

where

$$(2) \qquad N_i \geq (g_{0i} + g_{1i}\bar{D})Q/H_i,$$

and b_0 is the constant cost per unit of product associated with loading, unloading, and waiting; b_1 is the cost per unit of product per mile traveled, plus return, including operator labor and equipment operating costs; $\bar{D}$ is the average one-way road distance traveled per unit of product delivered; Q is units of product delivered per season; F is the annual cost of owning or renting a unit; N is the number of units; g_0 is the constant time requirement per unit of product delivered; g_1 is the time requirement per unit of product delivered per mile, plus return; H is hours available per season; and i is the type of delivery equipment. The first term on the right-hand side of equation (1) may be interpreted as the total variable delivery costs and the second term as the total fixed delivery cost.

If fractional delivery units may be added to the firm (e.g., if the firm can rent a unit for part of the season), then inequality (2) may be changed to an equation, and this equation may be used to eliminate N_i from equation (1):

$$(3) \quad TDC = (b_0 + b_1\bar{D})Q + \sum_i F_i)g_{0i} + g_{1i}\bar{D})Q/H_i.$$

A delivery-cost function can be obtained from equation (3) by eliminating $\bar{D}$. But to eliminate $\bar{D}$, some additional assumptions must be introduced concerning the nature of the road system, demand density, and market share.[1] Two models are considered. In both, it is assumed that the firm's trade area is served by a square grid road system and that demand density is uniform throughout the firm's trade area. In model I, the market share is assumed uniform throughout the firm's trade area. In model II, market share is assumed to be a linear function of distance from the plant.

[1] Demand density is the quantity of product demanded per unit area per time period, e.g., the tons demanded per square mile per season.

Model I: Uniform Market-Share Pattern

A delivery-cost function for model I can be derived by first expressing $\bar{D}$ as a function of quantity delivered, density, and the uniform market share and then using this expression to replace $\bar{D}$ in equation (3).

Following French, an expression relating $\bar{D}$ to quantity delivered, density, and the uniform market share may be derived as follows. With a square grid road system, the least-cost shape of the firm's trade area is a square tilted 45° to the road network. Let R represent the road distance in miles from the plant to the boundary of the firm's trade area. The firm's market share (S) at a point r road miles from the plant is given by $S = M$, where $0 \leq M \leq 1$, if $r \leq R$, and by $S = 0$ if $r > R$. This market-share pattern is depicted graphically by the solid lines in figure 1a. Let P represent the uniform demand density. The quantity of product delivered in a trade area that extends R miles from the plant to the boundary of the trade area is

$$(4) \qquad Q = 2PMR^2,$$

and average hauling distance is

$$(5) \quad \bar{D}_I = \text{total ton miles/total tons delivered} = (4PM/Q) \int_0^R \int_0^{R-x} (x + y)dydx = 2R/3.$$

Equation (4) may be used to eliminate R from equation (5) so that average hauling distance is given by

$$(6) \qquad \bar{D}_I = 0.4714(Q/PM)^{\frac{1}{2}}.$$

Finally, the long-run total delivery cost function for model I is obtained by substituting equation (6) into equation (3):

$$(7) \quad LTDC_I = [b_0 + B_I Q^{\frac{1}{2}} + \sum_i F_i(g_{0i} + G_{Ii}Q^{\frac{1}{2}})/H_i]Q,$$

where $B_I = (0.4714)b_1(PM)^{-\frac{1}{2}}$, and $G_{Ii} = g_{1i}B_I/b_1$. Equation (7) might be termed a restricted long-run, delivery-cost function; it is long run because the amount of delivery equipment is allowed to vary, but it is restricted because only one delivery technology is considered.

Equation (7) may be used to obtain, for a

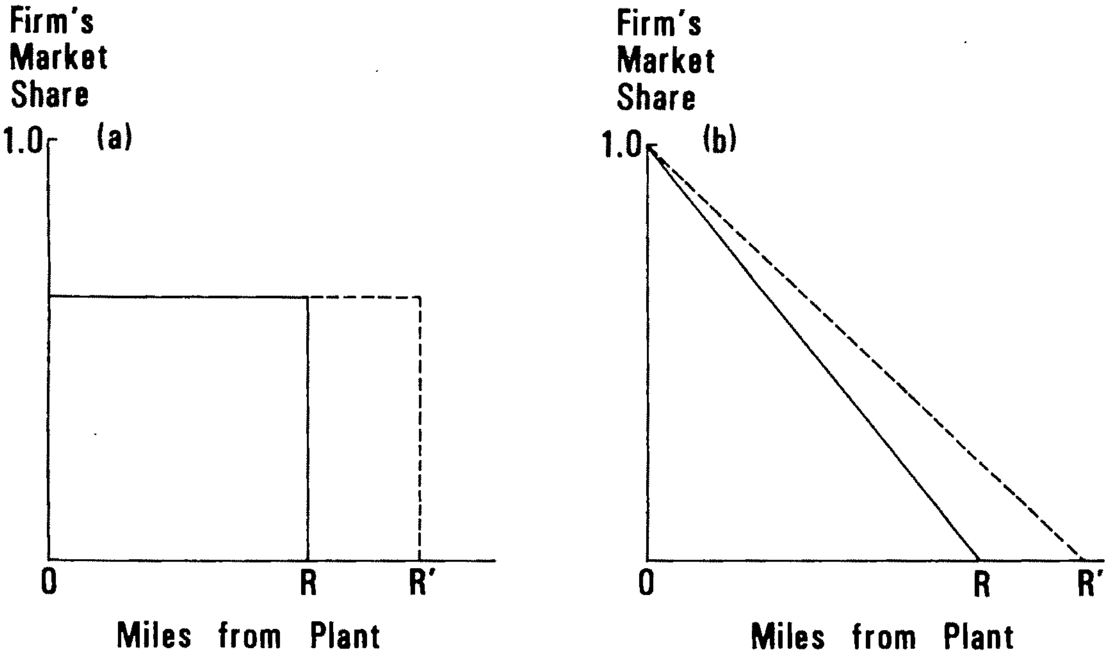

Figure 1. Comparison of uniform and decreasing market-share patterns

given demand density and uniform market-share pattern, estimates of delivery costs for a given volume and estimates of delivery-cost changes associated with volume changes. But these estimates would be based on an assumption about the market-share pattern that likely is unrealistic for most firms. Delivery-cost estimates for a given volume are based on the assumption that the firm's market share is exactly the same throughout the firm's trade area and that market share suddenly drops from this uniform level to zero at the boundary of the trade area (solid lines, figure 1a). The change in the market-share pattern assumed when volume changes is illustrated by the solid and dashed lines in figure 1a. An increase in volume from, say, Q to Q', would require an increase in the size of the trade area from, say, R to R' (equation (4)). But this implies that market share in the area from R to R' miles from the plant is increased from 0 to M, while market share in the area from 0 to R miles from the plant remains constant at M.

Model II: Linear Market-Share Pattern

In model II, the firm's market share within its trade area is assumed to be a linear function of road distance from the firm's plant. Specifically, the firm's market share at a point r road miles from the plant is given by $S = m_0 - (m_1/R)r$, where $0 \leq m_0 \leq 1$, and $m_0 - 1 \leq m_1 \leq m_0$, if $r \leq R$, and by $S = 0$ if $r > R$. The parameter m_0 represents the firm's market share at the plant location, and (m_1/R) is the rate at which market share changes with road distance from the plant. The restrictions on m_0 and m_1 prevent market share from being greater than one (100%) or less than zero within the firm's trade area.

This assumption permits a variety of market-share patterns. Market share at the plant location (m_0), may range from zero to one, and market share may increase, remain constant, or decrease with road distance from the plant. If $m_0 - 1 \leq m_1 \leq 0$, market share increases with road distance. If $m_1 = 0$, market share is constant (uniform); thus, model I is a special case of model II. If $0 \leq m_1 \leq m_0$, market share decreases with road distance. A specific decreasing market-share pattern is illustrated graphically by the solid lines in figure 1b.

The derivation of the delivery-cost function for model II parallels the derivation for model I. The quantity delivered in a trade area that extends R road miles in any direction from the plant is

$$(8) \quad Q = 4P \int_0^R \int_0^{R-x} [m_0 - (m_1/R)(x + y)]dydx = 4PR^2[m_0/2 - m_1/3],$$

and average hauling distance is

$$(9)\quad \bar{D}_{II} = (4P/Q)\int_0^R\int_0^{R-x}[m_0 - (m_1/R)(x+y)](x+y)dydx = R(4m_0 - 3m_1)/2(3m_0 - 2m_1).$$

Equation (8) may be used to eliminate R from equation (9) so that average hauling distance may be reexpressed as

$$(10)\quad \bar{D}_{II} = Q^{1/2}(4m_0 - 3m_1)/4(3m_0 - 2m_1)[P(m_0/2 - m_1/3)]^{1/2}.$$

Finally, the restricted long-run, total delivery-cost function for model II is obtained by substituting equation (10) into equation (3):

$$(11)\quad LTDC_{II} = [b_0 + B_{II}Q^{1/2} + \sum_i F_i(g_{0i} + G_{IIi}Q^{1/2})/H_i]Q,$$

where $B_{II} = b_1(4m_0 - 3m_1)/4(3m_0 - 2m_1)[P(m_0/2 - m_1/3]^{1/2}$, and $G_{IIi} = g_{1i}B_{II}/b_1$.

Equation (11) is an improvement over equation (7) because it is more general (equation (7) is a special case of equation (11), where $m_0 = M$ and $m_1 = 0$) and because it can be used to provide delivery-cost estimates for market-share patterns that likely are more typical than uniform patterns. For example, by setting $m_0 = m_1 = 1$, equation (11) may be used to estimate delivery costs for the market-share pattern shown in figure 1b. These cost estimates would be based on the assumption that market share is greatest near the plant and that it decreases with road distance from the plant until it reaches zero. Also, estimates of delivery-cost changes associated with volume changes would be based on the assumption that the firm's market share changes throughout its trade area when volume changes; that is, if volume increases from Q to Q', then the size of the trade area would increase from R to R' (equation (8)), and the market share at each point in the firm's trade area would increase as shown by comparing the solid and dashed lines in figure 1b. These assumptions seem likely to be applicable to more firms than are those underlying the uniform share pattern.

Impacts of Changes in Market-Share Patterns

Perhaps the questions of most interest to those conducting analyses of marketing firms concern the impacts of changes in the market-share assumption on cost estimates and other results of the analyses. Specifically, it may be of interest to know how changes in the market-share assumption (e.g., from a uniform to a decreasing share pattern) affect estimates obtained for delivery costs, delivery equipment requirements, trade area size, firm costs, and the least-average-cost firm size.

Delivery Operation

First, consider the impact of changes in the market-share pattern on delivery costs. The market-share pattern affects delivery costs through its impact on the average hauling distance required for any given volume; that is, if the average hauling distance for a given volume is the same for two different market-share patterns, then the delivery cost for a given volume is the same for the two patterns. Thus, the qualitative impact of changes in the market-share pattern on delivery costs for a given volume is known if the impact of changes in the market-share pattern on average hauling distance for a given volume is known.

A convenient way to compare average hauling distances for any of the market-share patterns consistent with models I or II is to calculate and compare values of a market-share index. The index may be defined such that the index value for a uniform pattern is simply the uniform share, and the index value for a nonuniform pattern is the uniform share that results in the same average hauling distance as the nonuniform pattern. The market-share index value ($\hat{M}$) for any market-share pattern consistent with models I or II is given by

$$(12)\quad \hat{M} = 0.5926(3m_0 - 2m_1)^3/(4m_0 - 3m_1)^2.$$

This expression was obtained by equating equations (6) and (10), solving for M, and denoting the solution value $\hat{M}$. The higher the index value for a market-share pattern, the lower is the average hauling distance for a given volume.

This market-share index leads to a convenient way to specify delivery-cost functions for alternative market-share patterns. The market-share index is in effect the uniform market share that is equivalent to any uniform or nonuniform market-share pattern consistent with models I or II. For example, the market-share index for the decreasing share pattern depicted in figure 1b (model II with $m_0 = m_1 = 1$) is, from equation (12), $\hat{M} = 0.5926$. Therefore, this decreasing share pattern is

equivalent to the uniform share pattern where $M = 0.5926$, and the delivery-cost function for this market-share pattern may be obtained by setting $M = 0.5926$ in equation (7). In general, the delivery-cost function for a market-share pattern with index $\hat{M}$ is given by

$$(13) \quad LTDC = [b_0 + BQ^{1/2} + \sum_i F_i(g_{0i} + G_iQ^{1/2})/H_i]Q,$$

where $B = (0.4714)b_1(P\hat{M})^{-1/2}$, and $G_i = g_{1i}B/b_1$.

Equation (13) may be used to show the qualitative impacts of changes in the market-share pattern on delivery costs for a given volume. Changes in the market-share pattern that do not change the market-share index do not change the delivery cost for a given volume, e.g., a change from a uniform market-share pattern with $M = 0.5926$ to a decreasing share pattern where $m_0 = m_1 = 1$ does not change the delivery-cost function. Changes in the market-share pattern that increase (decrease) the market-share index reduce (increase) delivery costs for a given volume, i.e.,

$$(14) \quad \partial(LTDC)/\partial\hat{M} = -BQ^{3/2}/2\hat{M} - \sum_i F_iG_iQ^{3/2}/2\hat{M}H_i < 0.$$

The qualitative impacts of changes in the market-share pattern on delivery equipment requirements for a given volume also may be determined by using the market-share index. The number of units of the ith type of delivery equipment (N_i) required for an annual volume (Q) is

$$(15) \quad N_i = (g_{0i} + G_iQ^{1/2})Q/H_i.$$

A change in the market-share pattern that increases (decreases) the market-share index will reduce (increase) the number of units required for a given volume because

$$(16) \quad \partial N_i/\partial\hat{M} = -G^{3/2}/2\hat{M}H_i < 0.$$

Different market-share patterns that have the same index will have the same delivery equipment requirements for a given volume.

The market-share index, however, may not be used to determine the impacts of changes in the market-share pattern on the distance from the plant to the boundary of the trade area (R). For any given volume (Q), R depends on the specific market-share pattern

$$(17) \quad R = (1.2247)Q^{1/2}/[P(3m_0 - 2m_1)]^{1/2}.$$

An increase in the intercept (m_0), or a decrease in the slope (m_1), of the market-share pattern reduces R for a given volume:

$$(18) \quad \partial R/\partial m_0 = -3R/2(3m_0 - 2m_1) < 0,$$

and

$$(19) \quad \partial R/\partial m_1 = 2R/(3m_0 - 2m_1) > 0.$$

R will not in general be the same for different market-share patterns that have the same index.

Least-Average-Cost Firm Size

To analyze the impacts of changes in the market-share pattern on the least-average-cost firm size, an assumption must be introduced about plant costs. Assume that given the number of hours available per season total plant costs (TPC) depend on hourly plant capacity and average volume per hour during the season:

$$(20) \quad TPC = Z_1 + Z_2qH_p, \; q \leq k,$$

where $Z = Z_1(k, H_p)$, $k = k(K, H_p)$, k is maximum hourly output that can be achieved with good management and usual operating conditions, K is rated or design capacity per hour for the plant facility, H_p is number of hours available per season for operation of plant facility, $Z_2 = Z_2(k, H_p)$, and q is average volume per hour during the season. The first term on the right-hand side of equation (20) is fixed plant costs, and the second term is variable plant costs.

To obtain a long-run plant-cost function from equation (20), it is assumed that $\partial(TPC)/\partial K = \partial Z_1/\partial K + (\partial Z_2/\partial K)qH_p > 0$. Given this assumption, the cost of producing any volume Q ($= qH_p$) is minimized if plant capacity (K), and maximum hourly output, $k = k(K, H_p)$, is as small as possible, i.e., if $k = q$. The long-run plant-cost function ($LTPC$) is as small as possible, i.e., if $k = q$. The long-run plant-cost function ($LTPC$) is therefore obtained from equation (20) by setting $q = k$ so that $k = Q/H_p$:

$$(21) \quad LTPC = Z_1(Q/H_p, H_p) + [Z_2(Q/H_p, H_p)]Q.$$

To obtain the long-run, average combined-cost function ($LACC$), sum equations (13) and (21) and divide by Q:

$$(22) \quad LACC = Z_1(Q/H_p, H_p)/Q + Z_2(Q/H_p, H_p) + b_0 + BQ^{1/2} + \sum_i F_i(g_{0i} + G_iQ^{1/2})/H_i.$$

The impact of a change in the market-share pattern on $LACC$ for a given Q is

$$(23)\quad \partial(LACC)/\partial\hat{M} = -B_1Q^{\frac{1}{2}}/2\hat{M} - \sum_i F_iG_iQ^{\frac{1}{2}}/2\hat{M}H_i < 0.$$

If there exists a unique annual volume Q^* that minimizes long-run average combined costs, the design capacity per hour of the corresponding plant facility (i.e., the least-average-cost firm size) is obtained by setting

$$(24)\quad \partial(LACC)/\partial K = [\partial(LACC)/\partial Q][\partial Q/\partial k][\partial k/\partial K] = 0$$

and solving for K^* provided that the second-order condition is met. The annual volume Q^* is obtained by using $k^* = k(K^*, H_p)$ and $Q^* = k^*H_p$. To obtain N^*_i and $LACC^*$, substitute Q^* into equations (15) and (22), respectively. These characteristics of the least-average-cost firm (i.e., K^*, k^*, Q^*, N^*_i, and $LACC^*$) depend on the market-share index but not on the specific market-share pattern. The distance from the plant to the boundary of the least-average-cost firm R^*, however, does depend on the specific market-share pattern. Given Q^* and the specific market-share pattern (i.e., values for m_0 and m_1), R^* may be obtained from equation (17).

The qualitative impacts of changes in the market-share pattern on K^*, k^*, Q^*, $LACC^*$, N^*_i, and R^* may be determined from comparative static derivatives. By substituting K^*, k^*, and Q^* into equation (24), the identity $L = [\partial(LACC)/\partial Q^*][\partial Q/\partial k^*][\partial k/\partial K^*] = 0$ is obtained. The comparative static derivatives and their expected signs are

$$(25)\quad \partial K^*/\partial\hat{M} = (-\partial L/\partial\hat{M})/(\partial L/\partial K^*) > 0,$$

$$(26)\quad \partial k^*/\partial\hat{M} = (\partial k^*/\partial K^*)(\partial K^*/\partial\hat{M}) > 0,$$

$$(27)\quad \partial Q^*/\partial\hat{M} = (\partial Q^*/\partial k^*)(\partial k^*/\partial\hat{M}) > 0,$$

$$(28)\quad dN^*_i/d\hat{M} = (\partial N^*_i/\partial Q^*)(\partial Q^*/\partial\hat{M}) + \partial N^*_i/\partial\hat{M} \gtreqless 0,$$

$$(29)\quad d(LACC^*)/d\hat{M} = [\partial(LACC^*)/\partial Q^*][\partial Q^*/\partial\hat{M}] + \partial(LACC^*)/\partial\hat{M} < 0,$$

$$(30)\quad dR^*/dm_{0|dm_1=0} = (\partial R^*/\partial Q^*)(\partial Q^*/\partial\hat{M})(\partial\hat{M}/\partial m_0) + \partial R^*/\partial m_0 \gtreqless 0,$$

and

$$(31)\quad dR^*/dm_{1|dm_0=0} = (\partial R^*/\partial Q^*)(\partial Q^*/\partial\hat{M})(\partial\hat{M}/\partial m_1) + \partial R^*/\partial m_1 \gtreqless 0.$$

Expressions (25) through (27) show that a change in the market-share pattern that increases the market-share index, *ceteris paribus*, increases the design capacity and the normal operating capacity of the least-average-cost firm and increases the least-average-cost annual volume. An increase in the market-share index may either increase or decrease the stock of delivery equipment (expression (28)) but is expected to reduce the combined average cost associated with the least-average-cost firm (expression (29)). Expressions (30) and (31) show that changes in the intercept or the slope of the market-share pattern may either increase or decrease the size of the trade area served by the least-average-cost firm.

Implications for Marketing-Firm Analysis

These results concerning the specification of delivery-cost functions for the alternative market-share patterns and the impacts of changes in the market-share patterns should improve the accuracy and usefulness of results obtained from marketing firm analyses. The accuracy of the results will be improved if attempts are made to measure actual market-share patterns and to incorporate these patterns into the specification of delivery-cost functions by using equations (12) and (13). The more nearly accurate are the assumptions used about market share in specifying cost functions, the more nearly accurate are the cost estimates for given levels of volume, estimates of cost changes associated with given changes in volume, estimates of delivery equipment requirements, and estimates of the least-average-cost firm size.

Results should also be more useful because they can be used to address questions about how firms should attempt to achieve volume changes. A common conclusion of studies of spatially located marketing firms is that typical firms can reduce costs by expanding volumes to existing capacity levels and can further reduce costs by expanding capacities and volumes to least-average-cost levels. The stated or implied recommendation is that at least some firms should increase their volumes, which in turn implies that market share within existing trade areas should be increased, that trade areas should be expanded, or both. But the results of studies have not provided estimates of how cost savings are affected by the

way in which increased volume is achieved. These estimates, which can be obtained by using the procedures just discussed, may be quite useful to firms. For example, a firm facing a decreasing share pattern may wish to know how savings are affected if volume is increased by maintaining the decreasing share pattern as compared with achieving a market-share pattern with a higher index. The cost of achieving and maintaining the higher market-share index, which may be an increasing function of the market-share index, may then be compared with the additional cost savings.[2]

This last point raises a question concerning least-cost location patterns. Least-cost location patterns have been derived given the assumption that market-share patterns are uniform (Williamson). But it may be that, for many spatially located firms, market-share patterns decrease with distance from the plant because costs of achieving and maintaining higher (e.g., 100% uniform) market-share patterns exceed the delivery-cost savings that result. Then the derivation of a least-cost location pattern would need to be based on the assumption that firms have decreasing market-share patterns. A cursory analysis suggests that if firms have decreasing market-share patterns it is not possible to derive a space-filling location pattern whereby each firm achieves the least-average-cost annual volume and trade area size.

An Empirical Application

A study of costs of retailing anhydrous ammonia fertilizer in north central Iowa illustrates the use of the procedures suggested here for measuring marketing firm costs and provides some quantitative estimates of impacts of changes in the market-share pattern on anhydrous ammonia delivery and combined retailing costs and on characteristics of the least-average-cost firm and trade area. In the study, long-run average plant costs are estimated for six levels of annual volume. Three market-share patterns are specified, and, for each market-share pattern, long-run average delivery and combined costs, delivery equipment requirements, and trade area size are estimated for each of the six levels of annual volume.

Estimates of long-run average plant costs are obtained from cost estimates for six model retail plants. Seasonal capacities for the model plants range from 450 to 3,200 tons (first row, table 1). Following the procedure used to derive equation (21), long-run average plant cost estimates (second row, table 1) are obtained by calculating the average total plant cost at the seasonal capacity for each model plant. The estimates include costs of owning and operating plant facilities, which typically include a storage vessel, a pumping system to transfer the product from rail cars or truck transports to the storage vessel and from the storage vessel to nurse tanks, a scale, and an office building, and administrative and management costs and costs of advertising and of providing services to customers.

Three alternative market-share patterns are specified. One of these, the decreasing share pattern (model II with $m_0 = m_1 = 1$), is suggested by results of a preliminary study of five anhydrous ammonia retailing operations in north central Iowa. In this study, the market share of each firm in each one-mile increment surrounding its plant is estimated by using the following procedure:[3] (*a*) the firm's 1971 sales records are used to determine the number of tons the firm sold in each one-mile increment, (*b*) the total number of tons sold in each increment by the firm and its competitors is estimated, and (*c*) for each increment, the number of tons the firm sold is divided by the estimated total tons that all firms sold to arrive at an estimate of the firm's market share for the increment. The general characteristics of the estimated market-share patterns for the five firms suggest a decreasing share pattern. Market share is 100% near the plant location; it decreases with road distance from the plant location, and firms with greater annual volumes have larger trade areas; i.e., market share remains positive for these firms in more distant one-mile increments. The two other market-share patterns, a uniform 100% pattern and a uniform 33% pattern, are chosen arbitrarily.

Estimates of long-run average delivery costs, delivery equipment requirements, and trade areas are obtained by using equations (12) and (13), (15), and (17), respectively. The market-share index values obtained from equa-

[2] Costs associated with gaining and maintaining a market-share pattern that has a higher index might include, for example, increased advertising and customer service costs or price reduction.

[3] The first one-mile increment includes the area from zero to one road miles in any direction from the plant, the second one-mile increment includes the area from one to two road miles in any direction from the plant, etc.

Table 1. Estimated Long-Run Average Costs, Delivery Equipment Stocks, and Market Area Size for Three Market-Share Patterns

	Model Firm					
Item	1	2	3	4	5	6
Annual volume (tons)	450	675	900	1,800	2,300	3,200
Plant cost per ton	$ 7.74	$ 7.05	$ 6.68	$ 6.00	$ 5.80	$ 5.54
100% uniform share pattern						
Delivery cost per ton	$11.41	$11.74	$11.60	$12.04	$12.15	$12.52
Combined cost per ton	$19.16	$18.79	$18.29	$18.04	$17.96[a]	$18.06
Number of pickup trucks	1	2	2	5	6	9
Number of nurse tanks	8	12	16	32	41	58
Number of applicators	6	9	12	24	31	44
Distance from plant to boundary of trade area (miles)	4.0	5.0	5.7	8.1	9.1	10.8
Decreasing market-share pattern						
Delivery cost per ton	$11.55	$11.91	$11.80	$12.55	$12.78	$13.03
Combined cost per ton	$19.29	$18.95	$18.48[a]	$18.55	$18.58	$18.57
Number of pickup trucks	1	2	2	5	7	10
Number of nurse tanks	8	12	16	33	42	59
Number of applicators	6	9	12	25	32	44
Distance from plant to boundary of trade area (miles)	7.0	8.6	9.9	14.0	15.8	18.7
33% uniform share pattern						
Delivery cost per ton	$11.75	$12.15	$12.89	$13.20	$13.43	$14.07
Combined cost per ton	$19.49	$19.20[a]	$19.57	$19.20	$19.23	$19.60
Number of pickup trucks	1	2	3	6	8	12
Number of nurse tanks	8	12	17	34	43	62
Number of applicators	6	9	13	25	32	46
Distance from plant to boundary of trade area (miles)	7.0	8.6	9.9	14.0	15.8	18.7

[a] Minimum average combined cost for market-share pattern. For the uniform 33% market-share pattern, combined average costs are a fraction of a cent lower for firm 2 than for firm 4.

tion (12) are 0.5926 for the decreasing share pattern, 1.0 for the 100% uniform pattern, and 0.333 for the 33% uniform pattern. Three types of delivery equipment are used in anhydrous ammonia retailing: nurse tanks to transport the product from the plant to farms; pickup trucks to tow nurse tanks; and applicators to inject the product into the soil. It is assumed that delivery equipment could be added only in discrete units, so the number of units of each type of delivery equipment required for a given annual volume is calculated and then rounded up to the nearest integer value before the delivery-cost estimate is calculated. The lower portion of table 1 shows long-run average delivery costs, long-run average combined costs, the stock of delivery equipment, and the size of trade area required for the capacity annual volume of each model firm for each market-share pattern.

Each column in table 1 shows, for a given annual volume, the impacts of changes in the market-share pattern on delivery and combined costs, on delivery equipment requirements, and on the size of the trade area. Delivery and combined costs are lower and the number of units of delivery equipment required is the same or lower for patterns with higher index values.[4] An increase in the intercept of the market-share pattern with the slope held constant (e.g., a change from a uniform 33% to a uniform 100% pattern) or a decrease in the slope of the market-share pattern with the intercept held constant (e.g., a change from a decreasing market-share pattern to a uniform 100% pattern) reduces the size of the trade area needed for a given annual volume. These impacts are consistent with the signs of the partial derivatives in expressions (14), (16), (18), and (19).

The results in table 1 also are consistent with expressions (27) and (29): the least-average-cost annual volume increases and the minimum average combined-cost decreases as

[4] An increase in the market-share index decreases the delivery equipment time required, but because the last fraction of a delivery unit required is rounded up to a full unit, the number of units required may not decrease.

the market-share index increases. Delivery equipment stocks of the least-average-cost firm increase with the market-share index, which suggests a positive sign for the comparative static derivative in expression (28). Also, the results show that an increase in the intercept or the slope of the market-share pattern increases the distance from the plant to the boundary of the trade area of the least-average-cost firm, which implies positive signs for the comparative static derivatives in expressions (30) and (31).

The results show that changes in the market-share pattern have a substantial impact on the least-average-cost capacity of an anhydrous ammonia retailing firm but only a small impact on combined average costs. The plant capacity and delivery equipment stock of the least-average-cost firm for the decreasing share pattern are less than half of those for the uniform 100% market-share pattern. Combined average costs of the least-average-cost firm are estimated to be less than 3% higher for the decreasing than for the uniform 100% market-share pattern.

These and some other results of the study are used to offer recommendations about cost-reducing adjustments for a typical retailer. Average annual volume for a typical retailer was 521 tons, and survey information indicates that the typical retailer had ten applicators, fifteen nurse tanks, and one pickup. It is estimated that a typical retailer could reduce costs by \$3.36 per ton, or by 15%, by reducing his stock of delivery equipment to the level required by the more efficient retailers surveyed. The typical retailer could realize further, but less substantial cost savings (from \$19.31 to \$18.95 or \$0.36 per ton), by increasing his annual volume to the capacity level for model firm 2. If the retailer further increases his annual volume to the least-average-cost level for the decreasing share pattern, his costs would drop by only about \$0.47 per ton (from \$18.95 to \$18.48). A comparison of combined average costs for the decreasing and 100% uniform share patterns indicates that a retailer's opportunities are relatively small for further cost reductions by achieving a 100% uniform market share within his trade area. For example, if volume is increased from 900 to 2,300 tons by converting a decreasing share pattern to a 100% uniform pattern, costs would only be reduced from \$18.48 to \$17.96 per ton, or by less than 3%. These cost savings likely would not offset the additional costs of gaining and maintaining a uniform 100% market-share pattern.[5] Estimates of cost savings available through other adjustments (e.g., expanding season length) are presented in Raikes and Heubrock.

Summary and Conclusions

A common assumption underlying the specification and estimation of cost functions for firms with assembly or delivery operations has been that the firm has a uniform market share within the trade area it serves. This assumption probably is quite unrealistic for many firms, and a more plausible assumption is that market share changes, and probably decreases, with distance from the plant. The approach suggested here is to measure market-share patterns of representative firms, to approximate actual patterns with linear patterns, and to incorporate the appropriate linear pattern into the specification of the delivery-cost function. A procedure for specifying delivery-cost functions for alternative linear market-share patterns was developed. Expressions that show qualitative impacts of changes in market-share patterns on costs and related results were derived, and some quantitative estimates were presented of impacts of changes in market-share patterns on costs and related results for anhydrous ammonia retailing firms.

Some limitations and possible extensions of the study should be noted. The specification of the delivery-cost function is based on assumptions that there is a square grid road system and that delivery technology is not a function of volume. These assumptions fit anhydrous ammonia retailing in north central Iowa, but the cost function would have to be respecified to fit situations in which these assumptions are not appropriate. The procedures presented here permit incorporation of only linear market-share patterns into the specification of delivery-cost functions. Incorporation of nonlinear patterns would require different procedures. No conclusions about typical market-share patterns are possible. All that can be said is that market-share patterns for a small sample of anhydrous

[5] On the other hand, if additional costs of gaining and maintaining a uniform 100% market-share pattern are negligible, then a 3% reduction in combined average costs likely would result in a substantially larger percentage increase in profits.

ammonia retailers in north central Iowa were roughly consistent with the decreasing share pattern. The hypothesis that costs of gaining and maintaining market-share patterns with higher indexes exceed cost savings was suggested but not tested. Finally, no effort was made to determine efficient location patterns given that market share is a function of distance from the plant.

The approach suggested here does offer some advantages. Because it is possible to incorporate several alternative market-share patterns into the specification of delivery-cost functions, it should be possible to obtain more accurate estimates of delivery-cost–volume relationships. Also, the approach makes it possible to measure differences in cost savings associated with different ways of expanding volume, i.e., by changing the market-share pattern in various ways.

Prices, Farm Outputs, and Income Projections under Alternative Assumed Demand and Supply Conditions

Chung J. Yeh

A two-equation aggregate demand and supply simulation model with Koyck-type geometrically distributed lags is used to examine the impacts of alternative demand and supply shifts on aggregate farm output, prices, and income. Impacts of inflation on important farm sector indicators are also examined. Projected solutions to 1985 indicate that strong demand shifts are needed to maintain a favorable level of prices and farm incomes. Results further suggest that the U.S. farm sector is particularly sensitive to unexpected changes or shifts in demand, and supply and prolonged inflation in the general economy.

Key words: aggregate farm output, demand, income, inflation, price, projection, simulation, supply.

Since the end of World War II and especially during 1953–71, the major U.S. agricultural problem was excess farm output. Commodity supplies for most of this period grew faster than consumer demand. Consequently, large stocks were held by the federal government and commodity prices were depressed. The Commodity Credit Corporation (CCC) inventories were mostly above $3 billion, net farm income in current dollars remained around $11 to $13 billion, and government payments increased from $0.2 billion to well over $3 billion (USDA 1973, 1974a,b). An analysis of commodity supply functions, their interrelationships, and supply-control programs occupied the attention of agricultural economists during this period (Heady et al. 1961). Not until 1972 did U.S. agriculture experience high farm prices and net farm income. This condition continued through most of 1973–75 because of food shortages in some developing countries, a sudden increase in demand by nations in the communist block, and the depletion of formerly burdensome surplus CCC stocks. Accompanying this emerging benchmark, which Brandow (1974) regards as high demand for U.S. agricultural products by foreign countries and Hathaway considers the end of overcapacity, was a move toward a more market-oriented U.S. agriculture.

For the future, the questions often asked are whether we are in a period of a temporary bulge in the demand for U.S. farm output and will return to the tendency of overproduction or have we entered a new epoch in which it will be difficult for supply to keep pace with demand? This basic uncertainty translates into concern about farm prices and income and U.S. agriculture's ability to play an increasingly greater role in the world food situation. These problems can be examined in the context of aggregate U.S. farm output supply and demand.

The purpose of this article is to analyze and evaluate this uncertain agricultural future and in particular the possible adjustments in farm prices, output, income, and cost of production. Alternative demand and supply scenarios are employed to reflect different possible market conditions. In addition, impacts of inflation on important farm sector indicators are also examined.

The author is especially indebted to Leroy Quance for his very valuable suggestions and comments on both the earlier and the revised drafts of this article. The author also wishes to thank Luther Tweeten, William Kost, and two anonymous reviewers from this *Journal* for their helpful comments. Of course, only the author is responsible for possible errors and deficiencies. The views expressed in this article are not necessarily those of the Economic Research Service or the U.S. Department of Agriculture.

The Model

A simulation model is built around a simultaneous formulation of aggregate supply and demand equations for U.S. agriculture.[1] A Koyck-type distributed lag model is assumed in which both quantities demanded and supplied are functions of current and lagged prices. Furthermore, both demand and supply functions can shift at different rates from year to year. The original distributed lag forms are the aggregate demand function,

$$(1)\quad Q_{d,t} = \alpha_d PR_t^{\lambda^0\beta_d}\, PR_{t-1}^{\lambda^1\beta_d} \ldots PR_{t-\infty}^{\lambda^\infty\beta_d}\, e^{\sum_{i=t_0}^{t} g_{d,i}},$$

and the aggregate supply function,

$$(2)\quad Q_{s,t} = \alpha_s \left(\frac{PR}{PDFE}\right)_t^{\mu^0\beta_s}\left(\frac{PR}{PDFE}\right)_{t-1}^{\mu^1\beta_s} \ldots \left(\frac{PR}{PDFE}\right)_{t-\infty}^{\mu^\infty\beta_s} e^{\sum_{i=t_0}^{t} g_{s,i}},$$

where Q_d and Q_s are quantities demanded and supplied, respectively, and PR is prices received by farmers (endogenous variables); $g_{d,i}$ and $g_{s,i}$ are rates of shift in demand and supply in the ith year, respectively, $t_0 \leq i \leq t$, and $PDFE$ is prices paid by farmers for farm operating expenses (exogenous variables); β_d and β_s are short-run price elasticities of demand and supply, respectively; λ and μ are weights placed on PR_{t-1} and $(PR/PDFE)_{t-1}$; α_d and α_s are constant terms in least squares demand and supply equations, respectively; t is the index year; and t_0 is the base year.

Quance and Tweeten built a similar simulation model around a recursive formulation. The present model differs considerably from their formulation. First, their recursive model assumes constant year-to-year shifts in demand and supply. Historically, demand and supply have not shifted at constant rates, nor is demand and supply likely to shift at fixed rates in the future.[2] The present model assumes that the ith year shifts in demand and supply are $e^{g_{d,i}}$ and $e^{g_{s,i}}$. The cumulated shifts from the base year are $e^{\sum_{i=t_0}^{t} g_{d,i}}$ and $e^{\sum_{i=t_0}^{t} g_{s,i}}$ for demand and supply, respectively (equations (1) and (2)). This assumption provides the model with the capacity to examine historical trends and the flexibility to simulate the impacts of differing future year-to-year shifts in demand and supply.

Second, the model differs from Quance and Tweeten's formulation in that the quantity supplied reacts within one year to a change in market prices and all other geometrically weighted past prices. Current prices were included in the lagged supply function because estimates indicated that about 40% of cash receipts by farmers are from commodities whose supply can be reasonably considered a function of current prices (USDA 1974b). Furthermore, the data base and the data generated under the present model are annual averages. Clearly, through the averaging process current prices received contains about one-half of the first-year lag effects.

Finally, in the recursive formulation the cobweb effect begins to accumulate in a few years and the prices received index and equilibrium output fluctuate wildly from year to year. This unreasonable year-to-year variation is eliminated by using current prices in the lagged supply function.

The reduced equations of the distributed lag models are the aggregate demand function,

$$(3)\quad Q_{d,t} = \hat{\alpha}_d PR_t^{\beta_d}\, Q_{d,t-1}^{(1-\delta_d)}\, e^{\delta_d \sum_{i=t_0}^{t-1} g_{d,i} + g_{d,t}},$$

and the aggregate supply function,

$$(4)\quad Q_{s,t} = \hat{\alpha}_s PR_t^{\beta_s}\, Q_{s,t-1}^{(1-\delta_s)}\, e^{\delta_s \sum_{i=t_0}^{t-1} g_{s,i} + g_{s,t}}\, PDFE^{-\beta_s},$$

where $\hat{\alpha}_d$ is a constant term in the reduced demand function, $\hat{\alpha}_d = \alpha_d^{(1-\lambda)}$; $\hat{\alpha}_s$ is a constant term in the reduced supply function, $\hat{\alpha}_s =$

[1] This aggregate farm output model is one component of the ERS, USDA, National Interregional Agricultural Projections (NIRAP) System (USDA 1976). The system currently comprises six models. They are aggregate farm output, commodity, price-quantity, technology, input, and the state and regional models. Most of them are operational or near operational. As a component of the NIRAP system, this model provides the overall constraints on projections of alternative futures. The model has the capacity to simulate several alternative farm policies. Also, impacts of year-to-year changes in demand, supply, and inflation can be quickly evaluated.

[2] Their model not only fails to simulate the past trend with a reasonable degree of accuracy, which is essential for any simulation model, but also has limited capacity to analyze and evaluate certain future market conditions.

$\alpha_s^{(1-\mu)}$; and δ_d and δ_s are proportions of desired or optional adjustment in demand and supply in one year, respectively, $\delta_d = (1 - \lambda)$ and $\delta_s = (1 - \mu)$.

The reduced-equation system contains two equations in three endogenous variables (PR, Q_d, Q_s). The model is completed by adding an auxiliary equation (5) representing the relationship between Q_d and Q_s:

$$(5) \qquad Q_{d,t} = Q_{s,t}\,(1 - DIAA_t).$$

Equation (5) specifies that government policy is exogenous to the model and that the government exercises its policy through the control of the diversion rate ($DIAA$), which in turn is fed into the supply function to establish a general equilibrium. Under the assumptions, government diversion policies will shift the supply curve upward to the left.

Inflation is treated as exogenous to the model and is assumed to have negative impacts on the supply curves, namely, shifting the supply curves upward to the left by the amount $PDFE_t^{-\beta_s}$.

The reduced-equation model (equations (3) and (4)) permits the projection of prices received by farmers and quantity marketed (quantity demanded at the equilibrium). By allowing the diversion rate in equation (5) to vary, alternative farm policies can be examined. In a free market such as assumed in this study, the diversion rate ($DIAA$) is assumed to be zero after 1974.

The reduced equations determine only the prices received and farm outputs under alternative demand and supply scenarios. Additionally, the index of prices paid, farm income, and production expenses are estimated using the equations discussed below.

Inflation in the farm input sector is measured by the index of prices paid by farmers, which in turn is determined by its components. Components of prices paid (USDA 1975a) are divided into four subgroups: family living (FL), interest, taxes, and wages (ITW), interfarm sales (IFS), and other production items (PI). The indexes are then computed and aggregated according to equations (6) (for the index of prices paid by farmers including FL) and (7) (for the index of prices paid by farmers excluding FL):

$$(6) \quad PD_t = PD_{t-1}\Bigg(1.0 + \Bigg(0.395FLINF_t + 0.406PIINF_t + 0.096ITWINF_t + 0.103\left(\frac{PR_{t-1}}{PR_{t-2}} - 1.0\right)\Bigg)\Bigg),$$

and

$$(7) \quad PDFE_t = PDFE_{t-1}\Bigg(1.0 + \Bigg(0.67\,PIINF_t + 0.16\,ITWINF_t + 0.17\left(\frac{PR_{t-1}}{PR_{t-2}} - 1.0\right)\Bigg)\Bigg),$$

where the coefficients are the relative weights of expense components[3] and $FLINF$, $PIINF$, $ITWINF$, and PR_{t-1}/PR_{t-2} are the rates of inflation associated with FL, PI, ITW, and IFS at the farm level, respectively.[4]

Equations (6) and (7) assume that for the period 1967–74 for each 1% increase in the implicit price deflator, prices paid by farmers for FL, ITW, and PI will increase at 1.02%, 1.91%, and 1.02%, respectively. It is further assumed that from 1975 on, the relationships will gradually be restored to the 1953–71 levels of 0.78% and 0.59% for FL and PI, respectively, and 1% for ITW. The annual rate of restoration is $1/n$, where $n = 2$ for 1975, $n = 3$ for 1976, etc.

Production expenses are a function of changes in resource prices and changes in production inputs and are assumed to have the form

$$(8) \quad PE_t = PE_{t-1}\Bigg(1.0 + \Bigg(0.67\,PIINF_t + 0.16\,ITWINF_t + 0.17\left(\frac{PR_t}{PR_{t-1}} - 1.0\right)\Bigg)\Bigg)\left(\frac{RESX_t}{RESX_{t-1}}\right),$$

where $RESX_t$ is the index of production inputs in year t.

Gros[illegible] receipts in year t are equal to the quantit[illegible]ed (QP) in year t weighted by the prices [illegible]ived index and is given by

[3] These estimates are based on the 1958 price weights used by the USDA in the construction of the agricultural price index. In 1958, an average farmer spent 39.5% of his total expenditures for FL, 9.6% for ITW, 40.6% for PI, and 10.3% for IFS. If FL is excluded from the computation, then the weights are 67% for PI, 16% for ITW, and 17% for IFS.

[4] For the period 1953–71, the farm sector appears to have experienced the same degree of inflation experienced by the general economy measure by the GNP implicit deflator. For each 1% increase in the implicit deflator, farm operating expenses increase 0.982% and farm expenses including family living increase 0.902%. Farmers were especially hard hit during the 1967–74 period and experienced 50% or more inflation than the general economy. The relationships are 1.34%, 1.63%, 1.62%, and 1.65% for FL, ITW, PI, and PE (farm operating expenses). For 1953–74 as a whole, the relationships are 1.02%, 1.91%, 1.02%, and 1.27% for FL, ITW, PI, and PE, respectively.

$$(9) \qquad GFR_t = QP_t \frac{PR_t}{PR_{67}}.$$

Gross farm income is defined as the sum of gross farm receipts and government payments (G). In a free market government payments are assumed to be zero. However, in a controlled market government payments are assumed to be equivalent to the payments for set-aside acreages under a government diversion program ($DIAA$):

$$(10) \qquad GFI_t = GFR_t + G_t.$$

Net farm income is the difference between gross farm income and production expenses:

$$(11) \qquad NFI_t = GFI_t - PE_t.$$

The Parameters

The reduced demand function equation (3) has two parameters. They are short-run demand elasticity (β_d) and the lag parameter in demand ($\delta_d = 1 - \lambda$). There are numerous statistical estimates of the elasticity of demand for food at the aggregate level. The earliest estimates ranged from a high of −0.34 by Brandow (1961) to a low of −0.24 by Waugh. A separate estimate by Girshick and Haavelmo and Bucholz, Judge, and West placed the elasticity at −0.25. The latest work by George and King produced an elasticity of −0.24. Unfortunately, none of these are farm-level estimates, nor are they short-run estimates. Theoretically, the short-run elasticity is less than in the long run, and the farm-level elasticity is less than at retail level. Tweeten estimated the short-run farm-level elasticity as −0.25 (1967, 1970), and Brandow computed the long-run farm-level elasticity at −0.23 (1961). This study uses −0.15 as the short-run farm-level demand elasticity and −0.214 as the long-run farm-level elasticity with the lag parameter in demand ($\delta_d = 0.7$). This set of elasticities seems to predict the 1967–74 historical period better than the elasticities estimated by the previous studies.

Parameters included in the reduced supply function equation (4) are short-run supply elasticity (β_s) and the lag parameter in supply ($\delta_s = 1 - \mu$). Heady and Tweeten presented three estimates of supply elasticities: (*a*) a direct least squares estimate of 0.1 in the short run and 0.6 in the long run, (*b*) a separation of the yields and basic production unit components of supply placing the short-run elasticity at 0.25 and the long run at 1.79, and (*c*) a separation of elasticities of production and elasticities of input demand resulting in a short-run elasticity of 0.256 and long-run elasticity of 1.518. A more recent estimate by Tweeten and Quance placed the short-run elasticities at 0.1 for decreasing price and 0.15 for increasing price; the long-run elasticities were 0.8 for decreasing and 1.5 for increasing price. After a considerable number of simulation runs and in particular after considering the ability to predict the 1967–74 historical period, it was decided to use 0.20 as the short-run elasticity and 1.0 for the long-run elasticity with the lag parameter in supply ($\delta_s = 0.20$).

Scenarios

In the reduced model, the exogenous variables are the shift in demand (g_d), shift in supply (g_s), and prices paid by farmers for farm operating expenses ($PDFE$). Since $PDFE$ is assumed a function of inflation (equation (7)), inflation is considered an exogenous variable in the model. The data base for these variables are divided into two periods: a historical period of 1967–74 and alternative scenarios for the period after 1974.

Increases in demand for farm outputs are measured by three variables—population, real per capita disposable income, and exports. Changes in these variables are further adjusted to the domestic and foreign shares of total demand for U.S. farm outputs.

U.S. population increased at an average of 0.97% annually from 1967 to 1974. With falling birth rates, the 1974 growth was only 0.72%. Real per capita disposable income grew at an annual average of 2.5% during the same period except in 1974, which had a negative growth of 3.4%. With assumed income elasticity for farm outputs at 0.15 and domestic demand accounting for about 85% of total demand for farm outputs, changes in demand due to increases in population and incomes was estimated at 1.18% annually for 1967–74.

Foreign demand for U.S. farm outputs declined slightly in the late 1960s. But in the early 1970s, the general upward trend accelerated and exports increased 38% in 1973, reaching an all-time high. As a result, the increase in foreign demand for U.S. farm output contributed almost 85% of the 8.51% total demand shift in 1973. The average increase in total

lemand due to the foreign demand was 1.53%. Thus, the increase in demand for U.S. farm ıutput, both domestic and foreign markets :ombined, averaged 2.71% for 1967–74.

For the period after 1974, demand shift rates .re derived from the constant-price compo-ıent of the Economic Research Service's Na-ional Interregional Agricultural Projections ;ystem (Smith). Under the baseline scenario, he demand shift is projected at 1.6%, com-ıounded annually. This assumes a series E ıopulation (a population growth rate of 0.85% o year 2000) and moderate growth in per :apita income and farm exports.[5] In addition, . low demand scenario of a 1.2% shift in de-nand and a high demand scenario of a 3% shift .re also examined in this study.

I turn next to shifts in the supply function. Since 1967, agricultural productivity in the J.S. has been growing at an average rate of % per year (USDA 1975b). The changes are nostly positive except in 1970, 1972, and 1974, vhen the changes were −0.6%, −1.1%, and -5.1%, respectively. The biggest one-year in-:rease in productivity was 8.8% in 1971.

Productivity projections are derived from he technology component of the NIRAP sys-em (Lu). The baseline productivity growth is :stimated at 1.14% per year compounded for he period 1975–84. The baseline assumes a % annual increase in research and education :xpenditures (R&E). A more ambitious "high echnology" assumption is a 7% increase in R&E annually plus three unprecedented ıreakthroughs in technology.[6] Under this as-umption, productivity growth is projected at .21% per year. However, 1.21% is a conser-'ative estimate of the potential upper bound ın productivity growth. To provide a wider :stimate for the high production scenario, this tudy uses 2%.

In this study, inflation is measured by the ;ross national product implicit price deflator. The rates fluctuated mostly around 3% to 6% ıetween 1967 and 1974 with an average of '.2% for the whole period (Council of Eco-ıomic Advisors). The 3.2% rate increase in 1967 was the lowest for this period, while the 10.2% increase in 1974 was the highest. By excluding the double-digit figure in 1974, the annual average drops from 5.2% to 4.4%.

Inflation appears to have slowed down considerably in 1975 from the 1974 level. However, it is still high, and it is reasonable to assume that such a high rate will not prevail in the long run. Thus, in this study, we assume that in the long run an average of 4% annual rate of inflation will continue. In addition, a rate of inflation of zero and its impacts are also examined.

As discussed above, for the period 1975–85, three rates of shift in demand—1.2%, 1.6%, and 3%, two rates of shift in supply—1.14% and 2%, and two rates of inflation—0 and 4%—are considered. The scenarios formulated from the alternative combinations of these rates are summarized in table 1.

The Results

Simulating the Period 1967–74

Actual shifts in demand and supply and rates of inflation are used in simulating the period 1967–74. In this simulation, the index of prices received is [illegible]erestimated while the projected equilibrium output is slightly underestimated (table 2). Most of the errors associated with

Table 1. Alternative Demand, Supply, and Inflation Scenarios, 1975–85

Scenario[a]	Shift in Demand	Shift in Supply	Rates in Inflation
	%	%	%
Low dem[illegible]			
I	1.2	1.14	0
II	1.2	1.14	4
III	1.2	2.00	0
IV	1.2	2.00	4
Moderate demand			
V	1.6	1.14	0
VI	1.6	1.14	4
VII	1.6	2.00	0
VIII	1.6	2.00	4
High demand			
IX	3.0	1.14	0
X	3.0	1.14	4
XI	3.0	2.00	0
XII	3.0	2.00	4

[a] The basic set of parameters associated with these scenarios are demand elasticities of −0.15 in the short run and −0.214 in the long run and supply elasticities of 0.20 in the short run and 1.0 in the long run.

[5] The moderate income growth with series E population as-umes a 3% annual growth rate for per capita disposable personal ıcome from 1973 to the year 2000. The moderate export level ses the conservative assumption of continued growth in import emand by foreign countries constrained by high prices and poli-ies of major importing countries to attain self-sufficiency and the ventual resulting in a return to trends established prior to 1972 for ereals.

[6] The three unprecedented breakthroughs in technologies are vinning in beef cattle, bioregulators, and photosynthesis en-ancement.

Note: The 1974 values are preliminary estimates.

the projected index of prices received were off by 10% except for the year 1970, which was overestimated by 26%. The errors associated with projected equilibrium outputs were mostly less than or near 6%. Four sources are basically responsible for these errors. First, the exact magnitudes of the parameters may be incorrect. Second, the initial conditions, especially the estimated quantity marketed and the supply shifts, are based on U.S. Department of Agriculture estimates. Although these data are adjusted to fit the definitions in this study, some statistical discrepancies and terminology problems exist. Third, assumptions concerning the impact of inflation at the farm level (equations (6) and (7)) might have overestimated the upward shift in the supply curve. Consequently, the prices received would have been overestimated and the quantity marketed would have been underestimated. Finally, there are also some random errors associated with the simulation.

The simulated prices paid were generally higher than the actual values, but most were within a 6% range. Of all the variables projected, net farm income seems to fluctuate the most violently, especially for the years 1970, 1972, and 1974, since net farm income has a relatively smaller value. Further, the errors associated with the net farm income estimates come from two sources—realized gross farm income and production expenses. Consequently, the compound errors on net farm income are magnified considerably.

To test the goodness of fit of the model, the following equation is used:

$$S = a + bA, \tag{12}$$

where S is simulated results, and A is actual values. Equation (12) is used merely to test the goodness of fit of the simulated values. A perfect fit of the model for the historical period would result in $a = 0$, $b = 1$, and $r^2 = 1$. Results indicate that all intercepts are 0 at the 1% level. However, at the 5% level, the prices paid and the production expenses are all significantly different from 0 (table 3). The b values are all equal to 1 except the prices paid at the 5% level and the production expenses at the 1% level. All projected values seem to be within reasonable enough ranges of the actual values to justify using the model for long-run analysis.

The Most Realistic Scenario for 1975–85

Perhaps the most realistic scenario is scenario VI—a 1.6% shift in demand, a 1.14% shift in

Table 3. Regression Coefficients and *t*-values between the Simulated Values and the Actual Estimates, 1967–74

Items	Prices Received	Prices Paid	Equilibrium Quantity	Gross Farm Receipts	Production Expenses	Net Farm Income

1985	601	738	58.1	85.6	51.9	33.7

[a] In 1974 dollars.

supply, and a 4% rate of inflation (table 4). Under this scenario, the prices received index increases 21% between 1974 and 1985. On the basis of 1910–14 prices, the index increases from 497 in 1974 to 601 in 1985. The equilibrium output increases 13%, from $51.5 billion in 1974 to $58.1 billion in 1985. The most critical problem is the sudden drop in prices received index and net farm income in 1975. This is due to the fact that between 1967 and 1974 demand shifts are relatively high, especially the 3.96% shift in demand in 1974, although the supply shift was estimated at −5.1% in 1974. Adjusting to normal weather conditions, supply shift is estimated to be 4% in 1975. Therefore, a sudden drop in demand in 1975 to 1.6% and a sudden increase in supply to 4% reduce the prices received index by more than sixty points, which in turn reduces net farm income (both in current and real) by around $11 billion. Although net farm income in current dollars begins to move above the 1974 level in 1980, real net farm income does not move above the simulated 1974 level by 1985. If inflation persists at an annual rate of 4%, by 1985 net farm income in 1974 dollars will decrease $5 billion, from $37.6 billion to $33.7 billion, while net farm income in current dollars increases more than $14 billion, from $37.6 billion to $51.9 billion.

Another problem is farmers' inability to pass increased costs to consumers. Between 1974 and 1985, production expenses are projected to increase 33%, prices received by farmers only 21%. However, under the 4% inflation rate assumption the inflation index increases 54% during the same period. Productivity growth more than compensates for the differences between the prices received index and the compounded inflation index according to the baseline scenario. The result is a relatively higher net farm income.

Alternative Scenarios, 1975–85

Four scenarios (V–VIII) are considered under the moderate shift in demand (table 5). Number VI, the baseline or most likely, has been discussed fully in the previous section. If the supply curve shifts at an annual rate of 2% instead of 1.14%, while shifts in demand and inflation are maintained at 1.6% and 4% annually, respectively (from scenarios VI to VIII), equilibrium output increases an additional 2% in 1985, equivalent to $1.1 billion. The prices recei[illegible]ex declined forty-eight points, from 6[illegible]3 (1910–14 = 100). Net farm income [illegible]rent dollars dropped almost $3 billion. The assumption of an almost 1% additional shift in supply is probably too high. However, there is an estimated 96 million acres of noncropland with high potential for conversion to cropland use, and there are some unprecedented technologies that could come off the shelf to boost agricultural productivity.

If the annual rate of inflation is reduced to zero while the supply shift is maintained at 1.14% (scenario V), the prices received index in 1985 drops more than 5% from the 1974 simulated level. But because of a 19% increase in equilibrium output, from $51.5 billion in

Table 5. Equilibrium Solutions under Alternative Scenarios, 1985

Scenarios	Prices Received (1910–14 = 100)	Prices Paid (1910–14 = 100)	Equilibrium Quantity	Production Expenses	Net Farm Income: Current	Net Farm Income: Real[a]
			Billion $			
1974 actual	465	576	55.1	74.8	27.2	27.2
1974 projected	497	518	51.5	64.3	37.6	37.6
Low demand						
I	446	526	59.1	62.0	41.8	41.8
II	570	734	56.2	82.1	44.0	28.6
III	410	521	60.2	57.7	39.7	39.7
IV	524	727	57.3	76.4	41.8	27.2
Moderate demand						
V	471	529	61.1	64.8	48.5	48.5

VII	433	523	62.3	60.2	46.0	46.0
VIII	553	731	59.2	79.7	49.2	32.0
High demand						
IX	569	538	68.5	75.6	77.8	77.8
X	726	751	65.2	99.6	86.6	56.3
XI	523	533	69.8	70.1	73.7	73.7
XII	668	743	66.4	92.5	82.1	53.3

[a] In 1974 dollars.

1974 to $61.1 billion in 1985, with production expenses remaining relatively constant, net farm income rose $11 billion from the 1974 level of $37.6 billion to $48.5 billion. A similar pattern also exists for scenario VII, which assumes a supply shift of 2%.

Under the high demand scenario, demand for farm goods would grow at an annual rate of 3% through 1985 (scenarios IX–XII). This rate could be achieved with export demand growing at an annual rate of 10%, domestic population, 1%, real per capita disposable income increasing 3% per year, and the income elasticity of demand holding at 0.15. Due to the high demand, prices received and equilibrium output are considerably higher than under the moderate demand scenarios. Consequently, net farm income is also higher. This situation can best be described by considering a shift to the high demand scenario X from the most likely demand scenario VI. The prices received index under this high demand scenario increases 125 points, from 601 to 726 (1910–14 prices). The equilibrium quantity increases a little over $7 billion. Net farm income in real dollars increases $22.6 billion, while net farm income in current dollars increases as much as $34.7 billion, from $51.9 billion to $86.6 billion. However, if supply is allowed to shift at 2% per year (from scenarios X to XII), the prices received index will decline around sixty points while the equilibrium quantity increases almost $1 billion.

If population were to grow at the 1974 rate of 0.72%, if the growth in real per capita disposable income and domestic share of farm output remains at the 1967–74 average rate of 0.41% and 85%, respectively, and if export demand remains constant at the 1974 level, then we would have a 1.13% annual increase in demand. Results indicated that the farm sector could not continue to experience such a low demand without some financial problems, especially if supply was to shift at a 2% annual rate. Under the low demand and high supply scenarios (scenarios II and IV), real net farm income (in 1974 dollars) in 1985 drops below the 1974 simulated net farm income level. It is quite possible that export demand may drop below the 1974 level and result in a much lower demand shift, which in turn will depress prices received by farmers, equilibrium quantity, and net farm income. However, long before such depressed conditions for the farm sector came about, additional public programs would likely be considered. However, it is beyond the scope of this paper to analyze such policy issues and implications.

Summary

Based on previous studies and results in this study, one of the most realistic sets of supply and demand parameters appears to be demand elasticities of −0.15 in the short run and

−0.214 in the long run with an adjustment coefficient of 0.7 and supply elasticities of 0.20 in the short run and 1.0 in the long run with a long-run adjustment coefficient of 0.20. The most realistic scenario is considered to be a 1.6% shift in demand, a 1.14% shift in supply, and a 4% annual general price inflation. In addition, eleven other scenarios were identified as possible alternatives.

Simulations built around the above parameters and alternative scenarios suggest that as long as a strong demand persists, prices received by farmers and net farm income will maintain at reasonable levels. It is extremely difficult to maintain a reasonable price level if demand drops unexpectedly and/or supply suddenly increases due to good weather. Inflation may not have much impact on the prices received and farm income in the short run. However, in the long run the accumulated impacts of inflation on real net farm income is a serious problem.

It is beyond the scope of this paper to analyze policy alternatives, although this simulation model has the capacity to simulate alternative policies and varied rates of demand shift, supply shift, and inflation from year to year. This study further suggests that more research is needed in the area of aggregate demand and supply parameters for the food and fiber system at the farm level. Precise magnitudes of these parameters vary considerably among the existing publications and researchers.

Spectral Analysis of Stochastic Properties in Regression: An Application in Supply Response Identification

Richard E. Just

This article demonstrates an empirical investigation of the applicability of the Nerlovian supply response model. Popular statistics, particularly those resulting from regression, may be inadequate and even misleading when a more general adaptive risk model is applicable. Because of the multidimensional nature of spectral tests, the frequency-domain approach is more robust. The empirical results present a case where popular statistics are misleading, but spectral results support the adaptive risk model. Even spectral techniques may be inadequate for distinguishing between the two models, but at least equal support for both models can be clear with spectral methods.

Key words: adaptive risk, Nerlovian model, spectral testing.

Spectral analysis of time series commonly finds four important areas of application in econometrics: (*a*) investigation of harmonic characteristics of sample time series (e.g., Rausser and Cargill), (*b*) investigation of effects of intertemporal transformation on time series (e.g., Hannan 1964, Nerlove 1964), (*c*) frequency-domain regression of time series and estimation of general distributed lag equations and equation systems (e.g., Hannan 1963, 1965; Wahba), and (*d*) investigation of stochastic specifications in regression. The investigation in (*d*) can be performed either in conjunction with the frequency-domain calculations of (*c*) or in an *ex post* sense after ordinary time-domain regression techniques have been applied. In the latter case the mean function (depending on exogenous variables) is first regressed from a time series, the spectral density of the estimated disturbance process is then computed, and assumptions relating to serial correlation in regression are then investigated (e.g., Anderson, chap. 10).

Applications in agricultural economics have thus far been almost entirely of the nature of (*a*) or the special cross-spectral analysis case of (*c*) and, as such, have been often criticized because of their lack of economic explanation.[1] The application of spectral analysis in this paper, however, corresponds to case (*d*) and thus demonstrates one use of spectral analysis in a model with economic content. Ordinary time-domain (rather than frequency-domain) regression methods are used because the general lag relationship estimated here is not a case included in the general model of (*c*) above. Spectral analysis is then used to investigate stochastic characteristics of regression equation disturbance processes. Due to the particular nature of this econometric investigation, the spectral results are further used to investigate hypotheses associated with several alternative econometric models. The empirical results, which pertain to the California field crop sector, are then used to demonstrate some general implications for estimation of the popular Nerlovian model. Results suggest that ordinary time-domain considerations in Nerlovian model estimation may not be sufficient to determine applicability because of the nature of an alternative lag model possibility that includes risk response. Apparently, unless more robust spectral methods are used, one may be led to

Richard E. Just is an assistant professor of agricultural and resource economics, an agricultural economist in the Experiment Station, and on the Giannini Foundation at the University of California, Berkeley.

Giannini Foundation Paper No. 413. The author wishes to thank Stanley M. Fletcher for helpful assistance in part of the empirical calculations.

[1] In theory, case (c) is a generalized distributed lag model and allows a great deal of economic explanation. However, applications have typically been only cross-spectral analyses and have thus considered only one independent variable (time series).

conclude that the Nerlovian model is applicable when in fact it is not. Even with the application of spectral analysis, the results may not be sufficient to discern between models. But, at least if not, the results indicate so. Several observations are also made with respect to the general problem of spectral hypothesis testing.

Empirical Discernment of Models

It is well known that for econometric purposes the Cagan adaptive expectations model differs from the Nerlovian partial adjustment model only in stochastic assumptions (Griliches, Zellner and Geisel). For example, where price (p_t) expectations are given by

$$p^*_t = \sum_{k=0}^{\infty} \beta(1-\beta)^k p_{t-k-1}, \qquad 0 < \beta < 1,$$

the Cagan model was originally specified as

$$(1) \quad y_t = a_0 + a_1 p^*_t + u_t, \qquad E(u_t) = 0, \quad E(u_t^2) = \sigma_u,$$

where u_t is a serially uncorrelated random disturbance (Cagan, Nerlove 1958). In the partial adjustment model, the assumption was that the desired value of the dependent variable follows the equation

$$(2) \quad y^*_t = a_0 + a_1 p_t + v_t, \qquad E(v_t) = 0, \quad E(v_t^2) = \sigma_v,$$

where v_t is a serially uncorrelated random disturbance (Nerlove 1958). Hence, where only a fixed percentage of the desired adjustment is accomplished each period, i.e., $y_t = y_{t-1} + \beta(y^*_t - y_{t-1})$, one obtains

$$(3) \quad y_t = \beta a_0 + \beta a_1 p_t + (1-\beta) y_{t-1} + v_t,$$

or, equivalently,

$$(4) \quad y_t = a_0 + a_1 p^*_t + (1-\beta) u_{t-1} + v_t,$$

where

$$u_t = \sum_{k=0}^{\infty} (1-\beta)^k \, v_{t-k}.$$

Thus, both equations (1) and (4) represent the same regression equation except that disturbances in equation (1) are serially uncorrelated, while those in equation (4) follow a first-order autoregressive process.

In subsequent work it has been generally acknowledged that verification of one set of stochastic assumptions or another does not give conclusive evidence regarding the underlying behavior mechanism. For example, it is possible that disturbances in the adaptive expectations model follow a first-order autoregressive process and cannot be distinguished from those in equation (4) (Zellner and Geisel). The assumptions in equations (1) and (4), as made above, lead to important differences in estimation procedures, at least with ordinary time-domain methods. In this paper one concern will be with discerning equation (1) from equation (4) empirically because of the associated implications for regression procedures. But it must be understood that the terms "adaptive expectations" and "partial adjustment" are used merely to describe the stochastic assumptions in equations (1) and (4) rather than the underlying behavioral influence.

To distinguish equation (1) from equation (4) on the basis of empirical results, both time-domain and frequency-domain approaches have been used. Zellner and Geisel use both maximum likelihood and Bayesian (time-domain) methods with consumption function data to estimate a model such as equation (3) under several alternative stochastic assumptions for v_t (possibly corresponding to equations (1) and (4)). Their results have served to emphasize the sensitivity of parameter estimates to parametric specification of the disturbance process and hence the need for determination of the appropriate model. Also, using consumption function data, Howrey has used the alternative approach of frequency-domain regression on the reduced forms of equations (1) and (4) (corresponding to equation (3)) from which estimates of disturbance spectra are produced directly (see (*c*) above). Howrey's results demonstrate the robustness of spectral analysis in the Zellner and Geisel problem because support is gained for an alternative not even considered in the earlier work. The problem in this paper involves an additional alternative that does not generally permit direct application of frequency regression. But an *ex post* application of spectral methods, such as suggested by Howrey's analysis of the Zellner and Geisel results, is possible and informative.

The empirical problem in this study differs from that considered by Zellner and Geisel and by Howrey because adaptive risk response is considered as an alternative to equations (1) and (4). Risk response has been a topic of growing interest in recent years, particularly with respect to microresearch. For example,

two invited paper sessions at the 1975 annual meetings of the American Agricultural Economics Association were devoted to risk response. The more general model that has been used econometrically is

$$(5) \qquad y_t = a_0 + a_1 p^*_t + a_2 s^*_t + u_t,$$

where u_t is serially uncorrelated and s^*_t is formed by geometrically weighting squares of observed price deviations from expectations

$$s^*_t = \sum_{k=0}^{\infty} \beta(1-\beta)^k (p_{t-k-1} - p^*_{t-k-1})^2$$

(King, Just 1975). The model in equation (5) is thus a generalization of the adaptive expectations model in equation (1), but the frequency regression methods advanced by Hannan (1965) and used by Howrey are no longer applicable because of the presence of squared terms in equation (5), even when equation (5) is expressed in reduced form.[2] Hence, following the general approach in Anderson (chap. 10), time-domain methods are used to estimate regression parameters, and spectral methods are used only in the analysis of residuals. Consistent methods of estimation for the parameters of equations (1) and (4) have been developed by Dhrymes when second sample moments exist asymptotically, and the method given by Just (1976) yields consistent estimators for the parameters in equation (5) when fourth sample moments of p exist asymptotically.[3]

[2] Even the modifications introduced by Howrey and Klein that deal with squared terms could not be employed without considerable truncation of the sums in equation (5) because the number of cross-product terms grows very rapidly as the maximum length of lag is increased. Indeed, upon expanding equation (5), one finds triple infinite summations of cross products of p. The time series in this study is likely far from long enough to adopt the necessary truncation required for this kind of frequency regression.

[3] These methods essentially consist of using the Klein transformation to treat all unobservable data as parameters to be estimated. Then ordinary or Aitkens regression procedures are used to perform a maximum likelihood search on β.

To demonstrate potential problems in empirically discerning the models in equations (1) and (4) from equation (5), data for wheat acreage response in the California San Joaquin Valley from 1949 through 1970 are used. The data are described in Just (1974). Hence, for the purposes of analysis, y_t in equations (1) through (5) represents acreage harvested. Because a time series of cost data was unavailable, the p_t variables represent only returns per acre (price × yield per acre). Also, because wheat production has been regulated by government programs (allotments and price supports) during parts of the last few decades, the estimated equations also include variables for the proportion of wheat program participation in terms of allotted acreages (z_t), the allotted wheat acreage on participating farms (g_t), and the price support for wheat times the proportion of wheat program participation (w_t). Using the estimation procedures indicated above, the (consistent) estimates for models (1), (4), and (5) in table 1 are obtained.

Since model (5) is rarely considered in studies such as this, suppose for a moment that only the results for equations (1) and (4) are available in table 1. With comparable fit, a common practice is to choose one model or the other depending on serial correlation statistics. In this case one would evidently be led to conclude that the Nerlovian model equation (4) is applicable since neither the Durbin-Watson statistic nor the serial correlation coefficient gives substantial evidence to the contrary.[4] The adaptive model in equation (1), on the other hand, appears inapplicable because of its inability to explain a seemingly autocorrelated disturbance process. The high

[4] Since equations are estimated in structural form (without lagged endogenous variables), the usual Durbin-Watson testing procedure can apply asymptotically. Although many other useful alternative statistics could also be considered, only the Durbin-Watson statistic is used for exemplary purposes because of its relative popularity.

Table 1. Estimated Wheat Acreage Relationships for the California San Joaquin Valley

	(764,017)	(37,037)	(0.1867)	(17,384)	(18,111)	(899)					

[a] Values in parentheses are standard errors from regressions conditioned on the maximum likelihood estimates of β.
[b] Values of ρ represent first-order autocorrelation among the $\hat{u}_t$ for models (1) and (5). In the case of model (4), ρ gives first-order autocorrelation among the prefiltered version of the $\hat{u}_t$, i.e., among the $\hat{v}_t$.

serial correlation coefficient and low Durbin-Watson statistic suggest that equation (4) may be a more appropriate model.

But another possibility exists. If equation (1) is estimated when equation (5) is applicable, then the residuals will actually be estimating

$$(6)\quad \begin{aligned} u^*_t &= u_t + a_2 \sum_{i=0}^{\infty} \beta(1-\beta)^i (p_{t-k-1} - p^*_{t-k-1})^2 - c_{u^*} \\ &= (1-\beta)u^*_{t-1} + a_2\beta(p_{t-1} - p^*_{t-1})^2 + u_t - (1-\beta)u_{t-1} - c_{u^*} \end{aligned}$$

if the term $a_2 s^*_t$ is not highly correlated with other variables in the model (where c_{u^*} is a constant that makes the expectation of u^*_t equal to 0 during the period of estimation). When the risk terms are not small relative to the true disturbance terms, the u^*_t process behaves very much like a first-order autoregressive process and thus leads to corresponding Durbin-Watson and serial correlation coefficients. In other words, if equation (5) applies, then estimation of the structural form in equation (1) or (4) will tend to produce residuals that behave the same way as the disturbances specified for equation (4) because of the low frequency nature of the risk variables that are excluded.

Although the results for equation (1) are sufficient to refute the simple adaptive expectation hypothesis, additional evidence is needed to distinguish between the partial adjustment mechanism and the adaptive risk mechanism. For this purpose a further comparison of equations (4) and (5) is needed. Considering the results in table 1, with respect to equation (5), it appears that positively correlated residuals in equations (1) and (4) are a result of risk response since the risk term is significant (asymptotically), fit is improved, the Durbin-Watson statistic is closer to 2, and serial correlation in residuals is reduced to near zero. Again, this may be an incorrect conclusion that gains support only because of the inadequacy of common time-domain statistics; that is, if u^*_t in equation (6) can have stochastic properties like the u_t disturbances in equation (4), then the reverse is also true. In each case the "autoregressive" parameter $(1 - \beta)$ in equations (4) and (6) is the same. Hence, if the model in equation (4) is applicable and equation (5) is estimated, the inclusion of s^*_t may have approximately the same effects as explaining the lagged u_{t-1} in equation (4). Consequently, the seemingly unexplained disturbances would be reduced approximately from $(1-\beta)u_{t-1} + v_t$ to v_t. When β is not near 1, as indicated by results in table 1, it is thus likely that fit will be improved, s^*_t will be significant, and because residuals more closely estimate v_t in equation (4), serial correlation will be reduced.

Hence, common time-domain statistics may be inadequate because of their highly composite nature. To gain information regarding possible departure from stochastic specifications hypothesized under each of the models in equations (1), (4), and (5), spectral analysis can be more useful because of its multidimensional nature.

Spectral Hypothesis Testing

Spectral methods in econometrics are most often applied to an observed time series (or a prewhitened, observed time series). But when regression is used, the disturbance series is only estimated, not observed. In a small sample situation, regression introduces serial dependence among estimated disturbances even when none exists among actual disturbances (because of the singularity of the distribution of the estimated disturbance vector). This same phenomenon will usually cause the covariance-stationary assumption of spectral analysis to be violated.[5] But, asymptotically, disturbances are consistently estimated, and necessary assumptions of spectral analysis are satisfied if true disturbances are covariance stationary. Hence, ordinary spectral techniques become asymptotically applicable for equations (1), (4), and (5) since the associated disturbance processes are covariance stationary.

The spectral density function of a covariance-stationary process $\{u_t\}$ is defined by

$$(7)\quad f(\lambda) = \frac{1}{2\pi} \sum_{h=-\infty}^{\infty} c_{uu}(h) e^{-i\lambda h}, \qquad -\infty < \lambda < \infty,$$

and describes the density of variance of the $\{u_t\}$ process over frequency λ.[6] Since the

[5] Covariance stationarity of a time series $\{u_t\}$ implies a constant mean, $E(u_t) = c_u$ for c_u constant, as well as a covariance function that is independent of t, $\mathrm{cov}(u_t, u_{t+h}) = c_{uu}(h)$. Note that $c_{uu}(h) = c_{uu}(-h)$.

[6] Frequency (angular frequency) represents cycles per unit time (multiplied by 2π). One-half cycle per time period corresponds to

spectral density function of different order autoregressive and/or moving average processes is distinctly different, the spectral density in equation (7) can be used to determine the stochastic structure of the $\{u_t\}$ process. The spectral density function is estimated by substituting the sample covariance function,

$$\hat{c}_{uu}(h) = \frac{1}{t_f - t_0 + 1} \sum_{k=t_0}^{t_f - |h|} u_k u_{k+|h|},$$

for $c_{uu}(h)$ in equation (7). The estimate so obtained is called the sample periodogram and is denoted here by $\hat{f}(\lambda)$. The periodogram is usually computed only at points $\lambda = 2\pi j/T, j = 1, \ldots, [T/2]$, where $T = t_f - t_0 - 1$, to allow use of fast Fourier transform algorithms and because estimates at those intervals are asymptotically independent. (The results indicated here are derived in Brillinger and in Jenkins and Watts.) Since $f(\lambda)$ can be represented as

$$(8)\quad \hat{f}(\lambda) = \frac{1}{2\pi T} |d_u(\lambda)|^2,$$

$$d_u(\lambda) = \sum_{t=1}^{T} u_{t_0+t-1}\, e^{-i\lambda t},$$

the complex central limit theorem implies asymptotic complex normality of $d_u(\lambda)$,[7] $d_u(\lambda) \to N_c[0, 2\pi T f(\lambda)]$, $\lambda \neq 0, \pm\pi, \pm 2\pi, \ldots$. Hence, the square has a chi-square distribution (asymptotically),

$$(9)\quad \frac{2\hat{f}(\lambda)}{f(\lambda)} \to \chi^2_{(2)}, \ \lambda \neq 0, \pm\pi, \pm 2\pi, \ldots$$

At $\lambda = 0, \pm\pi, \pm 2\pi, \ldots$, similar results hold except that either the real or complex component of $d_u(\lambda)$ vanishes and the chi-square distribution in equation (9) loses one degree of freedom.

A spectral hypothesis test based on these distributional results can be applied easily to the output (periodogram) from standard computer programs. The important property of the periodogram, which makes this possible, is the asymptotic independence of periodogram ordinates $\hat{f}(\lambda_j)$, $\lambda_j = 2\pi j/T, j = 0, 1, \ldots, [T/2]$.[8] With mutual independence, a periodogram can be regarded as a multidimensional statistic for which the significance probabilities can be determined independently in each dimension. Let the spectral hypothesis be given by H_0: $f(\lambda) = f_0(\lambda)$ for some specified spectral density function $f_0(\lambda)$. Suppose that an upper limit θ_j and a lower limit ϕ_j are specified for each periodogram ordinate and that the null hypothesis is rejected if any periodogram ordinate falls outside its limits. The critical region of the test is then given by

$$c = \{\hat{f}(\lambda): \hat{f}(\lambda_j) > \theta_j \text{ or } \hat{f}(\lambda_j) < \phi_j,\ j = 1, \ldots, [T/2] - 1\}.$$

With independence of the periodogram ordinates, the significance level of the test or the probability of the critical region under H_o is[9]

$$(10)\quad \alpha \equiv P\{c | f(\lambda) = f_0(\lambda)\} = 1 - \prod_{j=1}^{[T/2]-1} P\{\phi_j \le \hat{f}(\lambda_j) \le \theta_j | H_0\}.$$

Using the results in equation (9), which indicate an asymptotic chi-square distribution, and replacing $f(\lambda)$ by the specified $f_0(\lambda)$ under H_0, the calculations in equation (10) can be easily made,[10] and the θ_j and ϕ_j can be chosen to attain a specified significance level.[11]

One reasonable approach, where no specific alternatives are of interest, is to choose the θ_j and ϕ_j to equate the probabilities of the acceptance region of periodogram ordinates. This implies

$$(11)\quad (1-\alpha)^{1/([T/2]-1)} = P\{\phi_j \le \hat{f}(\lambda_j) \le \theta_j | H_0\},$$
$$= P\left\{ \frac{2\phi_j}{f_0(\lambda_j)} \le \frac{2\hat{f}(\lambda_j)}{f_0(\lambda_j)} \le \frac{2\theta_j}{f_0(\lambda_j)} \,\middle|\, H_0 \right\}, \quad j = 1, \ldots, [T/2] - 1.$$

$\lambda = \pi$, one-fourth cycle per time period corresponds to $\lambda = \pi/2$, etc.

[7] A complex random variable $x = v + iw$ has a complex normal distribution with mean $E(x) = E(v) + iE(w)$ and variance $\sigma_x = E[(x - Ex)(x - Ex)] = \sigma_v + i\sigma_w$ if $(vw)'$ has a two-dimensional multivariate normal distribution with mean $(EvEw)'$ and covariance matrix

$$\frac{1}{2}\begin{bmatrix} \sigma_v & \sigma_w \\ \sigma_w & \sigma_v \end{bmatrix}$$

[8] Here, $[T/2]$ represents the largest integer less than or equal to $T/2$.

[9] An alternative procedure has been used by Naylor, Wertz, and Wonnacott in testing hypotheses about the spectra of simulated processes. But their method provides only a bound on α that is such that their tests are always biased toward acceptance. The method in equation (10), however, is asymptotically exact.

[10] Although it is also well known that $\hat{f}(\lambda)/f(\lambda) \to \chi^2_{(1)}$ for $\lambda = 0, \pm\pi, \pm 2\pi, \ldots$, to avoid unnecessary complications in the asymptotic tests that are outlined in this paper, these end points will be disregarded. Their potential contribution is asymptotically unimportant, anyway.

[11] However, equation (10) does not determine ϕ_j and θ_j uniquely. Thus, ϕ_j and θ_j can be chosen to attain high power against alternative hypotheses of interest. Although the power of this chi-square test can be easily calculated for the specific alternative hypothesis using the distribution in equation (8), a discussion of the problems associated with maximizing power must be left for another paper.

Since $2\hat{f}(\lambda_j)/f_0(\lambda_j)$ has the distribution in equation (8) under H_0, the significance points ϕ_j and θ_j can be determined using chi-square significance tables when σ^2 is known,[12]

$$(12) \quad \frac{2\phi_j}{f_0(\lambda_j)} = \bar{\phi} \equiv \chi_{(2;1-\alpha^*)},$$

$$\frac{2\theta_j}{f_0(\lambda_j)} = \bar{\theta} \equiv \chi^2_{(2;\alpha^*)},$$

where $\alpha^* = \frac{1}{2}(1-\alpha)^{1/([T/2]-1)}$ and $\chi^2_{(n;\alpha)}$ is the α significance point of the chi-square distribution with n degrees of freedom. Hence, the chi-square testing procedure, which will be followed in this paper, corresponds to the following. First, draw an upper horizontal line at θ and a lower horizontal line at $\bar{\phi}$. If the simple path of $2\hat{f}(\lambda)/f_0(\lambda)$ crosses either the upper line or the lower line, then the hypothesis is rejected; otherwise, it is not.

If one is testing a null hypothesis of serial independence, then this test is particularly easy to perform since $f_0(\lambda) = \sigma^2/2\pi$ and is constant. Hence, on the basis of equations (11) and (12), one need only observe whether any $\hat{f}(\lambda_j)$ falls outside the single interval—say, $(\bar{\phi}, \bar{\theta})$—where $\theta = \theta_j$, $\phi = \phi_j$ for all $j = 1, \ldots, [T/2] - 1$. If a spectral estimator is computed by averaging adjacent periodogram ordinates (windowing), then the significance points can be determined with essentially the same calculations as above except that the degrees of freedom in the chi-square distribution would change (by a factor of the number of ordinates averaged). If σ^2 is unknown, then equations (11) and (12) still apply asymptotically when σ^2 is replaced by its estimate from regression results.

Another approach to spectral hypothesis testing, developed by Durbin, deals with the empirical spectral distribution function (the cumulated periodogram). Since appropriate modifications have been made in Durbin's method for the case where disturbances are only estimated by regression, his results usually find exact applicability in ordinary small sample regression. But in the applications in this paper, Durbin's method also applies only asymptotically since only asymptotic properties are obtained with each of the regression procedures that are employed. The null hypothesis that Durbin considers explicitly is H_0: $f(\lambda) = \sigma^2/2\pi$, which corresponds to serially uncorrelated regression disturbances as in models (1) and (5). But to consider other null hypotheses, his method can be easily modified by dividing the raw periodogram ordinates by their corresponding hypothesized values before cumulating. Yet, another approach—one that is used here—is to prefilter (or prewhiten) the time series so that the hypothesized spectrum corresponds to white noise in the filtered series.[13]

The test statistic suggested by Durbin is the estimated spectral distribution function (the normalized, cumulative periodogram),

$$(13) \quad \hat{F}(\lambda_j) = \sum_{i=1}^{j} \hat{f}(\lambda_i) \Bigg/ \sum_{i=1}^{[T/2]} \hat{f}(\lambda_i),$$

$$\lambda_j = \frac{2\pi j}{T}, j = 1, \ldots, [T/2].$$

Durbin has derived slight modifications of the usual Kolmogorov-Smirnov statistics that are necessary for small sample tests on the cumulated periodogram (computed from true disturbances). His test involves calculating lines of the form $y = c_0 + 2j/T$, where c_0 is a constant determined from significance tables. If the sample path of $\hat{F}(\lambda_j)$ crosses the line(s), then the hypothesis of serial independence is rejected; otherwise, it is not. In later work he has made modifications for the case where the periodogram is computed from least-squares residuals, which involve calculating a pair of parallel lines for a one-sided test or two pairs of parallel lines for a two-sided test. If the sample path of $\hat{F}(\lambda_j)$ crosses neither line of the pair(s), the hypothesis of serial independence is not rejected; if it crosses both lines of the pair(s), the hypothesis is rejected; if it crosses only one line of the pair(s), the test is inconclusive.[14] The upper line in each pair is calculated by

$$(14) \quad y = c_0 + \frac{2j}{(T-k)}, \quad 0 \le j \le \frac{(T-k)}{2},$$

where k is the number of regressors including the constant term. The lower line is given by

[12] Although not necessarily more powerful, the usual practice of dividing chi-square probabilities of rejection equally among high and low points is followed here.

[13] A time series $\{Y_t\}$ is a prewhitened version of $\{X_t\}$ if $\{Y_t\}$ is generated by

$$Y_t = \sum_{k=0}^{K} a_k X_{t-k}$$

for some constants a_k, $k = 0, \ldots, K$. For example, if $\{X_t\}$ is a first-order autoregressive process with autoregressive parameter ρ, then $Y_t = X_t - \rho X_{t-1}$ is serially uncorrelated (white noise).

[14] Although the significance points are only approximated by Durbin's methods when T or k are even, he argues that the error of approximation is negligible.

$$(15)\quad y = c_0 + \frac{2[j - (k-1)/2]}{(T-k)}, \qquad \frac{(k-1)}{2} \leq j \leq \frac{T}{2}.$$

Again, the c_0 term is associated with the significance level of the test and is determined from significance tables developed by Durbin.

In the case of ordinary regression, the Durbin test has the advantage of small sample applicability. But in any case the former chi-square test is usually easier to perform in practice because only the $\hat{f}(\lambda_j)$ in equation (8) rather than the $\hat{F}(\lambda_j)$ in equation (13) are usually obtained through standard computer software.

Some Empirical Results

Following estimation of the three equations (1), (4), and (5), as reported in table 1, consistent estimates of the disturbances were calculated for each model. In each case the periodogram in equation (8) was computed, and the corresponding sample spectral distribution function in equation (7) was also determined. The periodograms are shown in figure 1, and the corresponding sample distribution functions are shown in figure 2. In each case results are shown for the test of $H_0: f(\lambda) = \sigma^2/2\pi$ against the alternative $H_1: f(\lambda) \neq \sigma^2/2\pi$ with significance level $\alpha = 0.10$.[15] The significance points ϕ_j and θ_j, determined according to equation (12), are indicated with broken lines in figure 1. The significance lines in equations (14) and (15) are indicated with broken lines in figure 2. The upper pair of lines in each case corresponds to Durbin's one-sided test for excess low frequency, and the lower pair of lines corresponds to Durbin's one-sided test for excess high frequency. As Durbin indicates, the two one-sided tests can be combined to form a two-sided test with almost no loss in accuracy.

Again, the null hypothesis of serial independence must be rejected for the model in equation (1) as indicated by the statistics in table 1. Consider, the second alternative model—the partial adjustment equation in equation (4). Since the partial adjustment model corresponds to the adaptive expectations model except that disturbances are serially correlated, the spectral estimates from equation (1) in figures 1 and 2 provide some evidence for or against the partial adjustment model. The disturbance in equation (4) is a first-order autoregressive process. Apparently, the results for equation (1) are not inconsistent with the spectral shape of a first-order autoregressive process, e.g., one with excessive low frequency noise. To further investigate this possibility, the spectral results corresponding to equation (4) are useful. Here, the estimated disturbances in equation (4) were prefiltered to obtain estimates of v_t. Hence, under the usual partial adjustment specifications, the spectrum corresponding to equation (4) in figures 1 and 2 should be white noise. But apparently the spectral results do not highly favor the partial adjustment model. The chi-square test in figure 1 indicates rejection of the hypothesis corresponding to model (4), while the Durbin test in figure 2 leads neither to rejection nor acceptance.

Finally, consider the adaptive risk model in equation (5). Again, the hypothesized spectrum of regression disturbances is white noise. In this case both spectral testing methods in figures 1 and 2 lead to definite nonrejection of the spectral test corresponding to the adaptive

[15] Consistent estimation is only required under the null hypothesis. The hypothesis tests continue to apply, as in all statistical problems, even though the parameters may be estimated biasedly under the alternative hypothesis.

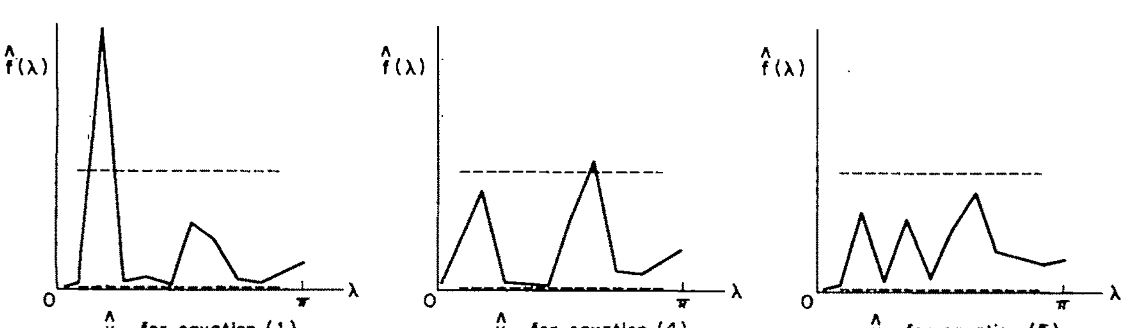

Figure 1. Estimated spectral densities for wheat acreage in the San Joaquin Valley

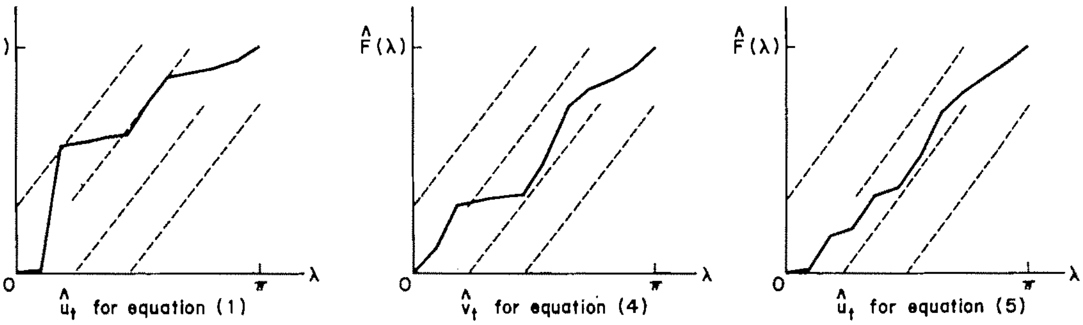

Figure 2. Empirical spectral distribution functions for wheat acreage in the San Joaquin Valley

risk model. Hence, in this particular empirical problem, spectral methods are apparently sufficient to provide some evidence for one model over another.

But it is not necessarily the case that spectral methods will lead to support of only one model or another. Based on the same arguments as those pertaining to the time-domain statistics above, it is possible that spectral tests will simultaneously support both models (4) and (5). This has indeed been found to be the case in a similar study of wheat acreage response in the Sacramento Valley of California. The particular empirical problem in this paper demonstrates that spectral methods can possibly lead to evidence supporting only one model in cases where time-domain methods are not conclusive. Furthermore, even though time-domain statistics appear conclusive, the arguments of this paper suggest that they may be misleading considering the types of alternatives that possibly exist. For example, one would expect tests based on the Durbin-Watson statistic or serial correlation coefficient to have an extremely low power against the alternative disturbance process in equation (6). For robustness, an application of spectral analysis appears advisable whenever the Nerlovian model is employed.

Another observation suggested by the results is that extensive testing (possibly including spectral methods and frequency-domain regression), with respect to geometric or general linear lag models under alternative stochastic specifications, may not be sufficient to conclude in favor of their applicability when alternatives such as equation (5) may also exist. The studies by Zellner and Geisel and by Howrey represent such attempts. Nonlinear lag models such as equation (5) are not usually considered in macroeconomic problems, but if they can possibly apply, then the conclusions by Zellner and Geisel and by Howrey, which favor a first-order autoregressive scheme, should perhaps be reconsidered. It seems that similar methods applied to microeconomic relations cannot be fully conclusive.

Conclusions

The results in this paper imply that empirical discernment of the Nerlovian partial adjustment model from an adaptive risk model is a delicate problem. If either model is operative, then time-domain estimation results for equation (4) alone (or possibly a comparison with results for equation (1)) will likely lead one to conclude in favor of the partial adjustment model. If time-domain results are also obtained for (5), then one would likely be led to conclude in favor of the adaptive risk model, again when either equation (4) or (5) are applicable. A further investigation with spectral analysis leads to more appropriate conclusions. In the empirical problem in this paper, spectral results favored the adaptive risk model. In general, it is possible that spectral results could equally support both models, i.e., both associated spectral hypotheses could be supported. Hence, empirical discernment would not be possible; but at least results would make clear the possible applicability of both models.

Notes

Welfare and Exchange Rate Effects of the Rhodesian Trade Embargo: An Elasticity Approach

Ewen M. Wilson and Paul R. Johnson

Trade embargoes, like wars, floods, and other catastrophes, put severe pressures on an economy. The response to such pressures is necessarily of considerable magnitude. The eleven-year-old trade boycott of Rhodesia, initiated by the British and sanctioned by the United Nations, provides an observation of such a response.[1] The observation is of interest since Rhodesia, a relatively small country, depends on exports of agricultural and mineral resources for a substantial fraction of her economic activity. Furthermore, the response has involved rather stringent foreign exchange controls and the maintenance of an overvalued exchange rate. The importance of the exchange rate as an economic policy variable has been forcefully expounded by Schuh. Many African countries maintain overvalued currencies (Haessel and Vickery). The exchange rate response and the cost (defined below) of the Rhodesian trade boycott is the subject of this analysis, which follows an elasticity approach.

Elasticity techniques have been increasingly used in recent years to analyze balance of payments, exchange rate, and welfare effects of international trade distortions (Floyd, Basevi, Walker, Johnson). Basevi's work on the exchange rate and welfare effects stemming from import tariffs and Walker's generalization of the latter work to analyze bilateral tariffs offer an appropriate analytical framework for the task at hand. However, we have converted the Basevi-Walker model to account for special peculiarities of the present study and to generate otherwise nonestimable price effects of the trade embargo on the Rhodesian import market. Welfare effects are viewed solely from the Rhodesian perspective and refer, following Basevi's definition, to import consumers' utility (area under the import demand curve) minus the cost of resources employed in the export market (area under the export supply curve). The layout of this paper, which is based on work by Wilson, is as follows. First, special peculiarities of the Rhodesian situation are discussed and assumptions made; second, the algebraic model is outlined; and third, empirical results are presented along with some conclusions.

Peculiarities and Assumptions

Historically, the Rhodesian economy has been trade oriented with export revenues accounting for approximately 45% of the gross national product (GNP) prior to 1966. Flue-cured tobacco exports, the single largest component of the foreign trade accounts, had by the 1960s established Rhodesia as a major supplier of unmanufactured tobacco, next to the United States. By virtue of this large share in world trade, Rhodesia may be assumed to face a less than perfectly elastic foreign demand for her tobacco exports; for exports other than tobacco and for imports the standard small country assumptions (infinite elasticities of import supply and export demand) presumably hold.[2]

The foreign trade policies of the Rhodesian authorities, based on observed response to the economic boycott, are assumed to be directed toward preservation of balance of payments equilibrium and exchange rate parity (essentially via foreign exchange quotas). The trade ban may be viewed from the Rhodesian perspective as a leftward (downward) shift of the export demand curves and an upward shift of the import supply curve. The vertical distance between the pre- and postembargo import supply curves (resulting partly from the ban on goods destined for Rhodesia and partly from Rhodesian import restrictions to preserve balance of payments equilibrium and exchange rate parity) reflects a price effect to Rhodesian importers. From the viewpoint of Rhodesia's trading partners, the trade ban represents a movement along their demand curves for Rhodesian goods, prompted by a leftward shift in the supply curve of Rhodesian goods. The vertical distance between pre- and post-

Journal Series Paper No. 4917, North Carolina Agricultural Experiment Station, Raleigh. Appreciation is expressed to two anonymous reviewers for constructive comments.

[1] The trade ban was initially imposed by Britain's Labor government in retaliation for the 11 November 1965 Unilateral Declaration of Independence by Rhodesia from Britain. In December 1966, the trade ban was extended by United Nations Security Council Resolution 232 on grounds of Rhodesia's "threat to international peace and security."

[2] These assumptions are equivalent to Basevi's "third case" (Basevi, p. 844). However, the comparison cannot be pursued very much further owing to the different interpretation given the model as discussed below.

embargo export supply curves is a measure of the export price effect of sanctions stemming from the decision of the world community to penalize trade with Rhodesia. In a sense the price effect in the export market is analogous to a foreign tariff on Rhodesian goods and reflects the risk of international penalty for "sanctions busting," "middlemen" fees for undercover trading operations, and so forth.[3]

The Algebraic Model

The analytic problem may be formulated in terms of a simple demand and supply model:

$$(1) \quad S_t = S_t(P_t^d),\ S_o = S_o(P_o^d),\ S_m = S_m(P_m^f),$$

and

$$D_t = D_t(P_t^f),\ D_o = D_o(P_o^f),\ D_m = D_m(P_m^d),$$

where S and D refer to quantities supplied and demanded, respectively, P refers to price, d is domestic currency values, f is foreign currency values, t is flue-cured tobacco exports, o is other exports excluding tobacco, and m is imports. More precisely, the supply and demand functions refer to excess supply and excess demand. The supply of exportables, after domestic demand has been accounted for, represents an excess export supply and is functionally related to domestic currency prices. The foreign demand for exports represents an excess demand after foreign supplies have been accounted for and is functionally related to foreign currency prices. Likewise, excess (domestic) demand for imports is a function of domestic currency prices, while excess (foreign) supply of imports is a function of foreign currency prices.

Foreign and domestic currencies are linked by the exchange rate

$$(2) \qquad \pi = P^d/P^f.$$

Changes in the exchange rate may be viewed as a shift of one or other of the curves depending on which currency the market is denominated in. For instance, when the export market is denominated in terms of domestic currency, devaluation (an increase in the domestic price of foreign currency) shows as a rightward shift of the export demand curve along the export supply curve (since export demand is functionally related to the adjusted foreign currency price). Likewise, in a domestic currency denominated import market, devaluation shows as an upward shift of the import supply curve along the unshifting import demand curve.

The balance of trade identity may be written in terms of domestic currency units as

$$(3) \qquad B = P_t^d X_t + P_o^d X_o - P_m^d M,$$

where B refers to the balance of trade, and X and M refer to exports and imports, respectively.

The price effect of the trade embargo on the Rhodesian import market is denoted by t_m, and the price effect in the export market is denoted by t_t for flue-cured tobacco and t_o for all other exports. Given a knowledge of respective demand and supply elasticities and based on ex post declines in export volumes, the magnitudes of t_t and t_o are easily approximated.[4] The derivation of t_m is more complex, since under our assumptions it depends not only on import market elasticities but also upon the magnitudes of t_t, t_o, and export market elasticities. The method employed to solve for t_m is based on algebraic manipulation of the balance of trade identity (3). Concerned as this study is with finite magnitudes, it is necessary to write the total differential of (3) in terms of the finite approximation

$$\begin{aligned}(4) \quad \Delta B &= P_t^d\, \Delta X_t + X_t\, \Delta P_t^d + P_o^d\, \Delta X_o \\ &\quad + X_o\, \Delta P_o^d - P_m^d\, \Delta M - M\, \Delta P_m^d \\ &\quad + \Delta P_t^d\, \Delta X_t + \Delta P_o^d\, \Delta X_o - \Delta P_m^d\, \Delta M.\end{aligned}$$

By following Basevi and Walker, making use of the foreign exchange rate identity (2), and choosing initial units such that prices and the foreign exchange rate equal unity, it is possible by utilizing the differential of the exchange rate identity (with higher order differences ignored) to transform equation (4) to an expression including slopes of respective demand and supply curves, percentage exchange rate change $\Delta\pi/\pi$, and sanctions price effects, t_t, t_o, and t_m. Our derivation also incorporates the profit-maximizing rule of equality of marginal revenue with marginal cost. By setting $\Delta B = \Delta\pi/\pi = 0$ and by converting to elasticities, it can be shown that

$$\begin{aligned}(5) \quad t_m &= \{X_t\eta_t\epsilon_t(1 + \eta_t)/M\eta_m Z^2\}t_t^2 \\ &\quad - \{X_t\eta_t[1 + \epsilon_t(1 + \eta_t)]/M\eta_m Z\}t_t \\ &\quad + \{X_o\epsilon_o/M\eta_m\}t_o^2 - \{X_o(1 + \epsilon_o)/M\eta_m\}t_o,\end{aligned}$$

where $Z = \eta_t - \epsilon_t(1 + 1/\eta_t)$, and η and ϵ are, respectively, demand and supply elasticities.[5]

Having obtained estimates of t_t, t_o, and t_m, it is a relatively simple matter to revert to the Basevi-Walker framework for estimating welfare costs and

[3] The tariff analogy is not quite so neat in the import market since here the price effect stems from two sources: first, the extra trading cost to foreigners emanating from the risk of selling goods to Rhodesia, and second, the Rhodesian import restrictions imposed to maintain balance of payments equilibrium and avert devaluation of the Rhodesian currency. In actual fact Rhodesian import restrictions primarily involved rationing of reduced foreign exchange earnings. Hence, this study can abstract itself from distribution and transfer questions that would arise under an explicit policy of retaliatory import tariffs. In order to avoid confusion, the remainder of this study will refer to "price effects" in the import and export markets rather than tariffs per se. Nevertheless, the tariff analogy may be helpful to readers accustomed to thinking in terms of the original Basevi-Walker model.

[4] Perhaps it should be stated that the embargo on Rhodesian exports was far from totally effective. A total embargo implies X_t and X_o equal 0, a situation that would make the following analysis redundant.

[5] Base prices in these elasticities are defined exclusive of export and import market price effects. For instance, the export demand elasticity for flue-cured tobacco, $\eta_t = \Delta D_t(P_t^f)P_t^f/\Delta P_t^f X_t$.

exchange rate effects of the economic boycott. This analysis is couched in terms of total elimination of t_t, t_o, and t_m (that is, $\Delta t_t = -t_t$, $\Delta t_o = -t_o$, and $\Delta t_m = -t_m$). Starting once again with equation (4), employing the same assumptions, setting $\Delta B = 0$, converting to elasticities, and solving for $\Delta\pi/\pi$ yields the exchange rate effect of a return to "normal" (preembargo) trading patterns. The solution is a quadratic equation in $\Delta\pi/\pi$, which for notational simplicity is rewritten as $\dot{\pi}$:

$$(6)\quad \dot{\pi}^2 \{X_tK_t/M + X_o\epsilon_o/M - A_m\} + \dot{\pi} \{X_t[2K_tt_t + A_t]/M + X_o[2\epsilon_ot_o + (1 + \epsilon_o)]/M + A_m(t_m - 1) - 1\} + \{X_tt_t[K_tt_t + A_t]/M + X_ot_o[\epsilon_ot_o + (1 + \epsilon_o)]/M + A_mt_m\} = 0,$$

where $K_t = \eta_t\epsilon_t(1 + \eta_t)/T_t^2$, $A_t = \eta_t[1 + \epsilon_t(1 + 1/\eta_t)]/T_t$, $T_t = \eta_t - \epsilon_t(1 + 1/\eta_t)(1 + t_t)$, and $A_m = \eta_m/(1 + t_m)$.[6] Based on the Basevi-Walker definition of welfare, we are interested in measuring the areas in the import market

$$(7)\qquad \int D_m(P_m{}^d)\, dM,$$

and in the export market

$$(8)\qquad \int S_t(P_t{}^d)\, dX_t + \int S_o(P_o{}^d)\, dX_o.$$

Thus, the net welfare effect of lifting the embargo is given by the gain in the import market—equation (7)—minus the loss in the export markets—equation (8). By substituting the appropriate terms used in deriving equation (6), it may be shown that the welfare effect is

$$(9)\quad W = MA_m(\dot{\pi} - t_m)[1 + 0.5(\dot{\pi} + t_m)] - X_t\epsilon_t(1 + \eta_t)(\pi + t_t)[(1 + 1/\eta_t) + 1/\eta_t)(\pi + t_t)/2T_t]/T_t - X_o\epsilon_o(\pi + t_o)[1 + 0.5(\pi + t_o)],$$

where the exchange rate effect ($\dot{\pi}$) is derived from equation (6).

Empirical Results and Conclusions

Due to restrictions on publication of post-1965 production and trade data, elasticity parameters are assumed constant for the pre- and postembargo situations. The Rhodesian flue-cured tobacco export demand elasticity (η_t) was estimated as -5.2 and the export supply elasticity (ϵ_t) as 0.73 (Wilson). For the supply elasticity of other exports and for the import demand elasticity, plausible values are selected and bounds set on these choices (viz., $\epsilon_o = 0.8$, 1.5, and 2.5; $\eta_m = -0.5$, -1.0, and -1.5).[7] Preembargo trade data (in millions of Rhodesian dollars) is taken as $X_t = 84.9$, $X_o = 226.7$, and $M = 233.3$ (mean 1964–65 data).[8] For the postembargo period, 1966–71, assuming constant export shares, the mean values are $X_t = 63.909$, $X_o = 172.791$, and $M = 225.5$. The sanctions price effect parameters, t_t and t_o, are computed from median elasticity values based on the 24% decline in exports (mean 1966–71 compared with preembargo). Upper and lower estimates of these parameters are also obtained based on the decline in mean export values from preembargo to 1966–68 (35% decline) and 1969–71 (13% decline), respectively. This yields $t_t = 0.20$, 0.38, and 0.55 and $t_o = 0.09$, 0.16, and 0.23.

The number of combinations of the elasticity and price parameters in equations (5), (6), and (9) is eighty-one. A summary of the outcomes is presented in table 1 for median, pessimistic, and optimistic parameter combinations and for the mean of all eighty-one outcomes.

There are two interpretations of the results in table 1. First, the welfare gain resulting from a resumption of preembargo trade,[9] in which case the exchange rate effect may be viewed as a potential appreciation of the Rhodesian currency. Second, the welfare cost of the status quo, in which case the exchange rate effect represents the level of overvaluation of the Rhodesian dollar. Since businessmen in Rhodesia have been complaining about a "shortage" of foreign exchange, the second interpretation is preferred. Thus, based on the median parameter outcome and also on the mean of all outcomes, the annual welfare cost to Rhodesia in the 1966–71 period was close to 80 million Rhodesian dollars. This is equivalent to about 7% of 1971 GNP. By the same token, the 1971 rate of overvaluation of the Rhodesian dollar was probably 8% to 10%, while the import price index was approximately 60% above its 1964–65 level. Under the most pessimistic combination of elasticity parameters, the welfare cost to Rhodesia amounted to less than 23% of 1965 GNP and less than 14% of 1971 GNP.

In the period since 1971, exchange rate pressures appear to have intensified in Rhodesia. The so-called "shortage" of foreign exchange has become more acute. The term "shortage" is of course a price-related concept: at a given price, demand for foreign currencies is greater than the supply forthcoming. The implication is that the price of foreign currencies in terms of Rhodesian dollars is too low, or what amounts to the same thing, the Rhodesian dollar is overvalued. Based on the empirical evidence presented here, the recent level of overvaluation has probably been well in excess of 10%. Black-market currency operations and frequent violations of Rhodesian foreign exchange regulations are further evidence of overvaluation. The overval-

[6] Base prices in these elasticities are defined inclusive of export and import market price effects. For instance, the export demand elasticity for flue-cured tobacco, $\eta_t = \Delta D_t(P_t^f)P_t^f/(1 + t_t)/\Delta P_t^f X_t$.

[7] Plausible does not mean pulled out of the air. These ranges are consistent with earlier empirical applications (Floyd, Basevi, Johnson) and with Harberger's "rule of thumb" (Harberger, p. 521).

[8] Since the model initially assumes prices and the exchange rate equal to unity, trade value data are synonymous with X_t, X_o, and M.

[9] Abstracting from the structural readjustments that have occurred in the post-1965 period.

Table 1. Estimates of Import Price, Exchange Rate, and Welfare Effects of the Rhodesian Embargo

Parameter Values	Implicit Import Price Effect, t_m (%)	Exchange Rate Effect, $\hat{\pi}$ (%)	Welfare Effect, W (million Rh $ per year)	Welfare Effect as Percentage of GNP 1965	1971
Median[a]	52.38	−8.24	79.8	11.1	6.9
Mean	64.41	−10.93	83.8	11.7	7.2
Pessimistic[b]	177.42	−27.79	158.1	22.1	13.6
Optimistic[c]	16.54	−0.04	33.3	4.7	2.9

[a] $\epsilon_e = 1.5$, $\eta_m = -1.0$, $t_t = 0.38$, and $t_e = 0.16$.
[b] $\epsilon_e = 2.5$, $\eta_m = -0.5$, $t_t = 0.55$, and $t_e = 0.23$.
[c] $\epsilon_e = 0.8$, $\eta_m = -1.5$, $t_t = 0.20$, and $t_e = 0.09$.

ued Rhodesian dollar provides a powerful incentive for illegal foreign exchange transactions, particularly since legal, though arbitrary, foreign currency allocations have distorted the import market.

The fact that Rhodesian authorities have chosen to support an overvalued currency may seem paradoxical. The overvalued Rhodesian dollar is equivalent to a tax on exports; it increases the foreign currency price of Rhodesian exports and thereby reduces their competitive trading position. However, it also maintains import prices at a level below that defined by exchange rate equilibrium. If import demand elasticity is less than unity, the lower price for imports will result in a reduced total domestic currency cost of imports. Evidently, the Rhodesian authorities perceive this to be the case and feel that lower domestic currency import costs outweigh the foreign currency earnings potential of increased agricultural and mineral exports. In other words, they hold that elasticity magnitudes are not sufficient for the Marshall-Lerner condition to be met.[10] However, based on elasticity values employed here, this perception is incorrect. Naturally, the present exchange rate policy has income distribution implications within the Rhodesian economy.

[10] In terms of our notation the Marshall-Lerner conditions states that depreciation of the Rhodesian currency reduces balance of payments pressure (improve the balance of payments) so long as η_m (absolute) plus the trade weighted sum of ϵ_t and ϵ_e is greater than unity.

The Effects of Income, Assets, Food Programs, and Household Size on Food Consumption

Donald A. West and David W. Price

The availability of food to American households is a continuing public problem. There is concern about adequate amounts of food for households and about the coverage and high costs of food distribution programs. Yet the relationships between food availability and its determinants, including food distribution programs, have not been examined closely. This is partly because major increases in these programs have occurred recently and partly because data on all major sources of food for households have not been available.

Studies by Prais and Houthakker, Friedman, Currie, and others have examined income food expenditure relationships among European and U.S. households. However, these investigations were conducted prior to the implementation of sizable food distribution programs.

Specific questions that have not been fully answered are: How is the value of food consumption affected by receipt of "bonus" food stamps and free lunches?[1] Have the relative impacts of income and household size on food expenditures changed? The purpose of this paper is to examine these questions using a 1972–73 sample of households containing eight- to twelve-year-old children in the state of Washington.

The Sample

The sample consisted of households containing a total of 995 children between the ages of eight and twelve. The sample was stratified by poverty level and ethnic group and contained larger numbers of Blacks and Mexican-Americans than would have been obtained by a random sample of the state's population.[2]

The child is the unit of observation, and the sample generalizes to the socioeconomic background of the child rather than the household. Household size in this sample is larger than a random sample of households of the state would yield for three reasons. First, the household was required to have an eight- to twelve-year-old child, which excluded all one-person and most two-person households. Second, Blacks and Mexican-Americans have larger households than Anglos. Third, the child being the unit of observation gave a higher probability of the larger household being selected. Where siblings were included, the household was assigned a multiple weight.

There are several advantages of this type of sample. The disproportionately larger percentage of households with low incomes provides a larger number of observations at the low income level, while still retaining an adequate percentage (62%) with incomes above 125% of poverty level. All households are at approximately the same stage in the family life cycle, most heads were thirty to fifty years of age, so relationships can be estimated net of the influence of life cycle (see Price 1969).

Forty-nine percent of the sample were Anglos, 26% were Blacks, and 25% were Mexican-Americans (table 1). Thirty-eight percent of the sample were in households with incomes below 125% of the poverty level. Just over one-fourth of the sample were in households receiving food stamps, and more than one-third received free school lunches.

Selection of Variables

The dependent variable in the analysis—value of food consumed—consists of all food items purchased plus food from other sources. Food from other sources includes food purchased with bonus food stamps, free U.S. Department of Agriculture commodities, free school lunches, gifts of food, food produced in gardens or on farms by the house-

Donald A. West and David W. Price are associate professors and associate agricultural economists at Washington State University, Pullman.

Scientific Paper No. 4532 of the College of Agriculture Research Center, Washington State University. Work was conducted under CARC Project No. 0103, Washington State University. The research was partially supported by a grant from the Foods and Nutrition Service, U.S. Department of Agriculture. The authors wish to thank Stephen Hiemstra, Leroy Blakeslee, two anonymous reviewers, and the editor of the *Journal* for helpful comments and constructive criticisms. The authors are responsible for errors or deficiencies.

[1] "Bonus" food stamps are defined as the face value of food stamps minus their cost to the recipient.

[2] The entire sample is in essence six different samples each representative of six different strata or populations within the state. These strata are income categories above and below 125% of the poverty level for each of three ethnic groups: Mexican-Americans, Blacks, and Anglos. School districts were stratified by size and geographic area within the state. Probability samples of districts and individual schools were then drawn. Within each school, lists of children in each of the six strata were compiled and random samples were drawn from each list.

hold, and meat obtained through hunting or fishing.[3]

Household income is the sum of annual earnings for all members of the household plus transfer payments (social security, veterans payments, welfare, unemployment compensation, alimony and child support, the value of USDA commodities received, and the value of gifts in the form of cash or commodities). Two components, the value of bonus food stamps and the value of free National School Lunch Program lunches, were specified as separate variables in order to estimate the effects of these programs.[4] Free school lunches were valued at $7 per child per month.[5]

Assets include the total market value of owned property (house, vehicles, and other property) plus liquid assets (checking and savings accounts, bonds, etc). Assets are a source of wealth from which families may borrow for food in periods when current income is inadequate. It should be important among households whose incomes follow seasonal patterns or who incur unusually large expenses. Owned assets permit a household to consume at levels consistent with anticipated "permanent" income in times when "transitory" incomes are low (Friedman, pp. 3–37).

Both household size and the age-sex composition of its members were specified with equivalent adult food scales (Prais and Houthakker, Price 1970). These scales, derived from analysis of household behavior rather than from nutritional standards, assign index values to household food expenditures where the weight for the first adult is 1.0 and then is proportionally less for each other household member.

Equivalent adult scales can also be used to account for economies of size. Using 1965 household survey data, Price estimated scale values that varied according to whether the child was the first, second, third, or fourth child of the household (1970). These values were incorporated with the scales showing age-sex differences to reflect economies of size. These revised scales were used to put household food consumption on an adult equivalent basis.

Conceptually, a weighted average of equivalent adult scales for all commodities would yield an income scale. The authors know of no one who has done this as yet. Instead, an income scale has been estimated by using the concept that differing size households with the same adult equivalent food

[3] Home-produced food was evaluated at the retail, grocery-store prices. Elk and deer meat were evaluated at beef prices.

[4] The USDA commodity distribution program was not analyzed separately, since only a small proportion of the sample received USDA commodities.

[5] The figure of 35¢ per lunch was near the average price 34.3¢ charged for lunches in Washington school districts in the 1970–71 school year (see West and Hoppe, p. 4).

expenditure are equally well off ("Estimating Equivalent Incomes on Budget Costs by Family Type"). This income scale was used in this study to adjust income, assets, bonus food stamps, and the value of free lunches.

The scales account for economies of size and age-sex differences in the sample from which they were estimated. However, they may not adequately specify economies of size that exist among other populations. Consequently, household size as expressed by the number of persons was included as an independent variable in this study to test for the presence of additional economies of size.

Two other variables were included in the model. These were meat produced on farms or obtained by hunting and the length of the pay period for the major income earner. The latter was included to measure the effect of household cash flows on food expenditures.

In the early stages of model development, a number of additional variables were included. These were meals purchased outside the home, ethnic status, female-headed households, education and occupation of household adults, current geographic location, and psychological variables representing need levels and management style. These variables were dropped because the theoretical justification for their inclusion was weak and because they had no significant effect on the value of food consumed.

Analysis

Relationships among the variables were first investigated using the University of Michigan's Automatic Interaction Detector (AID) (Sonquist, Baker, and Morgan). This analysis did not identify any strong interactions among the independent variables. Therefore, a single-regression model was estimated using the entire data set. However, the total unweighted sample does not accurately represent the state's population of households with school-aged children. About 95% of Washington's residents are Anglos, and the Anglo portion of the sample closely represents this population. Consequently, separate regression analyses were run for each ethnic group. This permitted full interaction between ethnicity and the other independent variables. Tests made of the reduction of the error sum of squares showed significant differences exist among the regression coefficients for the three ethnic groups (Johnston).

Income was specified in natural logarithms to account for decreasing rates of increase in food consumption. Household size was also specified in logarithms to capture decreasing economies of size. Application of Bartlett's test to error variances of four regression subsets indicated the presence of heteroscedasticity. The error variances were found to be proportional to the square of the natural log of income; consequently, the data were transformed by multiplying through by the reciprocal of the log of income (Johnston).

Results

Income exerts a significant but relatively small effect on the value of food consumed (table 2). The income elasticity is approximately 0.04. This value is low relative to those estimated in other studies (Reese, Feaster, and Perkins) but is reasonably consistent with the elasticity of 0.1 found for low income households in data from the USDA 1965 Household Food Consumption Survey (Egbert and Hiemstra 1969). By ethnic group the income coefficient is largest for Mexican-Americans, the group whose mean income per equivalent adult is smallest (table 1).

Two possible explanations for the low income elasticity are as follows. First, the range of observations does not include households with very low incomes, where food expenditures may be more responsive to income. The state of Washington has a relatively high Aid to Families and Dependent Children payment, which limits the number of observations at the extremely low end of the income range (Office of Program Planning and Fiscal Management). Second, the specification of the model differs from other studies. The value of food consumed includes food from nonmarket sources, some of which may be less sensitive to income. Additionally, the asset variable, which is correlated with income ($r = 0.52$), may be capturing some of the effect ascribed to income in models that omit assets.

The assets coefficient for the entire sample is significant and has a positive sign. It shows that an additional $10,000 in assets is associated with an increase of approximately $4 in the value of food consumed per month (both variables are on an equivalent adult basis). Other empirical evidence for the asset effect is limited; however, the estimates are consistent with Friedman's permanent income hypothesis and his results (Friedman).[6]

Among the ethnic subgroups, assets are significant only for Anglos (table 2). Mexican-Americans, who have the lowest mean income, have assets that average only about one-half the mean for Anglos (table 1).[7] Their low level of assets may account for the nonsignificant relationship with food consumption. The asset coefficient for Blacks is also nonsignificant, although the mean

[6] Assets, as defined in this study, fall within Friedman's classification of nonhuman wealth. For additional discussion on the theory of how nonhuman wealth protects a planned level of consumption against unexpected occurrences and of how proportional increases in nonhuman wealth and permanent income increase levels of consumption, see Friedman, chapter II, especially pp. 16–17.

[7] If one posits that assets (A) are a function of income (I), that relationship is $A = -25{,}364 + 137.29I + e$, where $A = 0$ at $I = 184.74$ (t-value $= 17.325$).

value of assets among Blacks is nearly as large as that for Anglos. This lack of significance may be due to a smaller proportion of equity in the assets, smaller sample size, and the smaller variance of the asset variable (table 1).

Given our analysis, one can only hypothesize why the asset effect appears stronger among Anglo households. Households with relatively low incomes may derive greater satisfaction from ownership of some minimum level of assets than they do from additional food. Only after this minimum level is attained are additional allocations made for food. This hypothesis requires further investigation, but it lies beyond the scope of this study.

The household size coefficient indicates that the monthly value of food consumed per equivalent adult is reduced by \$2.54 as household size increases by one person. This shows additional economies of size in food procurement and preparation not reflected in the equivalent adult scales used to adjust the data. Reasons why the scales may not control for all economies of size are: (*a*) the model specification in this study differs from the model used to estimate the scales; (*b*) less accurate estimates of size economies may have resulted from the USDA Household Survey data, since only about one-third of the households had six or more members; (*c*) economies of size may have increased over time with the adoption of home freezers and other improvements in food preservation; and (*d*) estimation errors in this study caused by correlation of household size with income and assets.

Among ethnic groups, economies of size were greatest for Mexican-Americans. This may be due to cultural food practices or to economic factors. Earlier work by Price indicates that economies of size vary among food groups (1970). Mexican-Americans may be serving more of the food items where such economies exist.

Bonus food stamps significantly increased the value of food consumed. The coefficient for this variable is interpreted as the propensity to allocate the additional income provided by the bonus stamps to food.[8] The coefficient for the entire sample shows that approximately one-third of the additional income from stamps is used to purchase food. This propensity is below the range of 0.60 to 0.72 estimated by Reese, Feaster, and Perkins for low income families. However, it exceeds the average propensity of 0.21 for all household income allocated to food in this sample. In comparison, the

[8] By law, food stamps can be used only for purchase of food. Bonus stamps (the value of the stamps minus their cost) however "free-up" cash income. The propensity to consume additional food is defined as the proportion of this "freed" income allocated to food.

marginal propensity fo consume food out of total income for the entire sample is about 0.05.[9] The marginal propensity to obtain food out of bonus stamp income (0.30) is still below the average propensity of food stamp recipients to consume out of all income (0.37). This is consistent with economic theory in which bonus stamps are viewed as an addition to income and marginal propensities to consume food are expected to decline as incomes increase.

Substantial differences exist among the food stamp coefficients for the three ethnic groups. Anglo recipients have a low propensity to consume food out of the bonus stamp income while the propensity for Mexican-Americans is highest at 0.61. The difference may be due to the way the ethnic groups view their low income position. If Anglos view their low income as temporary, their food purchases may be planned according to anticipated permanent income and, therefore, be less sensitive to what is viewed as temporary bonus stamp income. If Mexican-Americans, on the other hand, believe their incomes will remain low over time, they would allocate a higher proportion of bonus stamp income to food. The difference in response to bonus stamps is consistent with Anglos' consumption being more responsive to assets (an indicator of permanent income), while that of Mexican-Americans is more responsive to current income.

The free lunch coefficient for the entire sample (0.598) indicates that an additional unit of this subsidy has a greater effect on food consumption than do food stamps. Examination of the ethnic group results shows that the free lunch effect is strongest among Anglos and weakest among Mexican-Americans. One explanation for the relative differences in the free lunch and food stamp effects among ethnic groups may be the attitudes of parents toward the school lunch. Anglo parents may view the free school lunch as largely supplemental to their children's diets and might then allocate the free lunch transfer to additional food. In contrast, Mexican-Americans may believe the free lunch provides a major part of their children's nutritional requirements and might utilize the cash income, otherwise spent for lunches, for nonfood items. A related study based on the same sample shows that the Mexican-American children receive a larger proportion of their daily intake of food from the school lunch than do the Black or Anglo children (Price et al. 1975).

Home-produced meat has a significant impact on the value of food consumed. Estimates for the total sample show the monthly value of food per equivalent adult increased by $3.32 in households that obtained some of their meat from nonmarket sources. Home-produced fruit or vegetables did not significantly affect the value of food consumed.

As Madden and Yoder found, increases in the length of pay period reduced the value of food consumed. The coefficients for the weekly, biweekly, and monthly period estimated with the entire sample are all negative ("other" pay periods is the omitted variable). They become larger in absolute value as the length of the pay period increases. Estimates by ethnic group show the effect of pay period is strongest among Mexican-Americans.

[9] The coefficient for the variables, natural log of income, is 1.910. Evaluated at the mean for this variable, the impact on value of food consumed is 10.249. The same impact can be obtained by attaching a coefficient of 0.04788 to the arithmetic mean for income per equivalent adult ($214.05).

Concluding Remarks

The USDA food stamp and free lunch programs increase the value of food consumed by eligible Washington households. The proportion of the additional purchasing power provided by the programs that is allocated to food exceeds the marginal propensity to consume food out of current income. It is, however, below the average propensity to consume food by low income households. Variation in specific program impacts exists among the ethnic groups. Bonus food stamps have a greater impact on food consumed among Mexican-Americans than among Blacks or Anglos, while the reverse occurs for the free lunch transfer.

The relatively small impact of current income and the significant impact of assets on the value of food consumed have important implications. These results are consistent with Friedman's permanent income hypothesis in which assets are used as an indicator of permanent income. These findings suggest the amount of assets owned should be considered as a criterion in determining eligibility standards for food distribution programs such as food stamps and free school lunches. Economies of household size in food consumption were also found to be substantial. This suggests a sliding scale for household size as a criterion for eligibility in the food delivery programs.

The study supports earlier research that shows that food purchases are inversely affected by the length of the pay period for adults in the household. For policy purposes, adoption of short pay periods and frequent allocations of food stamps in situations where it is desirable to maintain food outlays should be considered.

The Price Responsiveness of U.S. Corn Yields

James P. Houck and Paul W. Gallagher

Production economics theory shows that the profit-maximizing output of a commodity depends, among other things, upon product and input prices. Supply functions consistent with this theory have been estimated for many agricultural crops both in the United States and elsewhere. However, the biological nature of the production process, the time lags involved between planting and harvest, and the generally extensive use of land and climate leads naturally to the separation of total crop production into acreage and yield components.

Typically, acreage is viewed as the major decision variable with respect to input and output prices. Per acre yields are generally regarded as dependent upon technological trends, weather, and other more or less noneconomic influences. The recent work by Perrin and Heady is a good example of this approach. Only a little literature exists on attempts to measure the price responsiveness of crop yields (Guise, Hee, Krishna), although some recent methodological work can be found (Whitaker). This note concerns the price responsiveness of U.S. corn yields when both output and input prices are considered.

Theoretical Basis

Let the production function for corn be written as

$$(1) \qquad C = f(F, L),$$

where corn output (C) is a function of fertilizer (F) and land (L). Assume other inputs, technology, and environmental influences to be impounded in the function (f).

Suppose that the production decision is made in two stages. First, farmers decide on the amount of land (L_o) to plant to C. Later they decide at what level to fertilize it. The acreage decision may be influenced by expected prices, provisions of various government programs, crop rotation requirements, and other, possibly noneconomic, considerations. Neoclassical production theory based on profit maximization leads to a general supply function, which can be expressed as

$$(2) \qquad C = g(PF/PC, L_o),$$

in which the output (C) is a function of the prices of variable inputs (PF in this case), the output price (PC), and the already decided land input (L_o). The price ratio appears because profit maximization requires that the marginal physical products of variable inputs be equated to input-product price ratios. Thus, the supply function of equation (2) is homogeneous of degree zero in prices.[1] Again, the function g impounds everything else for convenience.

An output-per-acre yield function can be derived from equation (2) as

$$(3) \qquad Y = C/L_o = h(PF/PC, L_o).$$

This function, aggregated over all producers, is the theoretical basis for the empirical study of corn yields and prices that follows. On well-known a priori grounds, we expect the net relation between Y and PF/PC to be negative. Similarly, the net relation between Y and L_o also will be negative if production occurs in the rational area where the marginal product of L is less than its average product (Y in this case).

Estimating Equations and Data

The theoretical development of equation (3) sidesteps several important variables, apart from other inputs, that are crucial to an empirical analysis of time-series data on corn yields. Among them are technological change, government programs, and weather plus other environmental factors. Moreover, the time lag between production decisions and harvest requires special attention to the specification of price, policy, and weather variables.

The following is a general, composite statement of the several corn-yield response equations actually estimated with crop year data over the 1951–71 period (all data used here are from official USDA publications):

$$(4) \quad Y_t = b_o + b_1(PF_{t-1}/PC_{t-1}) + b_2L_t + b_3W_t + b_4D_t + b_5T_t + e_t,$$

where Y is the U.S. corn yield in bushels per harvested acre; PF is the weighted average of USDA fertilizer price indexes (1967 = 100) published in

James P. Houck is a professor of agricultural and applied economics, University of Minnesota, St. Paul, and Paul W. Gallagher is an agricultural economist, Economic Research Service, U.S. Department of Agriculture, Washington, D.C.

Minnesota Scientific Journal Series Paper 9456. The research was supported jointly by the Minnesota Agricultural Experiment Station and the Economic Research Service, U.S. Department of Agriculture.

[1] If other variable inputs had been included specifically, equation (2) would exhibit their prices relative to P as additional determinants of Y.

September, December, March, April, and June;[2] PC is the average price received by farmers for corn in dollars per bushel; L is harvested acreage of corn in millions; W is the weather in the growing season—the proxy variable used is the USDA index of average pasture moisture conditions in five midwestern states (Illinois, Indiana, Ohio, Iowa, and Nebraska) in percentage of normal during the growing season; D is one or more zero-one variables reflecting acreage restrictions on corn and the 1970 corn blight experience; T is the technology trend value, 1951 = 1, 1952 = 2, etc.; e is a random, serially independent, mean-zero variable with finite variance assumed to reflect the net impact of all unspecified variables influencing Y_t; and t is a subscript indexing the crop year.

For this analysis, the production function for corn, whatever its true form, is assumed to generate yield functions that are approximately linear in price ratios and other variables over the relevant range. The earlier assumption that acreage (L_t) is determined in advance of yield (Y_t) is carried over to the empirical analysis.

Numerous versions of the general expression in equation (4) were estimated by ordinary least squares (OLS) in preliminary analyses. In particular, corn acreage was added and dropped, the weather proxy was used with both current and lagged values, a zero-one policy variable was investigated, and technology was reflected by a linear trend in some versions and by a logarithmic trend in others.

Data more recent than the 1971 crop were not used because the particular weather proxy (W) was not available from USDA after that crop year. Since this research effort focused on price effects and not upon the isolation and measurement of weather impacts, alternative proxies were not sought out. However, further and more refined work along these lines will require other measures for weather effects.

Of course, alternative specifications of the price variables as well as the other variables are clearly possible. The single-period lag on the corn price, for example, implies the simplest sort of price expectation formation. Similarly, the fertilizer price data is an aggregate index averaged over the previous crop year; it also might be sharpened considerably.

Major Results

Four of the estimated equations are summarized in table 1. Equation (1.4) was used in figure 1 to illustrate the behavior of actual versus estimated corn yields over the data period. These equations are representative of the array of results obtained, especially insofar as the fertilizer-corn price ratio is concerned. They provide clear evidence of price responsiveness in corn yields.

Although the results are nearly self-explanatory, a few comments are appropriate. For about half of the data period, corn production was strongly affected by a variety of voluntary acreage control programs applied by the federal government (Houck and Ryan). The programs affected acreage directly and yields indirectly. Consequently, statistical estimates also were calculated when corn acreage, L_t in equation (4), was replaced by a zero-one variable ($D61$) to reflect the acreage-controlling policy regime, equations (1.2) and (1.4). The significant positive coefficients estimated for this variable confirm the yield-increasing tendencies of programs seeking output reduction via land constraints. Using both L_t and $D61$ in the same estimating equation did not produce acceptable results. The serious negative impact of the unusual 1970

[2] Each reported fertilizer price index observation was weighted by the proportion of the crop year to which it applies. The reporting month was considered as the midpoint of the individual period and the observation itself representative of the entire period.

Note: Variable definitions: see text; in addition, $D61$ = 0 in 1951–60 and 1 in 1961–71; $D70$ = 1 in 1970 and 0 otherwise; and LNT = natural log of T.

[a] Elasticity with respect to PF, calculated at data means.

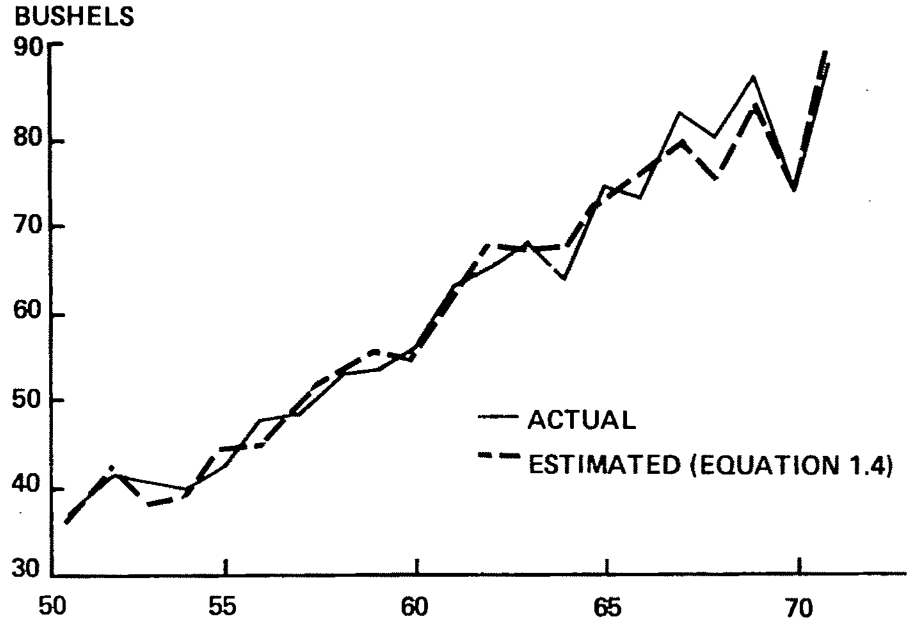

Figure 1. U.S. corn yield per harvested acre

corn blight was removed from the analysis by means of *D70*. Incidentally, the estimated 15.3 to 17.3 bushels per acre net impact of the blight is consistent with most agronomic measurements of that phenomenon.

The weather proxy (*W*) used here is imperfect, but it does provide generally sensible results. The consistently positive lagged effect of W_{t-1} presumably shows the net impact on yield contributed by carryover from the previous year's soil moisture.

The linear and log trend variables are meant to account for the yield-increasing effects of mechanical and biological technical change. The log trend is appealing for corn because it increases at a declining rate over the data period.[3] For instance, in the early 1950s, the log trend and its coefficient account for annual yield increases on the order of 6 to 9 bushels per acre. By 1970–71, this annual trend effect was only about 1.5 bushels per acre.

The coefficients on the price ratios display *t*-values that are relatively large. They suggest statistical significance at levels beyond the 99% confidence range. The larger estimated price ratio coefficients seem to be the most significant and occur in the two equations featuring the log trend, (1.3) and (1.4). It is clear that significant net price response is present in corn yields.[4] This is quite reasonable with a highly fertilizer-responsive crop like corn. Extensive analyses using other variable input prices, individually or in groups, were not attempted.

These estimates were computed for an era in which neither fertilizer nor corn prices were as volatile as in more recent years. Still, they do suggest that the relative price of fertilizer has exerted a measurable influence on corn yields apart from weather, trend, and government acreage programs. The yield consequences of future fluctuations in relative fertilizer prices, should they occur, could at least be approximated with these elasticities.

Implications for Supply Elasticity

Because production is acreage multiplied by yield, total supply elasticity is the sum of the acreage response and yield response elasticities with respect to product prices (Allen, p. 253). Some recent estimates of the short-run acreage response for corn (with respect to a one-year lagged price) imply quite low acreage elasticities in the neighborhood of 0.1 to 0.3 (Houck and Ryan, Ryan and Abel, Houck et al.).

The negative price elasticities shown in table 1 refer to isolated changes in fertilizer prices relative to corn prices. Because the two prices enter the estimating equation in ratio form, the yield elasticity of an isolated change in corn prices relative to fertilizer prices is the same value except that the sign is positive.[5] Hence, yield elasticities with re-

[3] The origin of the log trend was moved back to 1946 to give softer curvature to the trend at the beginning of the data period. The extent of this adjustment was arbitrary but suggested by examination of indexes for quantities of farm machinery and other nonfarm inputs used in the Midwest.

[4] One might reasonably argue that among the independent variables in this analysis the weather proxy (*W*) is the most likely to exhibit measurement error, especially in its relation to corn production (Johnston, p. 282). This line of reasoning leads to the conclusion that estimated price ratio coefficients are asymptotically biased toward values absolutely smaller than the true parameters and therefore strengthens the argument that sizeable price response exists.

[5] This can be shown by looking at the following simplified

spect to corn prices are in the neighborhood of 0.24 to 0.76.[6]

These results, although not fully comparable in underlying data and methods with previous acreage response studies, do provide solid evidence that taking acreage response estimates as approximations to total supply elasticities is to seriously underestimate the price responsiveness of corn production when fertilizer price is held constant. Rather than a short-run supply elasticity of less than 0.3 with regard to its price, corn may actually have a total supply elasticity as high as 1.0, other things held constant. In any case, analyses of corn production changes in response to price changes, either from the market or induced by government policy, should explicitly take into account the relation between corn and fertilizer prices faced by farmers and its effect on per acre yields.

equations: $Y = a - b(PF/PC)$; then $\partial Y/\partial PF = -b(1/PC)$, and the elasticity with respect to PF is $(\partial Y/\partial PF)(PF/Y) = -b(PF/PC)(1/Y)$. On the other hand, $\partial Y/\partial PC = b(PF/PC^2)$, and corresponding elasticity is $\partial Y/\partial PC(PC/Y) = b(PF/PC)(1/Y)$. So the two elasticities are identical except for sign.

[6] The analyses also were run with the corn-fertilizer price ratio as an independent variable. The estimates were as statistically significant as those in table 1 and identical up to two significant digits.

Market Performance in the U.S. Vegetable Oil Industry: An Application of Simulation for Market Analysis

R. McFall Lamm, Jr.

Studies of market performance in agriculture have traditionally concentrated on the farm and retailing aspects of the marketing process, since price and cost data are generally available for farm and retail markets. This is not usually the case for food processing industries, however. Firm cost data are seldom made available voluntarily by food processing companies, and even price lists are difficult to obtain. These constraints have limited the extent to which studies have been able to adequately assess market performance in food processing industries.

The purpose of this note is to discuss the use of simulation as a tool for market performance analysis. A specific application is made to the processing sector of the domestic vegetable oil industry, a highly concentrated sector for which price and cost data are not readily available. Using representative plant and firm models, returns on five products are estimated over time by simulating production and marketing functions at actual input and output prices by months for the period January 1974 through December 1975. The results indicate that market power in the vegetable oil industry was insufficient to generate excessively high returns over this period and demonstrate the potential of the simulation approach for use in studies of market performance.

Foundations of the Analysis

Five measures or conceptual approaches have been applied to market performance analysis when price and cost data are not available. These are productivity measures, marketing bill measures, flow analysis, market structure measures, and the application of welfare economics (Marion and Handy). The measure of market performance used in this study, the market rate of return, is a consequence of recent efforts by the Economic Research Service to identify the cost and profit components of the marketing margin for different food products and is an outgrowth of marketing bill measures. The market rate of return, considered in the proper framework, "lies at the heart" of the analysis of market performance (Caves, p. 101). In this respect the rate of return, when it can be determined, serves as a far better measure of market performance than any of the other measures or conceptual approaches that have been applied to market performance analysis.

Recently, Griffin proposed the use of the process analysis approach for determining empirical industry cost curves on the basis of a representative industry firm (1972, 1974). In this study simulation is substituted for process analysis in a similar procedure for determining empirical industry cost curves. Marshallian representative firms are taken as the basis of the analysis, with the estimated rates of return for the products of the representative firm being taken as approximations of the rates of return on the same industry products. The points of reference to which the rate of return applies in this study then are the product markets in which the representative firm participates, not the aggregate rate of return to the representative firm itself.

Three representative firms and six representative plants were identified in the processing sector of the U.S. vegetable oil industry for this study. These six plants included a soybean processing plant, a vegetable oil refining plant, a cooking oil bottling plant, a margarine manufacturing plant, a shortening canning plant, and a mayonnaise manufacturing plant. Of the three Marshallian representative firms, the first was defined to include soybean processing as its primary function, the second to include vegetable oil refining, cooking oil bottling, margarine manufacturing, and shortening canning as its primary functions, and the third firm was defined to include mayonnaise manufacturing as its primary function.

The System Model

The six-plant, three-firm system simulation model of the processing sector of the domestic vegetable oil industry was constructed by specifying the technical parameters of representative stage, plant, and firm production functions item by item. Representative stages, plants, and firms were selected on the basis of plant visitations and communications with individuals knowledgeable on the industry structure. The traditional economic engineering ap-

Boehm on earlier drafts of this paper are gratefully acknowledged.

proach (French, Sammet, and Bressler) was used in the specification and actual measurement of linear non-substitutable production functions. Information for specifying the levels of the technical parameters for the production functions was obtained by collecting data during visits to over forty plants and firms in the industry, by utilizing census data on plant specifications, and by consulting with equipment manufacturers. The entire system model was constructed to be jointly interactive so that all model plants and firms could be operated simultaneously within the simulation framework. If all technical parameters of each plant and firm are specified correctly, then the complete system simulation model should be representative, since by definition it is composed of representative production stages, plants, and firms.

Each of the three firms included in the simulation model were assumed to be spatially separated. Hence, transportation costs were incurred in shipping crude soybean oil from the soybean processing firm's plant to the second model firm's vegetable oil refining plant and in the shipping of refined vegetable oil to the third model firm's mayonnaise manufacturing plant. The vegetable oil refining plant, the cooking oil bottling plant, the magarine manufacturing plant, and the shortening canning plant, all operated by the second model firm, were assumed to be located at the same site. All assumptions concerning spatial location reflect prevalent industry patterns.

The results of a simulation experiment cannot be considered valid unless the underlying model is verified as accurate. Two methods were used to verify the accuracy of the model constructed for this study. First, actual plant and firm input and output data were used to check for inconsistencies in the generated input and output levels of the model plants and firms. No gross inconsistencies were found between actual industry input and output statistics and those generated by the model using this method. Second, the system simulation model was used to generate average costs for producing different industry products using 1975 prices. These generated average costs were then compared with available industry accounting average costs to check for inconsistencies. This comparison yielded certain discrepancies between actual industry accounting costs and average costs generated by the model.

For the cost verification method, detailed accounting data were available from industry sources on firm costs for three types of products. These were crude soybean oil, refined vegetable oil, and pint jars of mayonnaise. With respect to crude soybean oil, the cost of producing 1 pound of oil was estimated by the model to be 1.5¢, while an average of data for thirteen processing firms in the industry indicated an average cost of 1.8¢ per pound in 1975. To some degree the discrepancy between these figures is attributable to the inclusion of older, more labor-intensive plants in the composition of the firm accounting data. With respect to vegetable oil products, the costs of producing a refined vegetable oil, a margarine base oil, and a shortening base oil were estimated by the simulation model to be 1.2¢, 2.3¢, and 2.8¢ per pound of oil, respectively. The corresponding figures for similar but not identical products, as reported by one firm in the industry, were 1.0¢, 1.7¢, and 2.4¢. Again, the discrepancies can be accounted for by differences between the firm for which costs were reported and the simulated model firm—the industry firm's plant was considerably more modern than the model firm's plant. Finally, with respect to mayonnaise, the cost of producing pint jars of mayonnaise was estimated by the simulation model to be 23.6¢. Data from one firm in the industry indicated the cost of producing mayonnaise as 22.5¢ per pint. Also, in this case the discrepancy is attributable to variations between the structure of the model firm and the industry firm.

The attempts to verify the accuracy of the simulation model indicate that, when allowances are made for discrepancies, the model cost estimates are not greatly inconsistent with available industry data. Although accounting data could not be obtained to verify the accuracy of simulated costs of production for all the products considered in this study, each of the simulation plant and firm models were constructed using the same technique. Hence, any biases that exist in the estimation of costs for one product are likely to exist in similar degrees in the estimation of costs for other products.

A Multiple Period Simulation Experiment

To evaluate the economic properties of the model and to generate descriptive statistics to analyze market performance in the vegetable oil industry, a complete system simulation was performed on a month-by-month basis using data for the twenty-four-month period January 1974 to December 1975. One hundred and four monthly prices for inputs and outputs were collected for each of the twenty-four months in an attempt to re-create the actual environment in which plants and firms in the industry were operating over the period. The stochastic variables in the model were adjusted to remain at their mean levels so that random variations in plant performance would not affect costs or rates of return in any one period.

The simulation was performed so that at the end of each monthly period complete production cost data were generated for five final products of the vegetable oil industry on a per unit basis. These five products were 24 ounce bottles of cooking oil, 38 ounce bottles of cooking oil, pound packages of margarine, 3 pound cans of shortening, and pint jars of mayonnaise. Cost data were generated by components consistent with those used by the ERS.

For each of the five products forty-two separate components were identified for each of twenty-four periods, giving estimates of more than 5,000 separate cost elements.

In order to focus on the key results of the simulation, estimates of the rate of return for the five finished products considered are presented in table 1. The rate of return is defined as the per unit profit after taxes divided by the per unit value of assets. The information presented in table 1 reveals that the variation in profit over the twenty-four-month period was substantial for all five products. In addition, it is apparent that with the exception of margarine profits were generally greater for each of the five final products in 1975 than in 1974. This result contrasts with the fact that soybean prices and rates of return to soybean processors were considerably higher in 1974 than in 1975. These findings indicate clearly that with the exception of margarine finished product manufacturers were able to maintain and improve their rates of return as raw materials prices declined in 1975.

Market Power in the Vegetable Oil Industry

For every product market there is some socially optimal normal rate of return on equity that must prevail if resource allocation is to be efficient (Caves). Although there is a problem in ascertaining what exactly a normal rate of return on equity is, this does not constrain the comparison of relative rates of return for analytical purposes. In specific cases where a detailed study over a period of time indicates that the rate of return in one market is consistently greater than the rate of return in other similar markets and that the rate of return is substantially greater than any long-term interest rate realized over the period, then there is evidence of market power.

Referring to the information presented in table 1, it is readily apparent that the rate of return on cooking oil is substantially greater than the rates of return on the other products considered in this study. The mean rates of return for each of the five products are 0.0982 for 24 ounce bottles of cooking oil, 0.0856 for 38 ounce bottles of cooking oil, 0.0436 for pound packages of margarine, 0.0564 for 3 pound cans of shortening, and 0.0668 for pint jars of mayonnaise. The rate of return on 24 ounce bottles of cooking oil, the product with the highest rate of return, is more than twice the rate of return on margarine, the product with the lowest rate of return. Although a twenty-four-month period is probably not a "long run," it is useful to compare alternative investment opportunities available to firms in the industry over this period with their

actual rates of return. The rate of return on corporate triple A bonds averaged 0.0871 from January 1974 to December 1975. For purposes of argument, if this figure is taken as the opportunity cost of investment, then of the five product markets considered there were extra-normal rates of return over the period only for 24 ounce bottles of cooking oil. There were apparent inefficiencies in capital equity distribution in the processing sector of the domestic vegetable oil industry over the two-year period. These findings imply the virtual absence of any large degree of market power in the domestic vegetable oil industry during this period. Only in the case of 24 ounce bottles of cooking oil were there indications of some degree of market power.

Two arguments may be offered to explain the absence of a large degree of market power in the processing sector of the domestic vegetable oil industry, even though the sector is highly concentrated. First, and perhaps most important, is the fact that the vegetable oil industry is a nondurable goods industry. It is difficult, if not impossible, to establish the price stability necessary to sustain oligopoly within nondurable goods industries. Traditionally, oligopoly has been identified principally in durable products industries where prices can be maintained by varying inventories and order backlogs (Scherer). In the vegetable oil industry inventories must be limited because of the relatively short life of the product. Hence, prices are difficult to maintain as raw materials costs vary. For this reason the development of a large degree of market power in a multifirm food processing industry would not be expected à priori. Second, a number of potential competitors do not face large entry barriers. For example, in the cooking oil industry there are three major firms that dominate the market. But there are also several that produce private label cooking oil. These potential competitors would only have to place a different label on their product and overcome advertising barriers in order to enter. For the other products considered in this study the situation is similar—there are several potential competitors.

Within the vegetable oil industry the estimation of a mean rate of return for each product allows for a comparison of relative market power. A related measure of market power is the standard deviation of the rate of return. Since market power implies some degree of control over prices and profit by the firm, the temporal standard deviation of the rate of return is likely to be smaller the greater the degree of market power. The acceptance of this premise would imply the expectation of an inverse relationship between the mean rate of return and the standard deviation of the rate of return. Reference to table 1 indicates that except for margarine the results generated by the simulation are consistent with this hypothesis. Twenty-four ounce bottles of cooking oil have the highest mean rate of return and the lowest standard deviation. The implication then is that of the five product markets considered in this study, market power is greatest in the market for 24 ounce bottles of cooking oil and the least for 3 pound cans of shortening.

Conclusion

The results indicate little evidence of market power in the industry, even though most of the product markets of the industry are highly concentrated. This finding implies that some caution is in order when antitrust activities are urged against food processing companies when only data on market structure are available (Dahl, Hoffman, Walters). Each individual case should be considered with respect to the market rate of return and other relevant factors. In the processing sector of the domestic vegetable oil industry there is evidence to indicate that complete economies of scale have yet to be realized in some instances (Lamm, Lamm and Johnson). An arbitrary policy requiring more diversification in the vegetable oil industry might do more harm than good since the implementation of such a policy would prevent the attainment of full scale economies.

The use of simulation, as suggested in this paper, offers a viable and powerful method for evaluating market performance when industry accounting cost data are not readily available. The advantages of using the simulation approach are that it allows for the segregation of individual product markets from aggregates and for the use of explicit measures of market performance, measures that are more precise than the vague and sometimes misleading market structure measures frequently used. The only alternative that also has similar advantages is the use of accounting data. Since accounting data are generally not available for food processing industries and would present some classification and collection problems even if they were available, the simulation approach outlined here offers perhaps the best alternative available for detailed market performance analysis.

Estimating Optimum Size of Food Processing Plants Using Survivor Analysis

Sheldon W. Williams and James W. Gruebele

As applied to manufacturing plants, optimum size commonly refers to the range in volume over which average total costs, as depicted by the industry's long-run planning curve, are at a minimum (Bain). Knowledge of the limits to optimum size can guide managers in adapting operations to changing conditions. Government administrators and legislators also need that information in framing antitrust policies and in developing legislation to control conduct.

The purpose of this analysis is to appraise the potential usefulness of the survivor technique as an indicator of optimum size. The appraisal considers how trends in industry production and deficiencies in the data may affect the findings of survivor analysis and examines its use in policy formation.

Methods of Estimating Optimum Size

Various procedures have been used to determine optimum size. These include economic-engineering studies (French, Sammet, and Bressler), cost studies of existing plants (Pratten and Dean), and survivor analysis (Stigler, Saving). Markov chain analysis also has been used to project the future size distribution of plants, and thus indirectly to indicate optimum size (Judge and Swanson).

Engineering studies are comparatively expensive (French, Sammet, and Bressler) and may not take into account all factors in the environment in which plants operate (Saving, Sosnick). Heterogeneity of products and of operating conditions, differences in age and in the basis of valuation of physical assets, the operation of many plants at below their optimum volumes, and other problems make it impractical to determine the dimensions of the industry's long-run planning curve by plant cost surveys (Smith, Johnston). Markov chain analysis requires knowledge of what happened to each plant from period to period (Judge and Swanson). Moreover, Markov analysis commonly has been based upon the rather restrictive assumption that transition probabilities remain constant over time. Although Hallberg has suggested a modification to provide more reliable results, the need for this modification complicates use of the Markov technique.

The survivor technique, by comparison, is a relatively simple means of estimating optimum size. As described by Stigler, it rests upon the hypothesis that "the competition of different sizes of firms (or plants) sifts out the more efficient enterprises" (p. 73). It involves classifying the firms or plants of an industry by size and computing the share of industry output for each class over time. If the proportion of industry output by firms or plants of a specified size is maintained or increased, firms or plants of that size are presumed to be of optimum size.[1]

Survival of some firms may be influenced by their ability to exercise market power, to exploit monopsonistic positions in local labor markets, to use inexpensive family labor, or even to circumvent the law. For reasons such as these, survivor analysis may be more suitably applied to determination of optimum size of plants than of firms (Weiss, Mead).

Data Used

This application of survivor analysis is based upon information about the numbers of dairy manufacturing units, by size groups, reported in four USDA publications (Cowden and Trelogan; USDA 1959a, 1965a, 1974). The data originate in reports of production by firms that manufacture dairy products to the Statistical Reporting Service (SRS).

SRS reports production and numbers of manufacturing units separately for each type of product. In this analysis each unit manufacturing a product is treated as a "plant." This procedure, to which there is no feasible alternative, disregards the fact that two or more manufactured dairy products are produced in some plants and that certain manufactured products are produced, in some cases in relatively small volumes, in plants primarily devoted to processing fluid milk. The analysis thus involves manufacturing operations that range from spe-

Sheldon W. Williams and James W. Gruebele are professors in the Department of Agricultural Economics, University of Illinois at Urbana-Champaign.

The authors are indebted to the editor and two anonymous reviewers of the *Journal*, and to Lyle Fettig, for stimulating suggestions.

[1] Size should be measured by physical volume of output. In industries that are replacing labor with equipment, use of number of employees as an indicator of size may lead to confusing if not misleading results.

cialized single-product plants to parts of multiproduct operations. In 1961 the bulk of the production of butter and nonfat dry milk was in butter-powder plants and of American cheese and evaporated milk was in specialized plants (Williams et al.). However, it is impossible to assess in our data either the degree of plant specialization or the type and extent of its relationship, if any, to average volume per plant and to survival.

Ranges in Optimum Size

Optimum size was estimated for eight dairy manufacturing industries for periods for which data were available (table 1).[2] Upper limits to optimum size were not evident in any of those industries. In all except two, minimum optimum size increased. The two exceptions were nonfat dry milk, for which minimum optimum size was unchanged between 1963 and 1972, and evaporated milk, for which it declined.

Technological developments in production and changes in factor prices evidently were major factors in the changes in minimum optimum size. Between 1958 and 1972 weekly wages of dairy plant workers increased 83%, while prices of machinery and equipment increased 32% (U.S. Dep. of Labor, 1972a, b; 1973; 1975).[3] During that period, the average quantity of whole and skim milk equivalent manufactured per production worker increased 35% (U.S. Dep. of Labor, 1972a, b; 1973; USDA, annual, 1958–72), probably mainly as a result of increased mechanization. Nevertheless, it may be hypothesized that dissimilar trends in demand—here examined using production data—are a factor in the differing trends among industries in minimum optimum size (Stigler).

If the eight dairy manufacturing industries are ranked by percentage increase in production between 1963 and 1972, nonfat dry milk and evaporated milk, in which there were substantial decreases, are at the bottom of the array (table 2). While minimum optimum size did not increase in those two industries, among the others there was no apparent relationship between percentage changes in production and in minimum optimum size. In the butter industry, in which production also decreased, the percentage increase in minimum optimum size was larger than that in three of the five industries in which production increased.

On the other hand, the nonfat dry milk, evaporated milk, and butter industries, in which production declined, were the only industries in which plants that were of minimum optimum size in 1963 decreased in number between then and 1972. Increases in average size of plant also were less for evaporated milk and nonfat dry milk than for the industries with either increases or else smaller decreases in output. These limited observations suggest that an important decline in production may halt or reverse an upward trend in minimum optimum size and force out of production more than the usual proportion of an industry's larger plants.

But sharply declining production was not necessarily the only reason minimum optimum size did not increase in the nonfat dry milk and evaporated milk industries. Both industries involve comparatively large investments in specialized equipment, which may retard exits. Moreover, most nonfat dry milk plants were established during or since World War II. Apparently, new labor-saving technology has not recently been introduced into that industry to the extent that it has in the manufacture of cheese and butter.

Table 1. Minimum Optimum Sizes of Dairy Plants as Determined by Survivor Analysis

Industry	Minimum Optimum Plant Size		
	1957	1963	1972
	--- Million Pounds or Gallons per Year[a] ---		
American cheese	0.75	1.5	3.0
Swiss cheese	—	0.5	3.0[b]
Italian cheese	—	1.0	3.0
Creamed cottage cheese	—	2.0	4.0
Creamery butter	1.0	2.0	5.0
Nonfat dry milk[c]	—	10.0	10.0[b]
Evaporated, condensed whole milk (case goods)	—	55.0[b]	45.0[b]
Frozen dairy products	—	1.0	2.0

[a] All products except frozen dairy products in million pounds.
[b] Proportion of industry output in one or two groups of smaller plants increased slightly but not significantly; changes in other groups supported the estimate of optimum size shown.
[c] Spray and roller, for human food.

Limitations

Several factors may affect the reliability of the findings of survivor analysis. One is lags in adjustment. In each dairy manufacturing industry in which recent economic-engineering studies have been made (American cheese, butter, and nonfat dry milk), minimum optimum size in 1972 as determined by survivor analysis was considerably smaller than the volume at which minimum average

[2] The analysis involved adjusting 1944 data to the slightly different class intervals used in the later data. In all cheese and butter industries, the top open-end groups in 1963—and in creamed cottage cheese also in 1957—were subdivided to permit more detailed comparisons of changes between that and later years. This was done by making successive estimates until all possible distributions were considered that satisfied three constraints: number of plants, total production, and expected shape of the frequency curve. These constraints closely limited the number of acceptable estimates, all of which were taken into account in determining changes in optimum size.

[3] 1958 was the first year for which the indicated data were available.

Table 2. Dairy Industries' Production and Plant Sizes in 1972

Industry	Total Production	Plant Size: Minimum Optimum	Plant Size: Average	Number of Plants: Below Optimum Size in 1963	Number of Plants: Of Optimum Size in 1963	Number of Plants: All Plants
	Value in 1972 in Percentage of Value in 1963					
Italian cheese	266	300	246	79	172	108
American cheese	148	200	224	46	137	66
Swiss cheese	148	600	259	38	103	57

costs are shown on that industry's long-run planning curve in the pertinent economic-engineering study (Lilwall and Hammond, Nolte and Koller). For various reasons results of the two types of analysis are not expected to be the same. But in industries in which plant size is increasing, economic-engineering studies would be expected to suggest the direction of future changes in minimum optimum size as determined by survivor analysis. Consequently, it may be hypothesized that the smaller volumes shown by survivor analysis are due in part to lags in adjusting plant size to changing conditions.[4]

The process of replacing or modernizing facilities takes time. Consequently, in dynamic industries survivor analysis can be expected to reflect a lag until the industry fully adjusts to changed conditions. Such a lag may continue for some time if plants are operating in the relatively flat portion of the industry's long-run planning curve.

However, not all of the difference in minimum optimum size between survivor analysis and economic-engineering studies should be attributed to a lag. After a period of rising prices for equipment and buildings, lower levels of capitalization could help to account for the continuing competitiveness of moderately large plants built before the rise in prices. These and plants whose assets have been largely depreciated would have lower fixed costs than plants of similar capacity constructed at recent price levels. Moreover some manufacturing operations of sizes below that at which economic-engineering studies show minimum costs may continue to compete effectively because they have advantages in hiring labor, in special outlets for their products, or in other respects not taken into account in economic-engineering studies.

Several characteristics of the available data also may affect the findings of survivor analysis. Very wide group intervals reduce precision. This effect is intensified if there is a wide open-end group at the top of the distribution, particularly if total production of plants in that group is not reported.

Analysis is most practical in industries composed of large numbers of plants. Narrow group intervals in a distribution of a limited number of plants may confuse trends in minimum optimum size. It may be possible to mitigate this problem by combining groups. Whatever the characteristics of the frequency distribution, it is highly desirable that, except for the specification of new intervals at the top of the distribution as plants become larger, group intervals be uniform in all reports.

More specific conclusions might be drawn if numbers of plants by size groups could be determined at relatively frequent and uniform time intervals. In industries in which optimum plant size is increasing, the additional data might provide insights as to when and for how long various intermediate size categories were in the range of optimum size. Unlike the bulk of our findings, it might suggest that under some conditions the upward trend in optimum size is not a steadily progressive phenomenon without reversals.

Obviously, the more specialized the plants in the industry, the more likely it is that the apparent trends in optimum size reflect efficiencies in production of relatively homogeneous products. If plants are not specialized, trends may be influenced by factors associated with the production of different or changing product mixes. Limitations of our data in this respect have been noted.

A high level of profits might distort findings. Mead pointed out that in the Douglas Fir milling industry survivor analysis in the period 1941–51 would have been meaningless because the industry was so profitable that all but the completely inept could survive. There is no indication that such con-

[4] The extent of an apparent lag may be affected by the characteristics of the data.

ditions existed in any of the dairy manufacturing industries during substantial portions of the periods analyzed.

Policy Implications

Survivor analysis is potentially useful as a guide to firm policy. Information it provides can suggest whether plants have sufficient volume to compete effectively, needed volumes of raw material, and the like. Although based on past experience, findings of survivor analysis may also point out the direction of future changes.

In using the survivor technique, management needs to be alert to any limitations in the basic data or in the measure of size employed—and to ways in which those limitations, or a lag in adjustments, may influence findings. In the dairy manufacturing industries, factors such as price supports or difficulties in exiting may retard adjustments. On the other hand the trend to fewer and larger firms and to multiplant operations may expedite adjustments through changes such as greater flexibility in plant operations.

Since antitrust and trade policies are more concerned with firms than with plants, survivor analysis of plants will not provide as good a basis for those policies as will analyses of changes in firms, using either the survivor or the Markov technique. Nevertheless, many firms operate single plants and, with the reservations that have been noted, survivor analysis of plants indicates minimum optimum size for such firms. From it inferences may be made about relationships between competitiveness and market power, about the effects of structural changes on single-plant firms, and about needs for further research.

The bounds of optimum size shown by survivor analysis are influenced by all conditions affecting plant operations, external as well as internal. Moreover, this method of determining optimum size is simpler and much less demanding in its data requirements than alternative methods. Consequently, it offers potential advantages in terms of feasibility and cost as well as of responsiveness to influences not considered by economic-engineering and accounting studies.

Returns to Scale in Farming: Further Evidence

Irving Hoch

Over the past two decades, a number of studies have applied analysis of covariance to combined time-series and cross-section data in estimating agricultural production functions. This note reports on an application of that technique to California dairy farm production, including some extensions of the basic approach. A major objective is to present additional evidence on the question of returns to scale and to develop some general conclusions from that evidence.

Literature Review

Four previous studies are summarized in table 1. The Cobb-Douglas function was employed in these studies with elasticity sum measuring returns to scale. In the four studies, the elasticity sum for analysis of covariance is smaller than for ordinary least squares, attributable to the introduction of the firm effects. Timmer's study treated each of the forty-eight contiguous U.S. states as a "farm firm" and found increasing returns using ordinary least squares but decreasing returns after firm effects were introduced, at variance with Griliches's conclusion that increasing returns held for U.S. agriculture (p. 966).

The other studies used farms as units of observation and almost always had an elasticity sum close to 1.0 (constant returns to scale) for their least square estimates, with a substantial drop in the sum occurring when firm effects were introduced. Three interrelated explanations for this decline have been proposed: (*a*) technical efficiency increases with scale, so that the interfarm function overstates the intrafarm function; (*b*) the firm constant is regarded as an additional factor of production, in effect measuring management or entrepreneurial capacity, and its absence causes a form of omission-of-variable bias; and (*c*) simultaneous-equation bias occurs in ordinary least squares and is reduced or eliminated by analysis of covariance (Hoch 1958, 1962; Mundlak; Mundlak and Hoch).

The third explanation focuses on the possibility of bias when the production function is viewed as part of a system of equations containing decision (or profit-maximizing) equations. With the specification of disturbance terms in both production and decision relations, there is danger that the function estimated by least squares will be a blend of the underlying relationships, with a strong tendency for an estimated elasticity sum of one, regardless of the true sum. However, if profit maximization occurs with respect to anticipated output defined as the production function without a disturbance term, then the only sources of simultaneous-equation bias in ordinary least squares are the firm and time effects. Such are accounted for, and the bias removed, in the analysis of covariance.

Two related points are noteworthy. First, the simultaneous-equation framework implies that more efficient firms will become larger firms by virtue of maximizing behavior given an elasticity sum less than one. Second, the simultaneous-equation bias is symmetric; if the true elasticity sum is above one, least squares estimates will understate the sum with an estimate of constant returns again the limiting case.

The analysis of covariance results have sometimes been questioned. Timmer cites Griliches as suggesting a tendency for analysis of covariance to bias the estimated elasticities downward if there are errors of measurement in the variables (p. 145). Rasmussen was so concerned about the possibility of errors of measurement causing the elasticity drop that he rejected his analysis of covariance results (Rasmussen with Sandilands)! But analysis of probability limits shows that the bias introduced by measurement error does not change as one moves from ordinary least squares to analysis of covariance (Hoch 1963). Furthermore, empirical evidence presented below shows that an elasticity sum decline is not universal.

The Setting, Samples, and Variables Employed

The California Bureau of Milk Stabilization (BMS) collects data on individual dairy farm input and output, with each farm visited every other month. Records from this survey were obtained for each of six dairy regions defined for the state and applied in estimating dairy farm production functions.

For four of the regions more than one sample was

Irving Hoch is a fellow on the staff of Resources for the Future, Washington.

This paper reports on work carried out while the author was on the faculty of the Department of Agricultural Economics, University of California, Berkeley, and is a condensation of some sections of Hoch (1976). Readers interested in greater detail are directed to that publication. Quirino Paris, David Foote, and Emilie Lachmann made important contributions to the statistical analysis of this paper. Paris's Ph.D. thesis and the project reported here were initially part of a joint effort that evolved into independent studies. An anonymous reviewer and the editor of the *Journal* gave considerable help in the revision of the present paper. Giannini Foundation Research Paper No. 426.

[a] Averaged over four cases in each grouping.

defined, so that a total of twelve samples were obtained. More than one sample was obtained when subregions were defined, when market-milk and manufacturing-milk producers were grouped into separate categories, or when there was selection of a special sample consisting of producers who had left the survey at the time of the study.

Years covered varied between samples, reflecting availability of BMS data. The bulk of the almost 10,000 observations (92%) fell in the period 1960–64, with a relatively small number of observations in earlier years and in 1965. The number of observations per sample ranged from 318 to 1,446, with six samples near the lower bound, two of medium size with around 800 observations, and four near the upper bound with over 1,200 observations per sample. Number of farms per sample correspondingly ranged from twenty to sixty-seven. Observations available per farm showed marked variation, but the great majority of cases were on the order of twenty observations per farm. Details on sample coverage appear in Hoch (1976).

In all of the production function analyses the dependent variable was milk produced per month (in units of 100,000 pounds) measured on a 3.8% butterfat basis, so that all milk quantities would be in comparable units. This measurement was based on BMS formula converting milk of any butterfat content to its 3.8% equivalent.

Initial fitted functions were obtained by relating milk to five independent variables: feed, capital, cow service flow, labor, and operating costs. Specific definitions of variables are given in Hoch (1976).

Results for the five input cases were not very encouraging. Internal evidence suggested the existence of strong collinearity effects for some of the inputs, and it was also possible that there was an "outside" linear relation between milk output and cow service flow, a general problem in the use of "raw material" as input. Both the collinearity and raw material problems were handled by combining all the nonfeed costs into an aggregate labeled "All other input."

Besides the conventional input measures and the dummy variables for firm and year effects, additional sets of dummy variables were introduced in the production function analyses, representing months, cow breeds, and membership status in Dairy Herd Improvement Association (DHIA).

The primary vehicle of investigation was the Cobb-Douglas equation consisting of two inputs and the dummy variables expressed in simplified form as

$$Y = (KFTMBD)Z_1^{\alpha_1}Z_2^{\alpha_2}, \tag{1}$$

where Y is milk; K is an overall constant; F, T, M, B, and D are firm, year, month, breed, and DHIA effects, respectively; Z_1 is feed, and Z_2 is all other input. (The implicit index for the variables of equation (1) is fmt, where f denotes firm, m denotes month, and t denotes year.)

In practice, the logarithmic form of equation (1) is estimated with one dummy variable in each set assigned a coefficient of zero to avoid exact collinearity. For purposes of interpretation, the calculated effects were transformed to deviations from an average effect of zero in the logs and one in the antilogs.

Results

Estimates obtained for the Cobb-Douglas production functions are presented in table 2. The firm effects clearly have a crucial impact on the elasticities. In all of the "before" cases, the elasticity sum is close to one. For each of the ten market-milk samples, the elasticity sums drop after the firm effects are introduced. For each of the two manufacturing-milk samples, the elasticity sums increase. Hence, we infer decreasing returns to scale for market-milk producers and increasing returns to scale for manufacturing-milk producers. The results are generally consistent with the argument developed above that the introduction of firm effects causes the elasticity sum to diverge from constant returns. The increase occurring in the elasticity sum for the manufacturing-milk cases is worth stressing, for it tends to contradict the argument that a downward bias exists in analysis of covariance estimates. Manufacturing-milk producers were likely to face

an institutional situation of relatively low product price and a good deal of fixed input including human capital. Under these circumstances, increasing returns (or declining average costs) seems plausible.

The average over the ten market milk cases yields an elasticity sum around 0.8 in the "after" case, a result that conforms to the results of the Hoch (1962) and Mundlak studies shown in table 1. There is considerable variation between samples, however, with the "after" elasticity sum ranging from around 0.6 to 0.9. Samples from a given region usually have very similar elasticity estimates (usually less than one standard error apart). There was something of a reverse association between elasticity sum and scale of operation. Southern California had the largest average firm sizes and the lowest elasticities; the manufacturing samples had average firms that were small in size and showed increasing returns; and most of the other samples had in-between average firm size and in-between elasticity sum. (Average output for the Southern California cases was about 4 times the average for the manufacturing cases, and about 1.5 to 2 times that of most of the other samples.) There appears a suggestion of the classical S-shaped production function.

The significance of each set of dummy variables was tested and all were statistically significant. For most of the samples, the year effects showed a clear upward trend indicating that the production function was shifting up over time. Table 3 presents year effects averaged over all of the samples, and the upward trend is manifest for all years except 1965, perhaps reflecting a relatively small number of observations in that year. The possibility that the pattern over time might be explained by pasture conditions, presumably in turn reflecting weather variations, was examined by comparing the year effects to both current and lagged indexes of pasture conditions (data from Desai and Henderson). Little in the way of an overall relation emerged, lending some support to the hypothesis that the upward trend can be best interpreted as an indicator of technological advance.

The time effects had next to no impact on returns to scale. Typically, the elasticity sum showed a small decline (on the order of 0.01) in moving from ordinary least squares to time effects only.

It was initially hypothesized that membership in the DHIA would have a positive effect on productivity with higher output for given input. There was some confirmation for this hypothesis. However, the confirmation seemed much stronger be-

Table 3. Estimated Year Effects, Averaged Over All Samples

Year	Average Year Effect[a]	Number of Cases
1958	0.783	1
1959	0.884	4
1960	0.940	9
1961	0.985	11
1962	0.976	12
1963	1.000	12
1964	1.032	11
1965	0.980	6

[a] The 1963 effect was set equal to 1.000 for all samples.

fore firm effects were introduced, with DHIA effects estimated as above one in eleven of twelve samples with seven effects being significant. After firm effects were introduced, only eight of the effects were above one and only four were significant. The average over the twelve samples was 1.046 in the "before" case and 1.008 in the "after" case. Perhaps better operators tend to join the DHIA, and not accounting for such an association may yield an overstatement of the benefits of DHIA membership.

This result suggests by analogy that measured benefits of extension work and education may sometimes be overstated. The DHIA case and the more general cases of extension work and education can involve a selection process including self-selection so that participants in the activity are initially of higher quality. Not accounting for the underlying quality differences then yields a form of omission-of-variable bias and leads to overstatement of the benefits attributed to the information service or to the educational process. This bias probably occurs in the results obtained by Müller, who found a considerable effect attributable to an "information" variable. In addition, the absence of firm effects in his formulation gave essentially constant returns to scale for his elasticity estimates, corresponding to the "before" results in table 2.

There was good graphic evidence that the firm effects were distributed normally, and the hypothesis of normality was accepted by statistical test. In the antilogs, the firm effects implied that for given input 67% of all farms would produce between 0.85 and 1.17 of average farm output, while 95% would produce between 0.73 and 1.37 of that output. The firm effects had a high correlation with output, averaging 0.72 over all samples, and they correlated well with independent evaluations of producer efficiency made by the BMS field men.

The distribution of farm sizes can be explained by the production elasticities and the firm effects. As the elasticity sum approaches one, small differences in firm effects lead to much more pronounced differences in size of firm. For instance, at an elasticity sum of 0.99, a firm that is 10% more efficient than average will have an equilibrium output some 14,000 times the average output. Such results may suggest why agriculture is a competitive industry, while others tend to be oligopolistic or monopolistic. A firm with equilibrium output many orders of magnitude above its competitors will dominate the market and probably drive its competitors out of business well before it reaches equilibrium. Hence, we ought not expect a competitive industry to have firms with both an elasticity sum close to one and even modest differences in firm effects. If there is reason to expect differences in management ability between firms, an estimated elasticity sum approaching constant returns to scale should be a cause of concern and not of congratulation.

Supply elasticities can be derived from production function elasticities (α_q, $q = 1, 2, \ldots, Q$). Here again, returns to scale estimates are of considerable consequence. Under plausible assumptions, the elasticity of output with respect to price is $\Sigma\alpha_q/(1 - \Sigma\alpha_q)$. Hence, the supply elasticity will be greater than 1.0 if $\Sigma\alpha_q$ is above 0.5, and it approaches infinity as $\Sigma\alpha_q$ approaches 1.0. That latter result may be behind the complaint of Wipf and Bawden who have argued that supply curves derived from production functions are unreliable (p. 177); a major element of their critique is that elasticities appear too high relative to direct estimation of supply. Once again, a production elasticity sum below one consistent with the use of firm effects yields more reasonable results than constant returns to scale.

Subsidiary Investigations

Several subsidiary investigations seem noteworthy. In the first, a quadratic production function was estimated. Some results here were disappointing, with some coefficients having the opposite of the expected sign and with occasional deletion of a quadratic term because of collinearity. However, marginal returns estimated from the quadratic equation agreed in magnitude and in shifts with those from the Cobb-Douglas function for individual samples and for the average over the individual samples (table 4).

A second subsidiary investigation involved the introduction of slope shifters as well as the intercept shifters of the primary equation. Each elasticity then contained a time and firm effect as well as a constant element. Because the slope shifter approach introduces a great many additional variables, a degree of freedom problem can arise, avoided here by employing firms having a relatively large number of observations to form eleven market samples with about a dozen firms in each sample. Four variants were obtained, depending on whether slope shifters and/or intercept shifters were brought into the equation. Elasticity sums for these four cases averaged over the eleven samples employed were as follows: (*a*) 0.676, given both slope and

Table 4. Marginal Return Estimates, Averaged Over Ten Market Milk Samples

	Before Firm Effects		After Firm Effects	
	Quadratic	Cobb-Douglas	Quadratic	Cobb-Douglas
Feed	1.385	1.468	1.148	0.960
All other input	0.786	0.748	0.568	0.741

Note: Marginal return equals return for an incremental expenditure of $1, calculated at average levels of input and output.

intercept shifters, (*b*) 0.842, given slope shifters only, (*c*) 0.701, given intercept shifters only, and (*d*) 1.026, given no shifters (ordinary least squares).

Cases (*c*) and (*d*) parallel earlier results, with an elasticity sum a bit over 1.0 prior to an introduction of firm and time effects, and a substantial decline in the elasticity sum after those intercept shifters are introduced. Case (*b*) introduces slope shifters but omits the intercept shifters and its elasticity sum (on average) falls between the extremes of cases (*a*) and (*d*). Case (*a*) has both slope and intercept shifters, and some changes in elasticity sum occurred relative to case (*c*) at the level of the individual sample. However, the overall average for case (*a*) is essentially the same as that for case (*c*), and the individual differences were generally not large, which suggests that the differences are not very important.

These results support the use of case (*c*) (equivalent to the primary equation employed) when the objective is estimation of average values of elasticities. With the use of slope shifters there is the additional possibility of investigating systematic variation in elasticities, but results here appeared only mildly encouraging. Multicollinearity was a major problem, and disaggregation to the individual firm gave great variability in results with negative elasticities fairly common.

Maddala discusses an alternative to fixed effects analysis of covariance in pooling cross-section and time-series data, in which effects are treated as random. His rationale for the approach includes the arguments that "rarely is it possible to give a meaningful interpretation to the dummy variables," and that in some cases analysis of covariance entails the loss of a considerable number of degrees of freedom (p. 341). The arguments seem germane to the slope-shifting case but do not seem very convincing in the context of the primary investigation here, given the emphasis on interpreting and drawing inferences from the firm and time effects and the availability of many observations on individual firms.

Conclusions

Economists often express the strong intuition that constant returns to scale is an accurate representation of nature. In contrast, the empirical results here show a marked divergence from constant returns, explainable on the basis of a detailed model of firm behavior. Furthermore, the assumption of constant returns can lead to various embarrassments, including infinite supply elasticity and the likely incompatibility of competition and even small differences in technical efficiency between firms. In the empirical results, alternative approaches and functional forms often gave remarkably similar results, suggesting that the same underlying reality can be perceived—even if dimly—from different vantages.

The Retail-Farm Price Ratio, the Farmer's Share, and Technical Change

Allen K. Miedema

Technical change in the food marketing industry has been causally linked to the secular increase in the marketing margin, i.e., the margin between product prices at retail and prices of the related raw farm products. Technical change has also been adduced by Lianos to explain the decline in the relative share of farm workers. However, this work generally omits a formal neoclassical model of technical change that accounts for imperfect competition in input and product markets.

This paper synthesizes previous work by Muth and by Gardner in developing a more complete specification of the effects of technical change. This specification allows for noninfinite product demand and factor supply elasticities. These theoretical results are then analyzed empirically to derive some specific quantitative implications of technical change for the food marketing industry. Lianos' empirical estimate of the degree of capital-biased technical change in agriculture is reinterpreted with these alternative neoclassical specifications.

A Synthesis of Previous Results

In a recent article in the *Journal* Gardner examined changes in input-retail price ratios and input shares induced by exogenous perturbations in product demand and in factor supply functions. The analysis was based on the standard one-product, two-input model. That model is first restated in a form that differs unsubstantively from that given by Gardner. Another brief reformulation is given in logarithmic differentials as derived by Muth. With this reformulation Gardner's main results can be reproduced and extended with simple recombinations of Muth's results.

In the one-product, two-factor models equilibrium of the marketing industry is described by six equations: (*a*) a retail product (x) demand function (D); (*b*) a marketing industry production function (f), which is assumed to be linear homogeneous in the two inputs, a and b; (*c*) and (*d*) the marginal conditions on factor payments, i.e., equalities between factor prices (P_a and P_b) and the products of retail price (P_x) and marginal products (f_a and f_b); and (*e*) and (*f*) factor supply functions. These equations define the following system:[1]

(1) $$x = D(P_x),$$
(2) $$x = f(a, b),$$
(3) $$P_a = P_x f_a,$$
(4) $$P_b = P_x f_b,$$
(5) $$a = g(P_a),$$
and
(6) $$b = h(P_b),$$

where, as in Gardner's paper, a is purchased agricultural commodities, b is other marketing inputs, and x is food sold at retail. Prices are defined accordingly.

Muth has shown that equations (1) through (6) can be reformulated as[2]

(7) $$ZY = R,$$

where

$$Z = \begin{bmatrix} -1/\eta & 0 & 0 & 1 & 0 & 0 \\ 1 & -k_a & -k_b & 0 & 0 & 0 \\ 0 & k_b/\sigma & -k_b/\sigma & -1 & 1 & 0 \\ 0 & -k_a/\sigma & k_a/\sigma & -1 & 0 & 1 \\ 0 & -1/e_a & 0 & 0 & 1 & 0 \\ 0 & 0 & -1/e_b & 0 & 0 & 1 \end{bmatrix},$$

$$Y = \begin{bmatrix} EX \\ Ea \\ Eb \\ EP_x \\ EP_a \\ EP_b \end{bmatrix}, \text{ and } R = \begin{bmatrix} \alpha \\ \delta \\ \delta + \epsilon \\ \delta - (k_a/k_b)\epsilon \\ \beta \\ \gamma \end{bmatrix}.$$

The notation is defined in table 1. The complete mathematical derivations of the technical change parameters (δ and ϵ) are in Muth.

The solution of the system in equation (7) is $Y = Z^{-1}R$. Because of the way R is defined, Y may be

Allen K. Miedema is an economist in the Energy and Environmental Research Division at the Research Triangle Institute, North Carolina.

The author acknowledges the help and criticism of his associates at the Research Triangle Institute and of the *Journal* reviewers.

[1] None of these equations explicitly reflects its dependence upon any exogenous variables, but the presence of these exogenous variables in the demand, production, and factor supply functions is explicitly assumed. Following Muth, "the effect of changes in any such variables will be treated as a shift in one or more of these functions" (p. 222).

[2] Although Muth presents none of his work with matrix notation, the following matrix system is an exact restatement of his reformulated system. The five parameters (excluding k_a and k_b) in the vector R represent the combined shifting effects of the (omitted) exogenous variables in equations (1) through (6). Relative changes are defined as the logarithmic differentials of any variable. Thus, the relative change dt/t for an arbitrary variable t is the percentage change divided by 100.

Table 1. Variable Definitions

Variable	Definition
EX	$d(\ln x) = dx/x$ (the operator E is similarly defined for other elements of Y)
η	Own price elasticity of demand for x
e_a	Own price elasticity of agricultural commodity supply
e_b	Own price elasticity of marketing input supply
σ	Elasticity of substitution between a and b
k_a	Cost share imputed to agricultural commodities
k_b	Cost share imputed to marketing inputs
α	Relative change in food prices at any quantity on the new food demand curve
β	Relative change in the supply of a (the vertical relative shift in the supply function)
γ	Relative change in the supply of b
δ	Neutral component of technical change, defined as the relative (and equal) change in the marginal products of a and b (which is equal to the relative change in output) for the input quantities prior to the technical change
ϵ	Factor-biased component of technical change, defined as the relative change in a's marginal product, holding output constant for the input quantities used prior to the technical change

redefined as a linear function of the vector of exogenous perturbations (S):

$$(8) \qquad Y = Z^{-1}R = \Delta^{-1}GS,$$

where $\Delta = \sigma\eta - \sigma(k_a e_a + k_b e_b) + \eta(k_b e_a + k_a e_b) - e_a e_b$, usually a negative scalar defined by D'' in Muth and by $-D$ in Gardner, $G = [g_{ij}]$, a 6×5 matrix whose row elements are directly available as the coefficients (excluding D'') of the five elements of S in equations (24) through (29), respectively, of Muth's appendix, and $S = (\alpha, \beta, \gamma, \delta, \epsilon)'$.

To examine the shifting effects of exogenous variables in the food demand function, the agricultural commodity supply function, and the marketing input supply function, Gardner inserted three shift variables—N, W, and T, respectively—into those functions. Therefore, the following three parameters appear in his main results:

$$(9) \quad \eta_N = d(\ln x)/d(\ln N);\ e_W = d(\ln P_a)/d(\ln W); \text{ and } e_T = d(\ln P_b)/d(\ln T).$$

Muth, on the other hand, expressed the product demand and factor supply function shifts—α, β, and γ, respectively—as *ad valorem* shifts in the direction of the price axis. Thus, he defined α as the "relative increase in price at any given quantity on the new demand schedule" (Muth, p. 223). The parameters β and γ are accordingly defined as the relative increases in the supply prices of factors a and b, respectively, at any given quantity. Therefore, Muth's shift coefficients may be expressed in terms of Gardner's three parameters in equation (9) as

$$(10) \quad \alpha = -(\eta_N/\eta)\, d(\ln N);\ \beta = e_w\, d(\ln W); \text{ and } \gamma = e_T\, d(\ln T).$$

The appropriateness of these expressions, which follow from the inverse functions related to equations (1), (5), and (6), may be verified in Muth.

Since Gardner did not consider the effects on the factor share of agricultural commodities resulting from an exogenous shift in the marketing input supply function, that analysis is presented here for completeness. It follows definitionally that[3]

$$(11) \quad d(\ln k_a/\gamma) = (g_{53} + g_{23} - g_{43} - g_{13})/\Delta, \text{ for } S = (0, 0, \gamma, 0, 0)',$$
$$= [(1 - \sigma)k_b e_b(e_a - \eta)]/\Delta.$$

Since Δ is usually negative, the sign of equation (11) is determined by the size of σ, as is the case for the change in a's share resulting from a shift in the agricultural commodity supply function (see Gardner's equation (23)). If $\sigma < 1$, the farmer's share will fall as the marketing input supply function shifts upward. For example, if skilled labor specific to farm product marketing, e.g., butchers, were to become relatively scarcer, the marketing input supply function would shift upward and the farmer's share of the food dollar would decline. In any event identical conditions on the value of σ insure (except when $\sigma = 0$) opposite directional effects on the farmer's share from exogenous perturbations of the agricultural commodity supply function and of the marketing input supply function, respectively.

The Effects of Technical Change

Since Muth's formulation contains two additional shift parameters relating to neutral and factor-biased technical change, respectively, the model is extended to examine their effects on the retail-farm price ratio and on input shares. This approach allows the relaxation of the traditional assumption of infinite product demand and factor supply elasticities in the analysis of the effects of technical change.

The two shift parameters (δ and ϵ) decompose the components of technical change in the marketing industry into intensity and bias, respectively (table 1). Although both parameters are defined at the pretechnical change equilibrium position that is a disequilibrium position after the technical change, they completely describe the change in the shape of the production isoquants. Just as Gardner's results and equation (11) summarize the new equilibria that result from changes in the shape of the product demand and input supply functions, a similar analysis summarizes the new equilibria that result from a change in the shape of the production isoquants.

[3] Transformed back to Gardner's notation using the expression for γ from equation (10), this result can be restated as $E_{S_a T} = -e_T (\sigma - 1) S_b e_b (\eta - e_a)/D$.

Technical Change and the Retail-Farm Price Ratio

The effect of neutral technical change on the retail-farm price ratio is derived from equation (8) as

$$(12)\qquad d[\ln (P_x/P_a)]/\delta = (g_{44} - g_{54})/\Delta, \text{ for } S = (0, 0, 0, \delta, 0)', = \Lambda/\Delta,$$

where $\Lambda = \sigma(k_a e_a + k_b e_b) + k_b(e_a - e_b) + e_a e_b - \eta(\sigma + e_b)$. There are four feasible values of parameter combinations in equation (12) to explore in completely examining the directional impact of neutral technical change on the retail-farm price ratio. All such evaluations recognize that Δ is negative.

Case 1: $e_a > e_b$ or $e_a = e_b$. When the elasticity of agricultural commodity supply exceeds (or equals) that of market input supply, all terms in the numerator (Λ) of equation (12) are positive. The whole expression is negative for normal values of the parameters, so that the retail-farm price ratio declines with neutral increases in factor productivity when $e_a > e_b$ or when $e_a = e_b$.

Case 2: $e_a < e_b$, $\sigma > 1$. Since both e_a and e_b are positive and e_a is assumed less than e_b, e_a can be expressed as a fraction τ, which lies in the open interval (0,1), of e_b:

$$(13)\qquad e_a = \tau e_b,\ 0 < \tau < 1.$$

When the expression for e_a in equation (13) is substituted into the numerator (Λ) of equation (12) the numerator becomes

$$(14)\qquad \Lambda = \lambda_0 + \lambda_1 \tau,$$

where $\lambda_0 = k_b e_b(\sigma - 1) - \eta(\sigma + e_b)$ and $\lambda_1 = \sigma k_a e_b + k_b e_b + e_b^2$. When $\sigma > 1$, $\lambda_0 > 0$ for all normal parameter values; also $\lambda_1 > 0$ normally. Therefore, even when $e_a < e_b$, the retail-farm price ratio declines with neutral increases in factor productivity when $\sigma > 1$.

Case 3: $e_a < e_b$, $\sigma < 1$, $-(\lambda_0/\lambda_1) < 1$, $-(\lambda_0/\lambda_1) < \tau < 1$. Since Λ is an increasing linear function of τ, Λ assumes positive values for all $\tau > -(\lambda_0/\lambda_1)$. If $-(\lambda_0/\lambda_1) < 1$, there is some range of values for τ that implies a positive numerator in equation (12), namely, the range of values for which $\tau > -(\lambda_0/\lambda_1)$. When $\lambda_0 > 0$, despite the fact that $\sigma < 1$, P_x/P_a declines with positive neutral technical change. When $\lambda_0 < 0$, P_x/P_a is more likely to decline under this type of technical change if the elasticity of agricultural commodity supply is close to (a large fraction of) that of marketing inputs.

Case 4: $e_a < e_b$, $\sigma < 1$, $\tau < -(\lambda_0/\lambda_1)$. It follows from case 3 that $\Lambda < 0$ when $e_a < e_b$ and $\sigma < 1$ if $\tau < -(\lambda_0/\lambda_1)$. Since τ is always positive, this condition requires that λ_0 be negative. This condition occurs when $\eta = 0$. When $\sigma = 0$ it occurs only when the absolute value of η is less than k_b. In the limiting case when both σ and η equal 0, the critical value of τ is $1/(1 + e_b k_b^{-1})$. For example, when $\sigma = \eta = 0$, $e_b = 2$, and $k_b = 0.5$, the critical value of τ is 0.2. If under these conditions the elasticity of agricultural commodity supply (e_a) is less than $0.2e_b$ or 0.4, the retail-farm price ratio increases with a neutral increase in factor productivity. In general both extremely limited substitutability between agricultural commodities and marketing inputs and an inelastic demand for the retail product are necessary conditions for the retail-farm price ratio to increase in the presence of neutral technical change.

The effect of b-saving technical change on the retail-farm price ratio is similarly derived from equations (8) as

$$(15)\qquad d[\ln (P_x/P_a)]/\epsilon = (g_{45} - g_{55})/\Delta, \text{ for } S = (0, 0, 0, 0, \epsilon)', = \sigma(k_a e_a + k_b e_b - \eta)/\Delta.$$

Since the numerator in equation (15) is normally positive the whole expression is negative. The implication is that technical change that is b-saving will reduce the retail-farm price ratio.

Technical Change and Factor Shares

Equation (8) can also be used to assess the impact of neutral technical change on the share of revenues imputed to agricultural commodities:

$$(16)\qquad d(\ln k_a)/\delta = (g_{54} + g_{24} - g_{44} - g_{14})/\Delta, \text{ for } S = (0, 0, 0, \delta, 0)', = [k_b(1 + \eta)(1 - \sigma)(e_b - e_a)]/\Delta.$$

The three parenthesized expressions in the numerator may be positive, zero, or negative. If any one is zero, a's factor share does not change when neutral technical change occurs. Of the remaining eight possibilities, four imply that a's factor share increases and four imply that it decreases with neutral increases in factor productivity.[4] No more specific general statement can be made.

However, if the elasticity of agricultural commodities supply is lower than that of marketing inputs, if the elasticity of substitution between the two factors is less than unity, and if the demand for food is inelastic ($\eta > -1$), then neutral increases in factor productivity decreases the farmer's share of the food dollar.

The effect of a-biased technical change on the farmer's share of the food dollar can be derived as

$$(17)\qquad d(\ln k_a)/\epsilon = (g_{55} + g_{25} - g_{45} - g_{15})/\Delta, \text{ for } S = (0, 0, 0, 0, \epsilon)', = M/\Delta,$$

where $M = \mu_0 - \mu_1\tau$, $\mu_0 = -\sigma[-\eta + e_b(1 - 2k_a)]$, and $\mu_1 = \sigma e_b(-\eta + e_b + 2k_a)$.

Four feasible values of parameter combinations in equation (17) determine the directional impact of a-biased technical change on the farmer's share of the food dollar.[5]

[4] Since each of the three factors may be either positive or negative, the products of each of the eight possible signed combinations imply a positive or a negative sign for the numerator of equation (16).

[5] It is possible to identify a potential bias in Gardner's estimate

Case 1: $\tau > 1$. Since this condition implies that $e_a > e_b$, it follows by substituting $\tau = e_a/e_b$ into the expression for M that $M < 0$ when $\tau > 1$. Therefore, whenever the elasticity of agricultural commodity supply exceeds that of marketing inputs positive a-biased technical change increases the farmer's share of the food dollar.

Case 2: $\mu_0 < 0, \tau \lesseqgtr 1$. Since the numerator ($M$) in equation (17) is a declining function of τ (μ_1 is normally positive), M is always negative if $\mu_0 < 0$. This occurs if $k_a < (e_b - \eta)/2e_b$. Thus, *ceteris paribus*, the smaller the share of agricultural commodities is to begin with, the more likely it is to rise as a-biased technical change occurs.

Case 3: $\mu_0 > 0$, $(\mu_0/\mu_1) < 1$, $(\mu_0/\mu_1) < \tau < 1$. Since M is a declining function of τ, M assumes negative values for all $\tau > \mu_0/\mu_1$. When $(\mu_0/\mu_1) < 1$, those values of τ above μ_0/μ_1 imply a negative value for M and an increase in k_a resulting from an increase in ϵ. Therefore, agricultural supply elasticities close in value to those of marketing inputs are more likely to be accompanied by increases in the farmer's share of the food dollar when the positive agricultural commodity biased technical change occurs.

Case 4: $\mu_0 > 0$, $\tau \leq (\mu_0/\mu_1)$. Following the preceding logic, these conditions imply that M assumes a positive (or zero) value and hence that the farmers share of the food dollar falls (remain constant). Consequently, if the elasticity of agricultural commodity supply is small relative to that of marketing inputs, the farmer's share of the food dollar is more likely to fall when a-biased technical change occurs.

Empirical Applications

The implications of these results for agriculture can be further examined by empirical applications of equations (12), (15), (16), and (17). First, a sensitivity analysis is presented based on various ranges of reasonable parameter values. Then, the theory is applied to explain shifts in the farm product price-farm wage ratio and in farm labor's relative share in the farm production stage rather than in the marketing stage.

The four equations can be interpreted as elasticities since each is a ratio of logarithmic differentials. Given the precise definitions of δ and ϵ in table 1, equation (12) is the elasticity of the retail-farm price ratio with respect to neutral technical change, defined as an equal relative change in the marginal products of both a and b. Equation (16) similarly defines the elasticity of the farmer's share with respect to neutral technical change, while equation (15) can be interpreted as the elasticity of the retail-farm price ratio with respect to a-biased technical change defined as the relative change in a's marginal product that leaves output unchanged for the two inputs used prior to the change. Finally, equation (17) is the elasticity of the farmer's share with respect to a-biased technical change. All four elasticities represent percentage changes in variables associated with equilibrium positions before and after technical change.

In the sensitivity analysis it is assumed—as in Gardner's table 1—that reasonable hypothetical parameter estimates for these equations are $k_a = 0.5$, $\eta = -0.5$, $e_a = 1.0$, $e_b = 2.0$, and $\sigma = 0.5$. (Hereafter these estimates are referred to as the baseline values.) The analysis is completed by computing the value of each of the four equations eighty-four times: twenty-one times in increments of 0.25 over the closed interval [0,5] for each of three parameters (e_a, e_b, and σ) and over the closed interval [−5,0] for η while all other parameters are held at their baseline values. The results are shown in figures 1 through 4. For example, the plot labeled e_b in figure 1 shows the values of equation (12) when e_b is varied from 0 to 5 and all other parameters are held constant at their baseline values.

Figure 1 shows that over all of the chosen parameter values the retail-farm price ratio declines in the presence of neutral technical change. Over the selected parameter ranges induced changes in the ratio are least sensitive to changes in the elasticity of substitution. As dictated by the theoretical results, the retail-farm price ratio declines when a-biased technical change occurs (figure 2). Changes in the elasticity of farm product demand induce virtually no change in the ratio.

Figure 3 summarizes the effects of neutral technical change on the farmer's share. These calculations illustrate that the direction of the change is not easily predictable. For the baseline parameter values the farmer's share would decline with neutral technical change. Figure 4 shows that for all hypothesized parameter value combinations the farmer's share will rise with a-biased technical change, even when $e_a = 0$. When $\sigma = 0$ there is no change in the farmer's share, and it changes very little in response to changes in the product demand elasticity.

The sources of change in the relative share of labor in agriculture can also be analyzed. Lianos determined that technological progress in American agriculture has been capital using. His preferred estimate of the bias (B) of technological progress, defined strictly as the average difference between the logarithmic differential of the marginal product of capital and that of labor, is 0.129. This estimate

of the elasticity of substitution. As Gardner points out, $[d(\ln k_a/s_i)]/[d[\ln (P_x/P_a)]/s_i] = \sigma - 1$, for $i = 1, 2$, where s_i is the ith element of S (p. 406). Examination of equations (10) and (11) and Gardner's equation (17) reveals that the foregoing relationship also holds for $i = 3$, but this relationship does not hold for $i = 4$ or 5. From equations (12) and (16) and from equations (15) and (17), the solutions for $i = 4$ and $i = 5$ are $[d(\ln k_a/s_i)]/[d[\ln (P_x/P_a)]/s_i] \doteq [k_b(1+\eta)(1-\sigma)(e_b - e_a)]/\Lambda$ for $i = 4$ and $M/[\sigma(k_a e_a + k_b e_b - \eta)]$ for $i = 5$. Definitions of Λ and M are found in equations (12) and (16). These results imply that one has to exercise some care in interpreting $d(\ln k_a)/d[\ln (P_x/P_a)]$ as $\sigma - 1$. This relationship holds only in the absence of technical change.

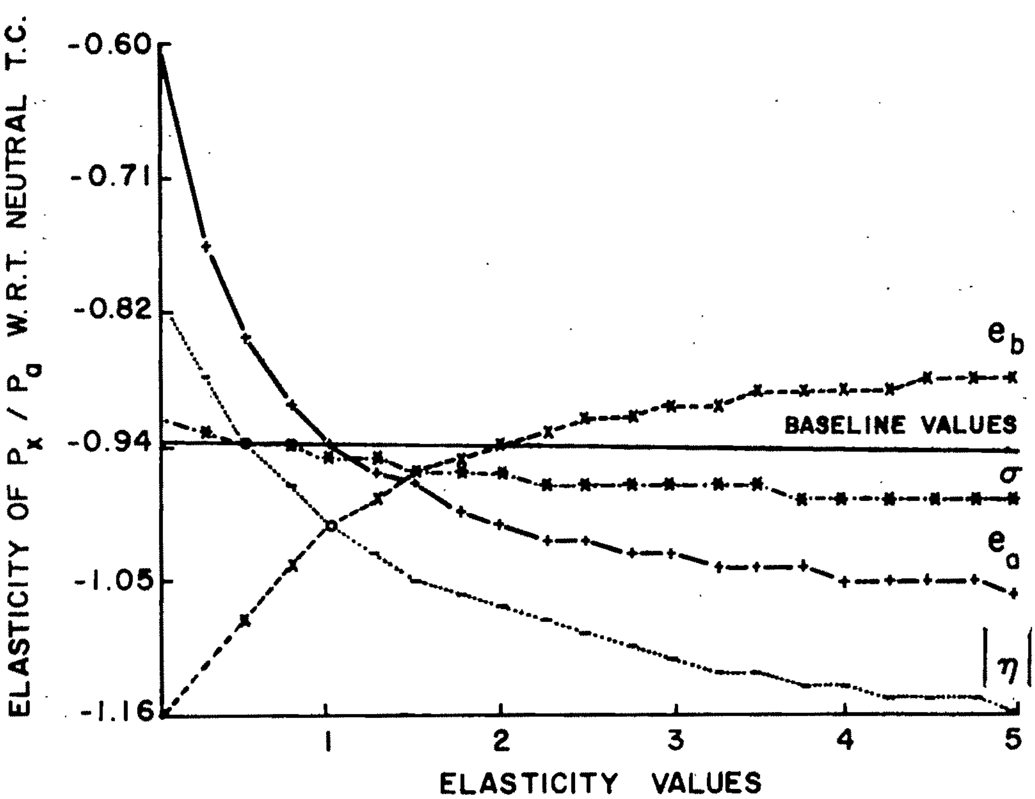

Figure 1. Sensitivity of equation (12) to variations in four elasticities

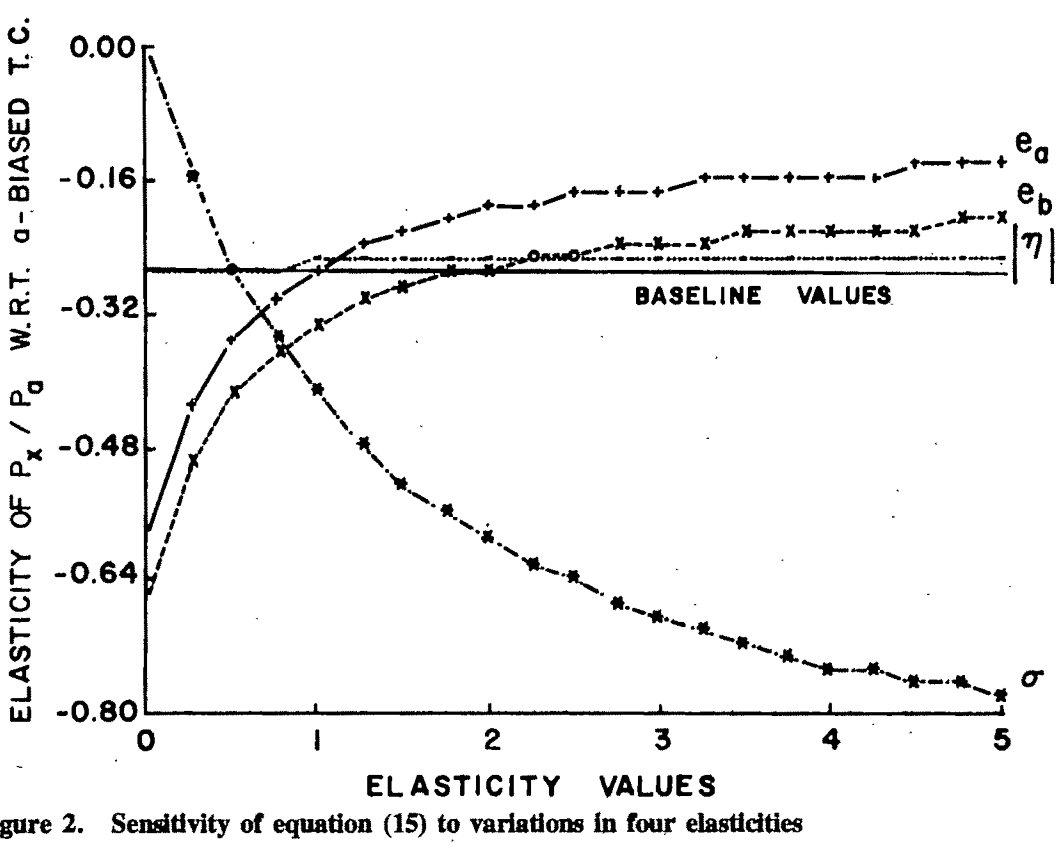

Figure 2. Sensitivity of equation (15) to variations in four elasticities

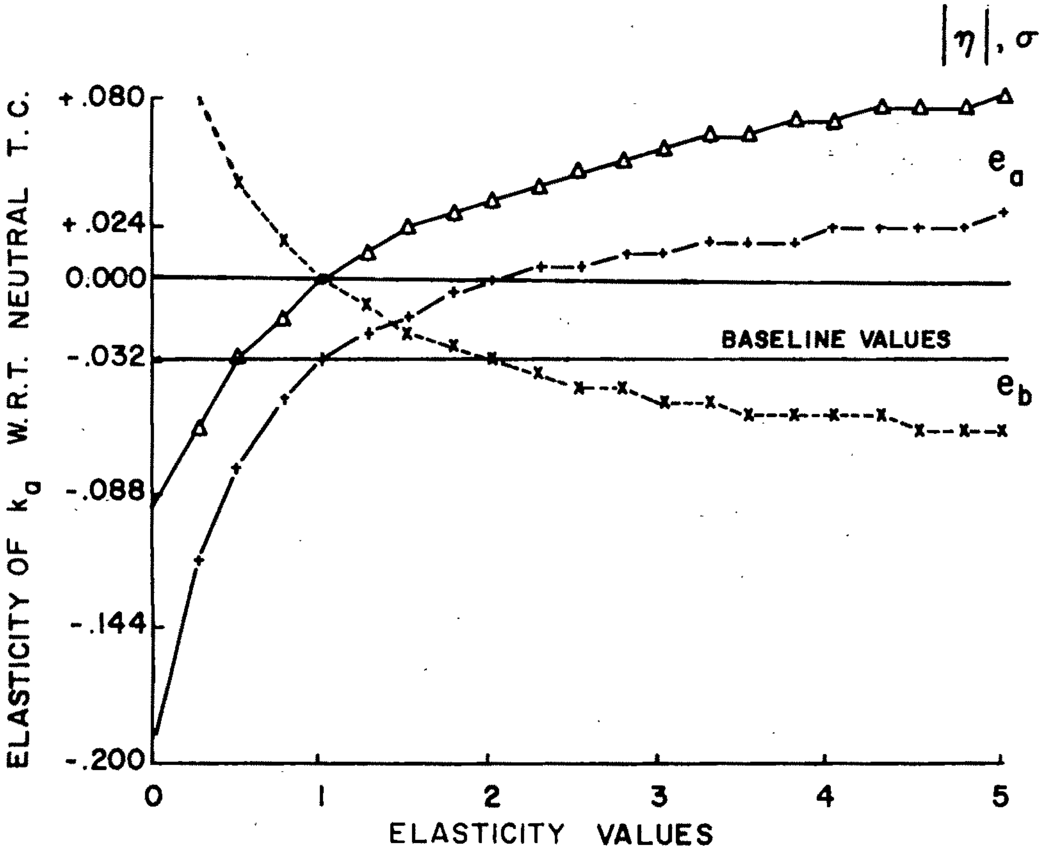

Figure 3. Sensitivity of equation (16) to variations in four elasticities

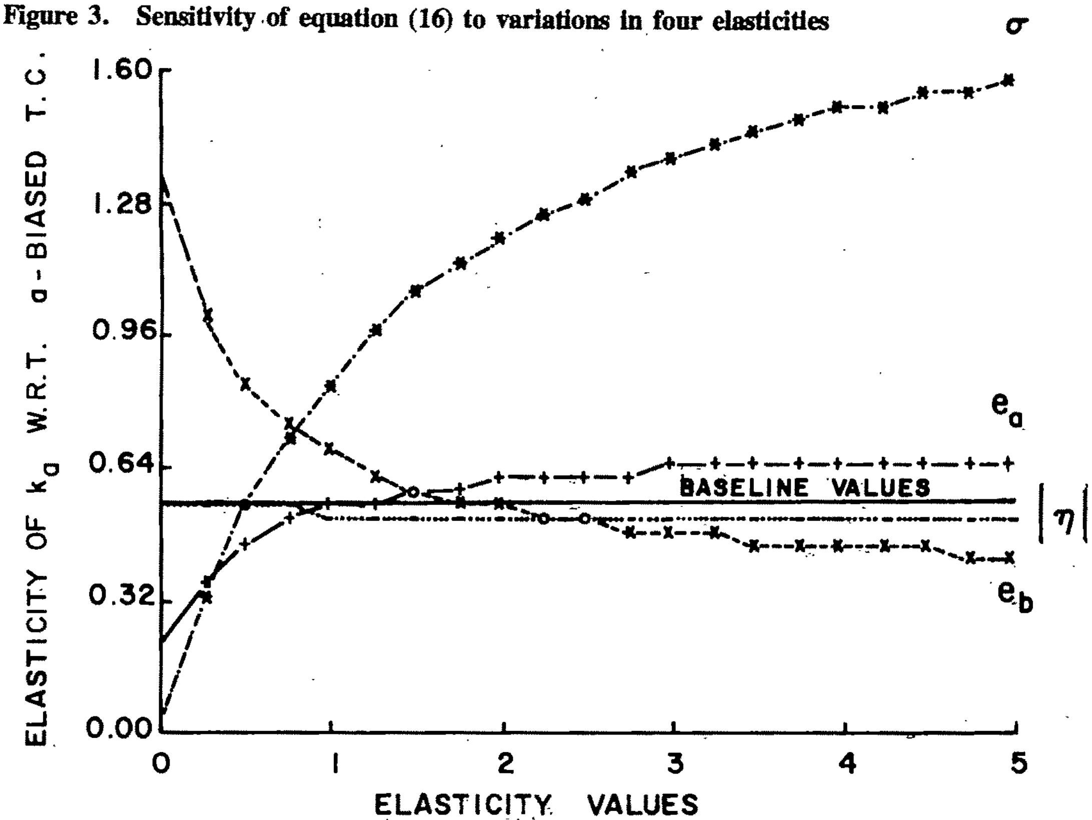

Figure 4. Sensitivity of equation (17) to variations in four elasticities

and Lianos' first estimate of 0.294 for the relative share of capital imply a value of ϵ equal to -0.09107.[6]

It is of interest to determine the percentage change in the farm product price-farm wage ratio and in the relative share of labor that accompany such a level of biased technical change. The elasticity of labor is available as the inverse of the coefficient on the farm labor variable in Wallace and Hoover. This estimate implies an elasticity of farm labor supply of about 18.87. If estimates of the elasticity of farm product supply (e_x) of the elasticity of substitution and of relative shares are available, these data in conjunction with the estimate of the labor supply elasticity are adequate to estimate the elasticity of capital supply.[7] Griliches's long-run estimate of e_x equal to unity is assumed, and Lianos' estimates of $\sigma = 1.524$ and $k_a = 0.294$ are used. These values imply an elasticity of capital supply of 0.336. All of these values are substituted into equations (15) and (17), which are then multiplied by -0.09107 to determine the two associated relative changes. These calculations are completed for two estimates of the elasticity of farm product demand, -0.5 and -0.35 (see Lianos for the sources of these estimates). The results suggest that Lianos' estimate of B implies a 3.85% annual increase in the farm product price-farm wage ratio in the first case and a 4.17% annual increase in the second case. Similarly, the relative share of labor decreases 16.87% annually in the first case and 16.69% in the second.

These results obviously imply much larger annual percentage decreases in farm labor's relative share than those predicted by Ferguson's model used by Lianos. The main reason for this is that equation (17) accounts for noninfinite factor supply and product demand elasticities while Lianos' basic model assumes all these elasticities are infinite. Lianos' model apparently is a better predictor than the one presented here, but he attributes all of the nonprice induced shifts in the relative share of labor to technical change. A major point of this and Gardner's paper is that many exogenous influences simultaneously affect movements in this share. (In terms of this paper all of the elements of S are possibly nonzero during any time period.) Therefore, the partial effect of Lianos's estimate of bias is larger than he indicated when reasonable estimates of factor supply and product demand elasticities are incorporated. Other exogenous effects, such as shifts in the factor supply and product demand functions, are likely responsible for observed reductions in the relative share of labor that are smaller than those predicted here.

[*Received October 1975; revision accepted May 1976.*]

[6] In the notation of this paper $B = d(\ln f_b) - d(\ln f_a)$. Muth's definition of ϵ implies that $B = -\epsilon(1 + k_a/k_b)$. Consequently, $B = 0.294$ implies the value of ϵ given in the text, assuming $k_b = 0.294$.

[7] This can be accomplished by solving the equation expressing the derived elasticity of product supply for e_b; this equation is given in both Muth and Wisecarver.

Accuracy of Least Squares Computer Programs: Another Reminder

William T. Boehm, D. J. Menkhaus, and J. B. Penn

In 1943, Hotelling reported on the potential inaccuracies of least squares algorithms. Since then, numerous studies have been published presenting the results of comprehensive tests of widely used least squares routines, algorithm refinement, and assessments of error bounds. Papers by Beaton, Rubin, and Barone; Freund; Ling; Longley; and Wampler provide a sample of the literature available. Most of the formal research on these issues has been conducted by statisticians, mathematicians, or computer scientists and/or has been published in the scientific journals of those professions. While probably aware of potential computer inaccuracies, agricultural economists and others using least squares programs in their research are often forced to rely on both the software packages and hardware available at their research station. They may or may not be familiar with the literature being published on computational accuracy and as a result may not explicitly question the accuracy of either the software or the hardware they use. The issue is real and of some importance. In 1976, for example, SPSS, Inc., distributed a newsletter warning users of that major software package that there "is a catastrophic error in the discriminant procedure. The discriminant function coefficients are incorrectly computed" (p. 2). While the problem was corrected once it was discovered, consider the plight of those who used the discriminant procedure from that package to conduct research and are now anxiously awaiting comments from reviewers regarding the publishability of their results and the associated policy implications.

The purpose of this note is to demonstrate once again and in a form meaningful to program users that even though substantial improvements in computer software and hardware have been made in recent years, computational accuracy can still be a problem. While it is admitted that accuracy is a multidimensional issue, our concern in this paper is with computational accuracy. The procedure employed is that used by Wampler. Results obtained from selected regression routines available to agricultural economists at four land grant universities are examined and compared.

No formal attempt is made here to explain why, for certain problems, some routines and/or machines may generate more accurate results. Such a discussion is beyond the scope of this note and would in large measure duplicate the literature now available. The interested reader is referred to Ling.

Procedures

Two problems, identified as equations (1) and (2), were used for the test. Values of the "endogenous" variables (Y) for the test were calculated from the following equations:

$$Y = 1 + X + X^2 + X^3 + X^4 + X^5, \tag{1}$$

and

$$Y = 1 + 0.1X + 0.01X^2 + 0.001X^3 + 0.0001X^4 + 0.00001X^5. \tag{2}$$

Both equations (1) and (2) are fifth degree polynomials. The values of the "exogenous" variable (X) were the integers 0, 1, 2, . . . , 20. True values for the parameters are, of course, the values used to calculate Y. There is no error term and therefore the true $R^2 = 1$.

The simple correlation coefficients among the X's were all greater than 0.816, six of the ten were greater than 0.958, and three were greater than 0.986. The high linear association between the regressors and the large variation in the data partially explain why these problems present such difficulty in obtaining consistently accurate parameter estimates.

Parameter estimates for the two test problems were obtained for a total of forty-two separate equations using an IBM 370 Model 165 (IBM1), CDC 6500 (CDC), IBM 370 Model 158 (IBM2), and a Xerox Sigma Seven ($\Sigma 7$) computer. The programs used included BMD2R, BMD3R, SPSS, SAS, TTLS, LSP, MDVR1 (single precision), and MDVR2 (double precision). The specific equations estimated by program and machine are summarized in table 1.

BMD2R and BMD3R (stepwise and multiple regression, respectively) are two regression options from the Biomedical Computer Programs (Dixon).

William T. Boehm is an assistant professor of agricultural economics at Virginia Polytechnic Institute and State University, Blacksburg, D. J. Menkhaus is an assistant professor of agricultural economics at the University of Wyoming, Laramie, and J. B. Penn is the program leader of the Policy Program Area, Economic Research Service, U.S. Department of Agriculture.

The authors wish to express their thanks to the *Journal* reviewers, particularly the editor, for comments on an earlier draft of this paper.

Table 1. Summary of the Equations Estimated by Program and Machine

Program Used to Estimate Equations	Computing Machine and Location			
	IBM1 North Carolina State	CDC Purdue University	IBM2 Virginia Tech	Σ7 University of Wyoming
BMD2R	X	X	X	X
BMD3R	X	X	X	X
SPSS	X	X	X	X
SAS	X		X	
TTLS	X	X	X	
LSP		X	X	
MDVR1				X
MDVR2				X

The multiple regression routine from the relatively new Statistical Package for the Social Sciences is identified as SPSS (Nie, Bent, and Hull). SAS denotes the multiple regression option from the Statistical Analysis System originally designed at North Carolina State University (Barr and Goodnight). TTLS is a program originally developed by Stroud, Zellner, and Chau to calculate parameter estimates for systems of equations (simultaneous and seemingly unrelated regression). LSP denotes a FORTRAN multiple regression program of unknown origin that has been modified to improve its accuracy (i.e., double-precision variable arrays), simplify the data input, and provide additional information (e.g., Durbin-Watson statistic, elasticities, R^{-2}) (Boehm, Penn). MDVR identifies a program developed at the University of Wyoming Agricultural Experiment Station (Roehrkasse).

The two test problems have been classified by Wampler as being highly "ill-conditioned," the former being slightly more ill-conditioned than the latter.[1] While polynomial fitting is common in applied economic studies, problems with data matrices such as these are admittedly seldom encountered in practice.[2] Suffice it to say that if computer routines successfully handle these test problems, computational accuracy should not be a serious issue for less ill-conditioned cases.

Results

Accurate parameter estimates were obtained for only nineteen of the forty-two equations estimated. The programs failed to compute estimates for some or all parameters in fifteen of the equations. In some cases when the calculated parameters were reasonably accurate, the coefficient standard errors were considerably larger than their corresponding coefficient estimates and thus, using classical t-tests and the usual null hypothesis (i.e., H_0: $B_j = 0$), would have been judged nonsignificant. However, any calculated coefficient standard error not equal to 0 was, strictly speaking, an error.

Estimates for the residual standard error, which should be zero, were inaccurately estimated for twenty-seven of the forty-two equations. The coefficient of determination (R^2) was reasonably accurate in all but six of the equations. However, in two of these equations the reported R^2 was greater than its theoretical bound.

The general nature of the inaccuracies obtained for equation (1) is summarized in table 2. The results indicate the rather wide variation in the estimates obtained for BMD2R, BMD3R, and TTLS using different machines. They also indicate that in general similar results were obtained for BMD2R and BMD3R on the two IBM machines at different locations. In fact, equation (1) estimates obtained using IBM equipment and BMD2R were identically inaccurate to the fifth decimal digit.

SPSS and SAS performed most satisfactorily of all programs used. Both the regression coefficients and the corresponding test statistics for all twelve equations estimated using these packages were computed accurately, regardless of the machine used. The CDC machine with its software component appears to be the best suited of all machines tested to handle problems with ill-conditioned data matrices, regardless of the computer program.

There may be at least three reasons for the substantially different results obtained and summarized in table 2. First, the programs may in fact be different. Revised versions may be available at some locations but not at others. In addition, some programs may be designed to use "system" invert routines that are different at different locations. Second, the degree of single-precision computational accuracy for the machines is different; it is about seven decimal digits for the two IBM machines, about six for the Xerox machine, and about

[1] The concept of an "ill-conditioned matrix" centers on the expected severity of round-off errors generated in inversion. While many numbers have been proposed to measure the degree of ill-conditioning, empirical results have shown them to be inadequate (Ling). The interested reader is referred to Newman for a discussion of a commonly used measure, the P-condition.

[2] There are, of course, techniques (e.g., BMD5R Polynomial Regression) that can be used to fit a power series. Polynomials are chosen for this test because they are difficult to fit via least squares. The interested reader is referred to Beaton and Tukey for a good discussion of the problems encountered in the fitting of power series.

ifteen for the CDC.[3] Finally, the algorithms of arithmetic for the machines are different. Therefore, depending on the functions being performed and the data, different machines doing the identical calculation may generate numerical results that are different.

Although not reported, improved results were obtained, regardless of machine or software package, for equation (2). In those cases where all variables were included in the estimated equation, resulting parameter estimates were quite close to heir true values. This was not the case for equation 1). Either the estimated coefficients were quite close to their actual values, or they were seriously n error (table 2). Such a result may suggest that for nost problems encountered in research any of the nachines and programs tested could be expected to generate adequate results. There are cases in agricultural economics research, however, when ill-conditioned matrices are common. Consider demand equations that contain several interrelated product prices and some measure of income as independent variables and quantity (some large number?) as the dependent variable. In such cases, the results should be interpreted carefully and with due regard for the potential computational inaccuracies.

Certain programming inadequacies were also uncovered in this experiment. Although it is true that program users most often are not able to "correct" programmer inadequacies, it is important to recognize explicitly that programmers and machines do have important influences on the generation of the numerical estimates ultimately used for policy analysis. We discovered, for example, that least squares programmers often incorporate features that operate as "default" mechanisms permitting execution to continue even though an impossible calculation (e.g., dividing by zero) has been requested. Furthermore, such features tend to operate without messages to warn the user.

Finally, while some programs failed to complete the computations for these problems, this result should not necessarily be interpreted as a criticism of the package. If the program fails to solve, it should serve as a caveat to the researcher that there are possible data problems. In most instances we would argue that it is better to have no solution than one that is incorrect or meaningless.

[3] The degree of computational accuracy for a machine is specfied here as a function of bits per word. It is recognized that computational accuracy is also dependent upon the type of calculation as well as the range of data input.

Conclusions

The results of this research and others like it indicate that there is still considerable variation in computational accuracy among regression routines and computers. There is also variation in the computational accuracy of other statistics that are commonly reported by agricultural economists, e.g., coefficient standard errors, residual standard error(s), and R^2. Such results continue to stress the importance of knowing not only the nature of the problem and the data but also the limitations of available computational equipment and software. In short, the computational accuracy issue appears to be alive and well!

The previous discussion may well leave the applied researcher with a feeling of helplessness and it probably should! However, to gain an awareness of whether bogus results are being obtained when using least squares in applied economic research, the following simple precautionary steps can be taken. First, prior to use, computer programs should be tested for their ability to solve the test problems we have used here. This will indicate which programs at a given location are best capable of handling ill-conditioned problems and may help identify those with programmer errors. Second, parameters should be estimated using alternative routines prior to publication or use. Given the serious nature of the issue, perhaps the editor of our *Journal* should require authors to submit regression results from more than one computer program prior to accepting papers for publication. Third, calculations should be repeated using scaled, or otherwise adjusted, data. Adding a large constant to one or more of the variables and reestimating can highlight rounding error for many routines. The constant coefficient for the transformed problem will be different, but the estimated coefficient for all the variables will remain the same in the absence of rounding error. Finally, while it may be of little value for some routines, we suggest that the columns of the exogenous variables should be switched and the runs repeated. While theoretically the order of variable vectors in the $X'X$ matrix makes no difference, the computational method being used and the nature of the data may be such that switching column vectors prior to inversion will help the researcher identify data sets that are ill-conditioned.

Transfer of Development Rights: An Analysis of a New Land Use Policy Tool: Comment

Leslie E. Small

In a recent article in this *Journal*, certain questions regarding the use of the transfer of development rights (TDR) mechanism in the vicinity of a specific highway interchange are investigated on an *ex post* basis (Barrows and Prenguber). The analysis focuses on the question of the characteristics of the development rights (DR) market that would be necessary "if restricted landowners were to be fully compensated" (p. 553). One of the conclusions is that "full compensation would have required widely fluctuating DR prices. Alternatively, stable DR prices would have meant that some owners would receive much more than full compensation and others less" (p. 556). On the surface, this would appear to be a serious flaw in the TDR mechanism. But the conclusion results from an unsatisfactory definition of "full compensation" and from a conceptually inadequate basis for the distribution of development rights. In this note I demonstrate that it is possible to achieve "just compensation," as defined by the courts, with stable DR prices.[1]

Barrows and Prenguber define full compensation as the "actual value *when sold for development* minus the agricultural value" (p. 554, emphasis added). Given this definition, they are correct in noting that the courts have ruled that full compensation is not required. In eminent domain cases, the courts must deal with the compensation question on an *ex ante* basis because there is no possible way to know what the actual price when sold for development would have been. Courts have consistently ruled that claims for compensation based on projections of what the land would have been worth for development some years hence can only be speculative in nature and are not compensable under the constitutional requirement of just compensation (Roettger). Lawyers and appraisers have developed a conceptually precise definition of just compensation as the difference between the market value of the property immediately prior to the taking and its market value immediately subsequent to the taking (Sando). In the case of the taking of development rights, this involves an assessment of the full market value (development value) of the land immediately prior to the imposition of the restriction on development and a separate assessment of the remaining use value (agricultural value in the case at hand) of the land at the time the restrictions are imposed.[2] The courts in effect have decided that the land market arrives at a general price level that best reflects the present value of expected future prices of land discounted for uncertainty regarding the nature and timing of the future development of a given area.[3]

Because the courts, acting in eminent domain cases, reject the concept of full compensation as defined by Barrows and Prenguber, the TDR mechanism can be analyzed more meaningfully by examining the characteristics of the DR market that would be necessary to provide the restricted landowner with just compensation. This approach is particularly appropriate because the TDR mechanism has been proposed as a possible alternative to the public acquisition of development rights through the use of the power of eminent domain (Rose, Woodbury).

The analysis of the relationship between just compensation and stable prices for DR is straightforward. With stable DR prices, just compensation could occur only if the initial distribution of DR among land parcels is in proportion to the "compensable value" (defined as the difference between market value and use value) of the parcels at the time at which the TDR program is initiated. In their analysis, Barrows and Prenguber allocate DR on the basis of the total assessed value of the land.

Leslie E. Small is an assistant professor of agricultural economics at Cook College of Rutgers University.

The author received helpful comments from W. Park.

[1] The term "stable prices" is used here to mean a pattern of prices over time such that the present value of the prices prevailing at any two points in time, discounted by the rate of interest appropriate for risk-free investments, is constant. With this definition of stable prices, the timing of the sale of a given landowner's DR has no effect on the present value of the amount he receives.

[2] Thus Barrows and Prenguber are somewhat misleading in their statement that "the courts have ruled that the full loss to the restricted landowner, i.e., the difference between the property's use value and development value, need not be compensated" (p. 551). This is correct only if development value is interpreted to mean the value that actually would have been received at some future point in time. If one interprets development value in the more usual way to mean current market value (reflecting development as the highest and best use), then the statement is incorrect.

[3] Barrows and Prenguber do calculate the present values of the prices required to meet their definition of full compensation, using a discount rate of 8%. But the resulting values are in no way comparable to the market value of the land immediately prior to the imposition of the TDR program. An *ex post* discounting of a known event is not the same as an *ex ante* discounting, through the market mechanism, of uncertain future events.

This approach, although perhaps dictated by the availability of data in the case study area, is conceptually deficient (and would lead to inequities among landowners) because it ignores the residual value of the land that remains with the landowner after he has sold his DR.[4]

In practice it is likely that any TDR program actually implemented is subject to challenges in the courts on the issue of compensation. The minimum requirements for a program to successfully withstand such challenges would probably be that an assessment of both market values and use values be made at the time that the TDR program is implemented, and that the DR be distributed to landowners in proportion to the difference between these values. Given this initial distribution of DR, one can conclude that price stability is a necessary condition for just compensation. Price stability alone is not sufficient because DR prices could be stable at a level either above or below that which would result in just compensation.

[Received February 1976; revision accepted July 1976.]

[4] In a footnote, Barrows and Prenguber raise a separate issue of whether the assessed values to be used should reflect the market conditions before or after the location of the road is known. With the TDR mechanism being applied only in the vicinity of an interchange, it would be impossible to establish the program prior to knowing the location of the highway. It would thus appear that to meet the requirements of just compensation, the assessed market values would have to be based on the situation prevailing after the location of the highway was known.

In discussing the distribution of development rights, Barrows and Prenguber state that "a TDR program would require downzoning" (p. 554). This is incorrect. Downzoning suffers from the deficiency that it immediately worsens the position of the landowners in the development districts. With downzoning, these landowners would suddenly be required to purchase DR for permission to undertake the same development that had previously been permitted by the original zoning. An alternative is to use a form of upzoning in the development districts. Under this arrangement, the landowner would still be permitted to develop up to the original density limit without the purchase of DR. But if he were to purchase DR, he would then be permitted to develop to the new (higher) density limit.

Transfer of Development Rights: An Analysis of a New Land Use Policy Tool: Reply

Richard L. Barrows and Bruce A. Prenguber

Transfer of development rights (TDR) has been subjected to considerable theoretical analysis since its recent introduction as a potential land use policy tool. In theory, TDR overcomes the problems of traditional zoning by ensuring compensation to restricted landowners through sale of development rights (DR). Landowners presumably cease to oppose restrictive zoning decisions, and TDR thus removes the economic incentive to thwart the community's land use plan. Compensation is the heart of TDR, and the critical issue is whether TDR results in compensation that is viewed as "fair" by both the courts and the community. Unfortunately, the issue is not as "straightforward" as Small suggests, and his proposal for development rights distribution would not mitigate the potential difficulties with TDR that we identified.

Small is incorrect when he argues that TDR must provide the owner with compensation equal to the difference between the market value immediately prior to the restriction and use value immediately after the restriction is imposed.[1] The level of compensation legally required of TDR depends on whether the courts view TDR as an exercise of the police power or the power of eminent domain. Further, if TDR is held to be a police power exercise, compensation legally required from DR sale depends on whether the preservation zone restrictions allow the owner a reasonable return on his property, as defined by the courts. Finally, the legal definition of just compensation may not be nearly as critical for TDR success as the notion of fair or just compensation held by members of the community. Each of these issues is explored in more detail.

If TDR is held to be a legitimate exercise of the police power and if the land use restriction in the preservation zone allows the landowner a "reasonable return" from use of his land, then legally no compensation is required from DR sale or any other source. The definition of reasonable return varies greatly but has generally been interpreted by the courts in terms of the reduction in property value with the imposition of the restriction (Large). Unfortunately, over eighty years of litigation has not resulted in any "conceptually precise" definition of the percentage by which market value must be reduced before a restriction is held to be a taking of property, requiring compensation under the Fifth Amendment (Sax, Large). A restriction that diminished the value of a property by 88% was held not to be a taking in a 1972 Massachusetts case, yet restrictions with much less effect on value have been declared an invalid exercise of the police power, a taking that requires compensation (Large). Since the definition of "taking" varies over time and space, very little can be said a priori about the relationship between stable DR prices and just compensation.

If a TDR program is held to be a police power regulation with no taking of property involved in the restrictions, then the DR market must meet only the community's definition for fair compensation. Ideas about what is fair certainly vary among groups and individuals in the community. Restricted landowners may argue that full compensation (difference between market or potential development value and restricted use value) should be provided by the DR market. Others may argue that because development values were created by the community growth, rather than individual action, no compensation is required (Costonis 1975). In order for the DR market to function smoothly, a TDR program must have the political support of the community because the DR market may be strongly influenced by expectations of future viability of the program and expectations of the likelihood of basic program changes by the local government.[2] Public support of a TDR program is partially determined by whether the public views as "just" the compensation available through DR sale. In the early years of a TDR program, there is little empirical evidence to judge its effectiveness in either guiding land use change or providing com-

Richard L. Barrows is an associate professor in the Department of Agricultural Economics, University of Wisconsin, Madison, and Bruce A. Prenguber is a natural resource economist in the Washington Department of Natural Resources, Olympia.

The authors wish to thank Douglas Yanggen for helpful comments on an early draft. Any errors are the responsibility of the authors.

[1] In the original article, the question asked was "What price per DR would have to be paid to fully compensate each preservation district landowner? Full compensation is defined as actual value when sold for development minus the agricultural value" (p. 554). It was also noted that full compensation was not required by the courts, and that in the case study full compensation was not necessarily identical to market value minus use value immediately after program initiation.

[2] This aspect of TDR has not been fully explored and is a fruitful area for future research.

pensation to restricted owners. In these early years, the community's feeling about just compensation and whether DR sale provides it may strongly affect program performance. In the end, a TDR program that legally requires no compensation may fail miserably because the compensation provided through DR sale was not judged to be just by the community.

If TDR is held to be a legitimate police power policy, in the same manner as zoning, and if the preservation zone restriction reduces the economic return on the property to such an extent that it clearly constitutes a taking of property, or if there is a danger that the courts may hold the restriction to be a de facto taking, then the effectiveness of the TDR program hinges on DR prices and value. Conceptually, an exercise of the police power can legitimately and legally reduce property value up to some maximum. For discussion purposes, define "maximum restriction value" as the value of the property under the most stringent restriction that would be allowed by the courts under the police power. If the TDR preservation zone restriction reduces the property value to some level (termed "TDR value") below the maximum restriction value, then a "taking increment" may be defined as the difference between the TDR value and the maximum restriction value. Then the critical question is whether the courts view DR as a legitimate form of compensation and whether the potential value of the DR is held to compensate for the taking increment. If so, then the potential DR value tips the balance toward a court decision upholding TDR as a legitimate use of the police power that involves no taking of property. Thus, under this scenario, the legally required minimum DR price is that which yields the property owner a total DR value equal to the taking increment.

The definition of the taking increment is extremely imprecise because the maximum restriction value is not well defined, as noted above (Large; Sax; Bosselman, Callies, and Banta). TDR involves an element of reciprocity (DR in exchange for restrictions), and the courts have occasionally found reciprocity appealing in ruling on the taking issue (Costonis 1975). Finally, several researchers have argued strongly for a new legal-economic definition of taking under the Fifth Amendment (Bosselman, Callies, and Banta; Sax). Costonis has argued for a new power—the accommodation power—to supplement the police and eminent domain powers (1975). The accommodation power could be used by the courts when a stringent land use regulation is required for environmental protection, yet it is unfair by community standards and is a taking by legal standards. Under these circumstances, the courts or government could use the accommodation power to compensate the landowner, and the compensation would equal the taking increment defined above (Costonis 1976).[3]

The American Law Institute's model land development code also keys the award to the "minimum development necessary to eliminate the unconstitutional taking" (American Law Institute, Sec. 4-402(5)). While this accommodation power fits nicely with a TDR program, it must be emphasized that it is purely hypothetical at this time. Finally, the definition of legitimate police power exercise has been expanding recently (Bosselman, Callies, and Banta; Large). Equivalently, maximum restriction value has been declining, and TDR may freeze this evolution in the definition of property rights by guaranteeing landowners compensation for restrictions that may not require compensation in a few years' time (Barrows and Prenguber).

Alternatively, the courts may view TDR as an exercise of the power of eminent domain, requiring compensation to affected property owners.[4] It is significant that, in the only court cases to date involving TDR, the courts held that TDR was an exercise of the power of eminent domain ("The Unconstitutionality of Transferable Development Rights"). Each case involved the New York City program for landmark preservation and was unique in its specific detail and circumstances. While it is difficult to predict court decisions on TDR programs to guide land conversion on the urban fringe, the available evidence suggests that the courts may view TDR cautiously.

If TDR is an exercise of eminent domain, then the issue is whether DR constitutes just compensation, and the situation is again more complicated than Small suggests. The courts have developed a very complex set of principles for defining just compensation. One principle, as Small notes, is that the compensation must be commensurate with the dimunition in property value. However, it is misleading to argue that the definition of compensation value is "conceptually precise." In general, it is true that just compensation is defined as the difference between market value immediately prior to restriction and use value immediately after restriction. However, since the property in question has usually not been recently transferred on the market, its market value is not observed but is imputed by the courts. Estimation of market value is particularly troublesome when "market forces and public regulations are entwined" (Costonis 1975, p. 1042). The courts may (and sometimes do) take into account any existing or probable restrictions on the

[3] Costonis defines the taking increment as the difference between "reasonable beneficial use" (equivalent to our maximum restriction value) and resource protection use (equivalent to our TDR value) (1975, pp. 1049–55).

[4] It has been argued that TDR programs are likely to be classified as eminent domain because "reasonable return is often defined in terms of the return on other property similarly situated" ("The Unconstitutionality of Transferable Development Rights," p. 1107). TDR programs that allow normal agricultural activity in the preservation zone might fare better under the definition of "reasonable return" than programs for which open space is the only use of the preservation zone. Of course, if agricultural activity would meet the definition of reasonable return, then traditional zoning for the same purpose would also not involve a taking.

property, such as zoning, when determining compensable value (Costonis 1975).[5] The courts have on occasion allowed a potential market value, contingent on a zoning change and subsequent development, to be the standard for compensation in eminent domain cases (Large, Costonis 1975).

A second principle for defining just compensation, crucial for TDR, is that payment must be in money, must be unconditional, and the value of the payment must not be based on uncertain future events (Rose). The major conclusion of our analysis of the DR market in the highway interchange program was that full compensation (or some percentage of full compensation) would have required widely fluctuating DR prices.[6] Similarly, the DR market is not likely to deliver the compensation required by the courts under eminent domain or would do so only coincidentally. Significantly, in the two New York TDR court cases to date, the courts ruled that the DR distributed to restricted owners do not constitute just compensation because the value of the rights is uncertain, determined by what may be an "unpredictable market of the future" (New York Supplement, p. 765). Neither court decision held TDR unconstitutional, and each case was decided on the specific circumstances of the properties. However, it is likely that the basis of decision in these cases applies to any TDR program—that DR are not adequate as (eminent domain) compensation because the value of the rights will be determined in a market that may be unstable and which would only achieve just compensation by coincidence ("The Unconstitutionality of Transferable Development Rights"). This is also the conclusion of our economic analysis of the DR market, although our analysis was framed in terms of economic full compensation in the absence of a court decision defining just compensation in the interchange area.

Small also criticizes the method used to distribute DR and offers an alternative scheme. To date, there have been at least five different proposals for DR distribution: (*a*) proportional to acreage (Maryland Senate), (*b*) proportional to market value (Chavooshian and Norman), (*c*) proportional to assessed value (Rose), (*d*) proportional to the difference between market value and restricted value at the time the TDR program is initiated (New Jersey Assembly), and most recently (*e*) proportional to the difference between "maximum restricted value" as defined above and restricted value under TDR (Costonis 1975). We did not argue that any system was preferable but simply analyzed the two most widely suggested systems.

Thus, the acreage and assessed value systems were analyzed in our article, and it was found that there would be little difference in DR distribution between the systems. It is possible to use other systems for DR distribution, although no system is without its problems. Small defines compensable value as the difference between market value and use value at the time the TDR program is initiated. This definition may not correspond to the courts' definition, but this alternative for distributing DR is conceptually superior to some because it does recognize differences in restricted value under TDR. In the case of the highway interchange program, the distribution of DR would likely have changed little under this system because the parcels were quite uniform and had similar market and use values at the time of highway condemnation action. However, as we note, immediately after the highway is initiated, the market values would have increased, and differences among parcels may have emerged.

Finally, Small argues that TDR would not require downzoning. In theory, this is correct—TDR is conceptually complete with no mention of downzoning, and in our article we never argued that TDR always requires downzoning. However, we believe that in practice most TDR programs to control urban growth require downzoning in order to produce compensation for restricted landowners. Compensation requires a strong demand for DR (Rose, Barrows and Prenguber). Currently, many urban fringe areas are overzoned—more land is zoned for development than will ever be built up. In these areas the supply of developable land at existing allowable densities precludes strong incentives for DR purchase. Small's suggestion of upzoning would further overzone these areas and would further reduce incentives for DR purchase. If a TDR program is implemented with no downzoning (or with upzoning) in the development districts, it is quite possible that development may proceed far into the future with no DR purchase. Thus, in many areas, TDR would require downzoning to force DR purchase in order to compensate restricted landowners. Small is correct to note that downzoning worsens the position of the landowners in the development districts, and we have argued that this might result in political pressures that may lock TDR programs into existing zoning levels, with disastrous effects on the compensation provided to restricted landowners.

In summary, Small's main argument can be restated more correctly. (*a*) If TDR is viewed as an exercise of eminent domain; (*b*) if just compensation, as defined by the courts in TDR cases, turns out to be the difference between some market value of the property (as defined by the courts) and its value at the time of TDR initiation; (*c*) if DR are distributed proportionally to the difference between this market value and use value; and (*d*) if DR

[5] The courts have viewed with suspicion local governments that restrict a property through zoning and then seek to acquire the property under eminent domain and pay only the restricted value.

[6] Small notes that our definition of full compensation is unsatisfactory because it is not equivalent to the court's definition of just compensation. We also note this difficulty, and unfortunately Small's alternative definition is only accurate in eminent domain cases and then only in those in which the market value of the property is unambiguous, i.e., there is no land use change underway or planned for the near future and no zoning on other land use restrictions on the property (Roettger).

prices are stable, then there exists some DR price such that restricted landowners are justly compensated. It is not likely that assumptions (*a*) through (*c*) hold simultaneously, even more unlikely that DR prices are stable, and extremely unlikely that a stable DR price coincides with that required for the assumed level of just compensation. Thus, while the existence of some stable DR price that provides just compensation may be logically demonstrated given appropriate assumptions, the proportion is not terribly useful to economists or decision makers seeking to analyze or implement TDR policies.

Future research should analyze the likely economic consequences and incentives created by TDR and the effect of variations in administrative decisions and definitions on TDR costs and incentives. This type of research is appropriate for economists and is more useful in advancing our understanding of the economics of TDR than vague theoretical pronouncements of TDR's advantages. Significantly, the courts have not relied on arguments of the theoretical or logical consistency of TDR but have examined the issues arising from its application. Proponents of TDR would be well advised to do likewise, and economists can play a valuable role by analyzing the likely economic consequences of applying TDR to real-world situations. We believe that economists must conduct more empirical research to define and overcome the potential problems of the very promising concept of TDR. It would be tragic if TDR were discarded as a land use policy tool simply because programs were initiated without sufficient preliminary analysis to ensure success.

Books Reviewed

Aresvik, Oddvar. ***The Agricultural Development of Jordan.*** **New York, Washington, and London: Praeger Publishers, 1976, xxviii + 375 pp., price unknown.**

To paraphrase the author, this book endeavors to present a fairly complete analysis of the structure and performance of the agricultural sector in the Hashemite Kingdom of Jordan since 1946 (p. vii). The contents cover most, if not all, of the traditional subjects one might expect in this type of book. Resources of land and water (chapter 6), main crops and forest products (chapter 8), livestock, poultry, fisheries (chapter 9), the range of policy issues (research, extension, and education), marketing, credit, land tenure, and special development problems (Jordan Valley development program) are all included. Probably too much information is provided for the reader, and some judicious pruning might have ameliorated some tedious sections. As a compendium of reasonably current information reflecting, in good part, the results of a 1974 symposium in Amman on Jordan agricultural development, this book is worth reading. It is a good introduction to the major issues facing the agricultural sector in Jordan.

There are difficulties with the book. Although it is a good source of basic information on the Jordan agricultural sector, it falls far short of being a reasonably complete analysis for that sector going back almost thirty years. It makes a valiant effort for the 1957–66 time period, but the major emphasis is on 1967–73. In view of the security problems in the Jordan Valley (over 40% of the sector's output) that precluded intensive cultivation and major rehabilitation efforts until 1970–71, it is difficult to criticize the book's deficiencies in this area. An honest effort was made to review the historical record of Jordanian agriculture. Unfortunately, the data base is not adequate to the task.

The list of problem areas in Jordanian agriculture, as outlined by the author, includes almost the entire text book list assignable to low-income, subsistence agricultural economies. Aresvik does not hide any of them. He is convinced that "The main agricultural problem is how to speed up the adoption of improved technology" (p. vii). As the final end point or cumulation of a series of other activities, he is probably correct. But what is lacking in the book is some effort to establish a priority system among the numerous issues facing the Jordanian agricultural sector. Land-tenure reform would appear to be a very high priority and the author probably would agree. Without placing tenant-shareholding arrangements on some legal contractual basis and providing greater equity, how will high-yield technology be adopted in the Jordan Valley, where 59% of the agricultural holdings are rented? Fragmentation of holdings falls in a similar category. Neglect of the small farm sector as to credit, inputs, etc., is another. As noted above, the list of issues is quite comprehensive. Not all are likely to be resolved in the future even with the best political intent and the continued high level of external financial assistance. So, are the Government of Jordan's priorities, if they exist on some measurable scale, correct or do they need to be revised?

This is an optimistic book. At times the reader is somewhat uncertain as to whether the text reflects the author's views or simply an uncritical acceptance of the contents of development plans put forward by the Jordanian government. Are Farmers Associations (pp. 316–17) really the key to the success of the Jordan Valley development program? Did they exist in fact when the book was being written? If not, what is the conceptual framework for their operation? If so, one minor question not mentioned in the text is who controls the Farmers Associations? How are decisions to be made and funds collected and allocated? This reviewer would consider that to be a critical issue to the numerous small farms owner-operated and tenant-sharecropper farmers in the Jordan Valley.

To repeat an earlier contention, I suggest that this book should be read by those interested in the problems and promises of the agricultural sector in Jordan. It contains a good source of basic information. In general, the analytical portions contain sound technical judgments and competent professional viewpoints. A more critical approach as to Jordanian agricultural planning and implementation (including the Government of Jordan's investment budgets) would improve the worth of the book. It does not, unfortunately, greatly assist the reader to reach "conclusions about strategies of agricultural development of general interest for poor countries and for agencies and organizations supporting such development" (p. viii). To what extent the book might help the Government of Jordan to refine its own agricultural development strategy remains to be seen.

Emerson, M. Jarvin, and F. Charles Lamphear. ***Urban and Regional Economics: Structure and Change.*** **Boston: Allyn and Bacon, 1975, viii + 360 pp., $12.95.**

This book is intended for students who have completed only an introductory economics course and

is designed to serve as a text for an undergraduate first course in regional and urban economics. It is considerably different from the Prescott and Lewis book, which is more of a report on several regional research projects in which the authors were involved. The book by Prescott and Lewis appeals to a more advanced audience than does that by Emerson and Lamphear and might appear on the reading list for a graduate course rather than as the text for an undergraduate introductory course.

Emerson and Lamphear have written well and done an excellent job of introducing the field of regional-urban economics. The major fault, depending on the teaching philosophy of the introductory course instructor, may be that they attempted to cover too much material, thereby treating each subject only briefly. This approach is adequate for the instructor who, during lectures, substantially supplements the basic text, but the instructor who lectures straight from the text will find the treatment of each subject to be cursory.

Following a good, brief introductory chapter, chapter 2 introduces regional interindustry structures by describing the input-output technique in a very elementary fashion. Chapter 3 then uses input-output to describe how regional-urban performance can be monitored. The discussion may again be too brief, even for an introductory text.

A good basic discussion of location analysis, relating it to basic economic theory through the use of graphs, is contained in the fourth chapter. Chapter 5 extends the previous chapter through a discussion of spatial price competition, again very adequately relating the topic to basic economic theory.

In chapter 6 is a discussion of the theories of city-size distribution and the economies of central places. Chapter 7 discusses regional structures and growth including regional production functions; economic base, sector, and stages-of-growth theories; structural linkages; and shift-share and threshold analysis. These topics are well related to the previous discussion of input-output.

Chapter 8 concentrates on interregional trade through a discussion of gravity models, comparative advantage, and export-base theories, while chapter 9 discusses interregional factory flows including capital, labor, and technology.

The next two chapters present a descriptive and theoretical analysis of urban structure. The treatment is too brief for such a complex subject. The subject is poorly related to previously described location theory and interdependence analysis. The public economy of urban regions, including the theory of public goods and four forms of governmental intervention in the free-market economy, is discussed in chapter 12.

Chapters 13, 14, and 15 turn to a discussion of the functions and problems of urban governments including employment, housing, transportation, pollution, provision of services, and land use control. These chapters form a good, general discussion concentrating on externalities and the incidence of costs and benefits.

The concluding three chapters focus on both the problems of nonmetropolitan areas and experiences and prospects in new town and community development, and present a brief discussion of alternative regional and urban futures.

Heady, Earl O., and Uma K. Srivastava, eds. *Spatial Sector Programming Models in Agriculture*. Ames: Iowa State University Press, 1975, xx + 484 pp., $12.95.

Bishay's book is the third volume in a series called Studies in Development and Planning, edited among others by H. C. Bos, director for the Center for Development Planning of the Netherland School of Economics, Erasmus University, Rotterdam. The first two dealt with the problems of economic integration and price consistency in development planning, respectively. The series consists of studies employing a quantitative approach to the methods and techniques of development planning. Bishay, a staff member at the Center, sets out to show how models, mainly linear programming ones, can be used to determine the optimum patterns of agricultural production in different regions, the corresponding domestic and international trade flows, and the agricultural investment plans in different space units.

After a brief introductory chapter that alludes to the many factors—soil, climate, seasonality, technology, management, institutions of tenure, and intersectional relationships, which make agricultural development a complex process to model, chapter 2 delineates the spatial dimensions. These include differences in production opportunities, transportation costs, and differences in regional objectives and interests.

A brief discussion of the Mennes, Tinbergen, and Waardenburg model of spatial development planning is introduced to serve as a starting point for the models that follow, but this is by no means clearly done. Models are classified as short run (where a fixed supply of regional and national resources are assumed) and long run (where productive capacities are increased through investment

programs). Chapter 4 develops some of these short-run models in which net revenues with output and input prices, evaluated at world market prices, are maximized subject to regional and national resource constraints. Export limitations and domestic and transportation costs are then introduced to provide extensions to the basic model. The reader will find the numerical applications in chapter 5 particularly useful along with the interpretation of the duals or simplex multipliers, as they are called here. The long-run models developed in chapter 6 extend the activity analysis to include land reclamation, livestock production, and regional and national investment in expanding production capacities, reclaiming land, and developing livestock quality. Appropriate constraints are introduced, too, in the form of upper bounds on regional and national agricultural investment funds and livestock intensification programs. Further extensions show how to include investment levels in target years, gestation delays, regional and national mobility of resources, and domestic and international transportation costs. Numerical specifications of these long-run models are provided in chapter 7 and again prove very useful. An appendix that shows the use of the semi-input-output methods to estimate the indirect effects of investment projects and another that looks at alternative formulations in relation to decentralized planning using decomposition techniques are also provided.

The Heady and Srivastava book essentially brings under one cover the work carried on by Heady and his associates over the past two decades in developing and applying programming models to look at the problems of production and spatial allocation in U.S. agriculture. Much of this work carried out at the Center for Agricultural and Rural Development, Iowa State University, has been previously available through the various USDA and Iowa State University technical bulletins as well as through articles in this journal. Here, it has been assembled in a manner that is designed to allow a progression from a simple prototype model of regional production and distribution to models that allow for the considerable detail through the inclusion of such factors as different agricultural technologies, transportation costs, domestic and export demand relationships, various pricing and other policy alternatives, income, and the measurement of employment and environmental impacts. Although an attempt is made to allow someone who is unfamiliar with this literature to progress from simple to more complex model structures, the variety of unspecified model variations prevents the book from achieving this purpose fully in spite of considerable expository detail.

There are altogether twelve chapters in the book, each devoted to a separate study or set of studies. Chapter 1, by Alvin C. Egbert and Earl O. Heady, summarizes three studies designed to determine the optimal regional location of wheat and feedgrain production in U.S. agriculture. A number of model variations are used to analyze the problem of deficit and surplus producing areas given the quantities required for consumption on a broad regional basis. Chapter 2, by E. O. Heady and N. K. Whittlesey, summarizes a study done by them that was used to determine the efficient interregional allocation of food and fiber production in the United States. This study extends the earlier work by including more homogeneous regions (144 spatially separated producing and 31 demand regions) and transfer and transportation activities. Chapter 3, by the same authors, extends their earlier study to analyze the relative costs of a variety of simulated land retirement programs by including regional land and crop quotas in the models. This policy issue was of considerable importance in U.S. agriculture in the late sixties, when this study was carried out. Chapter 4, by E. O. Heady and M. O. Skold, is a summary of a study that uses the same basic model developed in the Heady and Whittlesey studies (chapters 2 and 3) to 'project' the interregional shifts in grain production in the United States to 1975 by specifying conditions of technological improvements and demand growth associated with an increasing population. Feed requirements for livestock production as well as growth in exports were also incorporated in these models. Chapter 5, by R. F. Brokken and E. O. Heady, goes a step further by including the livestock sectors that had been excluded from previous studies by including some twenty livestock-producing and consuming areas. The model is used to look at interregional production and flows of wheat and feedgrain products along with those of livestock products. Chapter 6, by R. K. Eyvindson, E. O. Heady, and U. K. Srivastava, removes the simplifying assumptions of a single 'representative farm' for each region used in the earlier studies by incorporating farm size and additional land quality classes. The model results allow for the distribution of production between different farm size groups that may have different production efficiencies and resource constraints. Chapter 7, by H. C. Madsen, E. O. Heady, and K. J. Nicol, uses basically the same model developed by Skold and Heady (chapter 4) to estimate the projected trade-offs between different farm policies for 1975. Three separate price levels and a set of four government programs for land retirement are analyzed, and their effect on such factors as the level of farm incomes, costs of production, treasury costs, amount and location of land retired, and regional distribution of government payments are studied. Chapter 8, by S. T. Sonka and E. O. Heady, uses the same model to measure the economic impact of several types of farm programs on incomes and employment generated in rural areas and agriculturally related industries. The secondary impacts on income and employment are measured by using an input-output model of the U.S. economy to which the linear programming results on crop production and dis-

tribution are linked through changes in final demand. Chapter 9, by E. O. Heady, H. C. Madsen, K. J. Nicol, and S. H. Hargrove, is an application of a large-scale mathematical programming model to estimate the demand for land and water used in agriculture. This water demand-allocation model incorporates all major agricultural commodities, land resources for 223 agricultural-producing regions, and water resources for 51 water supply regions in the 17 western states and 27 consumer markets. Given relative yields, technologies, production and transport costs, and water requirements, the model estimates the comparative advantage in the allocation of land and water to competing uses. Further projections are made to 2000 to analyze water needs and irrigation developments in the context of an overall land use and agricultural policy. Chapter 10, by E. O. Heady, K. J. Nicol, and H. C. Madsen, uses the same model (chapter 9) by extending it to include some environmental impacts through environmental limits on chemical fertilizers, pesticides, livestock wastes, and soil losses. Chapter 11, by H. H. Hall, E. O. Heady, A. L. Stoecker, and V. A. Sposito, is a departure from the rest of the book in that it is devoted to a quadratic programming model of U.S. agriculture. After setting out some theoretical considerations relating to the use of nonlinear models to look at 'competitive equilibrium' and 'efficiency' (a section well worth reading in and of itself), the formulation and results of a spatial quadratic programming model are presented and compared with a similar linear model (chapter 5). Chapter 12, by J. A. Fedeler, E. O. Heady, and W. W. Koo, presents a regional linear programming model used to analyze a national and interregional grain transportation and production network.

The book is accompanied by a set of microfilms that contain all the data tables relating to the various chapters. Although this no doubt saves space, it is most frustrating for someone who wishes to examine these tables in greater detail while reading the book. Without access to a microfilm projector, these cannot even be viewed.

I found Bishay's book interesting as it takes agricultural development planning as its primary focus and treats it in both its national and international setting. I had hoped that this book could serve as a suitable textbook for a graduate course on the application of programming methods to problems of agricultural development. Unfortunately, I do not believe Bishay's book can serve this purpose although it presents some interesting ways of handling some important agricultural development problems in a programming context. The main reason for this is that although the models are clearly laid out, the numerical examples provided to illustrate their use are purely hypothetical. They never really confront the real world of development in the less developed countries (LDC's)—the data problems, the complexity of farm structure, the maze of policy and other interventions, the 'realism' of the assumptions, and the validity of the results. Even informal validation that requires a common sense judgment about the 'realism' of the results is not possible with hypothetical problems. The integration of investment activities and gestation lags in the long-run models presents enormous practical difficulties that remain concealed in a hypothetical exercise. In spite of these shortcomings, which reduce the credibility of the work among practitioners, the models explored here provide very useful ways of modeling spatial agriculture development as both the dynamic element of investments and the influence of the foreign sector are treated. One would hope that more real-world applications will follow from this work.

By contrast, the Heady and Srivastava book provides examples of modeling spatial agricultural development that are wholly credible because they are geared to real-world data, policies, and problems. Any practitioner can follow the model structure, see what data were needed to make the models operational, and evaluate the results for himself. The operational models turn out to be very large in size (the linear model in chapter 9 for example includes 5,426 activities and 3,220 equations) if they are to be used effectively for policy analysis. Models incorporating national and regional investment activities and agricultural exports and import limitations could very well be two to three times as large, a problem not addressed by hypothetical exercises.

The models proposed in both these books can presumably be used for policy analysis, but they raise questions, especially about the use of such models in LDC's, that need to be addressed further.

First, there is the critical problem of model validation. Statistical inference techniques as currently conceived are woefully inadequate for the purpose of validating complex sector models of the type currently being advanced for policy use. Even though validation is a more general concept than mere statistical inference, these books fail to address the issues squarely as do most practitioners using programming methods.

Second, to be useful in the agricultural sector, where a vast variety of heterogeneous units operate, a great deal of detail has to be incorporated, which makes applicable models very large. The associated data requirements and costs especially in terms of trained manpower make their use almost prohibitive in most developing countries, where research budgets, talent, and time are severely restrictive factors. Practitioners have to bring the effective costs of these methods down before they can become competitive with other more simple techniques.

Third, they are in general normative models and as such may have limited operational value in analyzing development problems. In specifying

what "ought" to be the spatial allocation of resources they fail to focus on what resource use actually is, how it came to be that way, and who, if anyone, will reallocate resources to conform to 'optimum patterns'.

Fourth, they are too aggregative for a sector that is known for its heterogeneity of response. These models almost seem to assume a 'central planning authority' that on the basis of known resources, technology, demand structures, transportation costs, and domestic and international prices allocates these resources optimally, provided it has the power to reallocate. But reality is different. In most cases these decisions are made by private farming units, and these allocate the resources in light of their own objectives and their own constraints and in response to their perceived economic opportunities. These models tell us nothing of how these decision units behave or respond to their environments. How do farmers, especially peasants in LDC's, perceive opportunities? What constraints do they face and what objectives do they have in mind? We know so little about these essential matters. Until and unless farm-level behavior is first understood and modeled, normative national models for the spatial allocation of agricultural resources provide few operational clues to the development of the agricultural sector, especially in LDC's.

Lastly, they do not yet provide an analysis of the richness of institutional structure and its constraints that may be crucial to the proper study of this sector. Imperfections in factor markets, tenure arrangements, factor immobility, discontinuities in investment decisions, and institutional rigidity are not treated, or when treated, only trivially.

In spite of these shortcomings the use of programming models to analyze a wide variety of issues in the agricultural sector is on the increase in both developed countries and less developed countries. These books provide useful guides to many aspects of this growing practice.

News

Announcements

Nominating Committee

Kenneth R. Farrell, president of the American Agricultural Economics Association, has appointed the following persons to the nominating committee: James T. Bonnen, Michigan State University, Chairman; B. R. Eddleman, Mississippi State University; Glenn E. Heitz, Federal Land Bank of St. Louis; Darrell L. Hueth, University of Rhode Island; William T. Manley, AMA, U.S. Department of Agriculture; Richard J. McConnen, Montana State University; W. Neill Schaller, Farm Foundation; and J. B. Wycoff, Oregon State University. This committee will nominate two persons for the office of president-elect and two sets of two paired candidates for directors of the Association. Individual members of the Association should submit their suggested nominees to Jim Bonnen by 10 December 1976.

Erratum

A printer's error in "Do We Need a National Food Policy?" by H. S. Houthakker in the May 1976 issue of the *Journal* distorts the meaning of the fourth paragraph of the article. The first sentence of the fourth paragraph (p. 259) should read "It follows that the desirability of a National Widget Policy should be judged against two alternatives, one being abstention, and the other a set of contradictory measures."

ERS Bicentennial Year Lectures

Throughout 1976 the Economic Research Service has sponsored a series of Bicentennial Year Lectures to give a platform in the U.S. Department of Agriculture to some of our nation's most outstanding economists. Speakers in the first half of the year included Theodore Schultz, Irma Adelman, Charles E. Bishop, and Karl Fox. George Brandow, D. Gale Johnson, Maurice Kelso, and Earl Heady are scheduled for presentations in the fall. ERS expects to publish the lectures in single publication early next year.

AAEA Awards Program

Through its awards program the American Agricultural Economics Association recognizes professional excellence in several subfields of agricultural economics. The AAEA recognizes professional achievement at the student, the young professional, and the more experienced levels, in research, teaching, and extension activities. Sixteen awards will be presented in 1977.

The program has a rich tradition as can readily be noted by a review of the roster of award winners over the years. The AAEA believes that this tradition will be continued in the 1977 program.

The 1977 program has been organized and will be conducted by committees representing a substantial professional input of nearly 100 committee members. We hope you will submit nominations for the categories outlined in this announcement. The general awards chairman is A. Gordon Ball, College of Agriculture, University of Guelph, Guelph, Canada N1G 2W1.

Distinguished Extension Programs

The distinguished extension program awards recognize achievement of excellence in extension economics teaching programs. Two awards are offered in 1977. One award will be given to an individual with less than ten years experience in extension education, and the other award will go to an individual with ten or more years of experience in extension education.

Nomination. Nominations may be made by any member(s) of the AAEA and selection will be made from among those nominated. The nominee must have been active in extension teaching for at least one year at the time of the nomination, and the content of teaching efforts must be principally in the field of agricultural economics. Each nomination must be made by separate letter accompanied by eight copies of documentary evidence indicating nominee's name and extension title; extension program area in which teaching is conducted; identification of the clientele served; objectives of the educational program; teaching techniques, educational methods, and materials utilized; and effectiveness of the extension teaching effort in terms of clientele response and/or establishment of the utility of the extension teaching program.

Evaluation. Each nominee will be evaluated on the quality of work as indicated by the documentary evidence submitted with the nomination relative to the following characteristics: effectiveness in teaching application of economic principles and tools of analysis appropriate to the problem and audience involved; ability to conceptualize new extension educational programs and application of new teaching concepts to existing programs; effectiveness in bringing about significant behavioral change and/or understanding of clientele; and contribution to im-

proved extension teaching in agricultural economics as evidenced by participation in appropriate professional activities and organizations.

Due dates. Nominations and supporting evidence must be submitted by 1 February 1977 to the subcommittee chairman: Everett Peterson, Department of Agricultural Economics, University of Nebraska, Lincoln, Nebraska 68508. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1977.

Distinguished Undergraduate Teaching

The distinguished undergraduate teaching awards recognize and encourage meritorious performance in undergraduate teaching in agricultural economics. Two awards will be given: one for an individual with less than ten years of experience as an undergraduate teacher, and one for an individual with ten or more years of experience as an undergraduate teacher.

Nomination. Nominations may be submitted by any member(s) of AAEA. Winners will be selected based entirely on the supportive material submitted. Renominations are invited providing the supporting evidence is updated and resubmitted. Nominees must be actively engaged in teaching at a professional level during the 1976–77 school year. Nominees must have demonstrated outstanding ability as an undergraduate teacher of agricultural economics. The format of the nomination material submitted should use as primary categories the five major criteria areas listed in the evaluation criteria section that follows. Include biographical data of the nominee—name, present position, education, and number of years of university-college teaching and experience in the profession. Supporting evidence must be limited to three pages for each of the five primary categories of the nomination. No more than three letters of reference from peers and students for each of the five primary categories should be included. Adjunct material may be included as an appendage to the nomination package if desired, for example, summaries of student class evaluations for courses taught. Eight copies of each nomination package are required.

Evaluation. Five major criteria areas will be used in evaluating nominations with relative weights as follows. (*a*) Quality of teaching (45%)—ability to motivate and stimulate student to learn (20%); innovation for presentation, evaluation measurements (15%); and mastery of subject, use and application to business conditions (10%). (*b*) Academic advising, counseling, and extracurricular activities of students (20%)—advising and counseling (14%); and catalyzing extracurricular activities of students, i.e., department clubs or organizations, student council or senate, student publications, convocations, seminars, community involvement (6%). (*c*) Campus participation in instructional, course, and curricular improvement efforts (15%)—department, college, and university-wide. (*d*) Professional improvement in teaching for benefit of self and peers (15%)—published textbooks, manuals, bulletins (5%); research papers related to improved teaching (5%); and participation in professional meetings and committees related to improved teaching and student activities (5%). (*e*) Department/college/university teaching awards (5%)—student association/alumni awards.

Due dates. Nominations and supporting evidence must be sent by 1 February 1977 to the chairman of the distinguished undergraduate teaching awards subcommittee: Richard W. Schermerhorn, Department of Agricultural Economics, University of Idaho, Moscow, Idaho 83843. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1977.

Outstanding Master's Degree Program

The outstanding master's degree program awards have as their objective development of professional excellence by individuals pursuing master's degree programs in agricultural economics. Three awards are offered. A cash supplement of $250 accompanies each award.

Nomination. Any department engaged in training agricultural economists at the master's degree level may submit nominations. Entries must be submitted by the head of the department where the degree is earned. A department may submit one nomination for each fifteen master's degree candidates or fraction thereof presented to a graduate school faculty during the year. To determine the number of eligible candidates, departments should limit consideration to candidates who will receive a degree in agricultural economics and to candidates who have taken agricultural economics as a field of emphasis. Nominations should include thesis or other comparable documentation. Selection will be made from documentation approved in final form by the student's advisory committee during the calendar year 1976, provided the candidate has met all other formal requirements for the master's degree. A published thesis may be entered in both the published research and master's program classes but will be eligible for only one award. Although a published thesis is acceptable, a copy of the thesis as submitted to the graduate faculty should be sent whenever possible. Three copies of all nomination materials (i.e., thesis) are required to be sent to the committee chairman. All copies will be returned after reading by the judges.

Evaluation. Copies of evaluation criteria may be obtained from any member of the subcommittee.

Due dates. All nominations and documentation should be sent by 1 February 1977 to the chairman of the outstanding master's degree award subcommittee: Dale J. Menkhaus, Division of Agricultural Economics, University Station, P.O. Box 3354, University of Wyoming, Laramie, Wyoming 82071. Recommendations of the subcommittee will be forwarded to the general awards committee chairman by 15 May 1977.

Outstanding Doctoral Degree Program Award

The outstanding doctoral program awards are given in recognition of development of professional excellence for persons pursuing a doctoral program in agricultural economics. Three awards will be given in 1977. A cash supplement of $250 accompanies each award.

Nomination. Entries must be submitted by the head of the department where the thesis or comparable document was presented in partial fulfillment of requirements for a degree. A department may submit one nomination for each twelve doctoral candidates or fraction thereof presented in agricultural economics to a graduate school faculty during the year. To determine the number of eligible nominations, departments should limit consideration to candidates who received a degree in agricultural economics and to candidates who have taken agricultural economics as a field of emphasis. Selection will be made from theses (or comparable documents) approved in final form by the student's advisory committee during the calendar year 1976, provided the candidate has met all other formal requirements for the doctoral degree. A published thesis may be entered in both the published research and thesis categories but will be eligible for only one award. Although a published thesis is acceptable, a copy of the thesis as submitted to the graduate faculty should be sent whenever possible. Three copies of a thesis must be sent to the subcommittee chairman. All copies will be returned after they have been read by the judges.

Evaluation. Criteria for evaluation of nominations may be obtained from any member of the subcommittee.

Due dates. Nominations and supporting evidence should be sent by 1 February 1977 to the chairman of the outstanding doctoral thesis award subcommittee: Terrence F. Glover, Department of Economics, UMC 35, Utah State University, Logan, Utah 84322. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1977.

Quality of Research Discovery

This and the following three awards are given to encourage excellence in publications in all areas of agricultural economics.

Rules. There are no requirements regarding the number of authors or professional experience. Nominations may be submitted by individuals, departments, or agencies. Nine copies of each publication should be submitted, unless expense for the individual is excessive. Return of the publications is not customary but can be requested. Nominations should be submitted for only one award in either the quality of research discovery or quality of communication category for 1976.

Nomination. A maximum of two awards are given. Entries must specify that the nomination is to be judged for the quality of research discovery. Entries must have been published in 1976.

Evaluation. The research must be a significant contribution to the field of knowledge in agricultural economics. The work should demonstrate excellence in research methodology and may deal with conceptualization of researchable problems as well as empirical verification.

Due dates. Entries should be sent by 1 February 1977 to the subcommittee chairman: Irving Dubov, Department of Agricultural Economics and Rural Sociology, University of Tennessee, Knoxville, Tennessee 37901. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1977.

Quality of Communication

The rules pertaining to the award for quality of research discovery also apply to this award for quality of communication.

Nomination. A maximum of two awards will be given. Entries must specify that the entry is to be judged for its quality of communication. Entries must have been published in 1976.

Evaluation. Entries must demonstrate superior communication of concepts or knowledge in any subject matter area or professional specialization (i.e., research, teaching, or extension) in agricultural economics to a specified audience. If dealing with transmission of research findings, the publication need not contain the author's original research but should improve communication within the profession as well as between it and other professions.

Due dates. Entries should be forwarded by 1 February 1977 to the subcommittee chairman: Irving Dubov, Department of Agricultural Economics and Rural Sociology, University of Tennessee, Knoxville, Tennessee 37901. Recommendations of the committee will be forwarded to the general awards chairman by 15 May 1977.

Publication of Enduring Quality

One award is offered for a publication with a publication date during the fifteen-year period 1952–66. Entries are judged on the basis of the enduring quality of their contribution to the profession.

Eligible entries are articles in this *Journal* (during part of the period considered, the *Journal* was known as the *Journal of Farm Economics*) regardless of whether the authors are AAEA members, and also other publications by authors, one of whom was a member of the AAEA at the time of publication. Entries must be submitted by departments or other administrative units, by colleagues, or by the authors themselves. Publications receiving an award in any other category in previous years are eligible for this award.

Entries should be sent by 1 February 1977 to the subcommittee chairman: Vernon R. Eidman, Department of Agricultural Economics, University of Minnesota, Minneapolis, Minnesota 55455. Nine copies of the publication should accompany the entry. Recommendations will be forwarded to the general awards chairman by 15 May 1977.

Outstanding Journal Article

The editor and editorial council of the *Journal*, with the editor as chairman, will choose the outstanding article in the 1976 volume of the *Journal*.

AAEA Fellow

Nominations for AAEA Fellow should be sent to the secretary-treasurer, John C. Redman, University of Kentucky, Lexington, by 1 December 1976. Any living AAEA member may be nominated. Those submitting nominations should be prepared to submit upon request biographical information in support of the nominee.

General Recognition

Awards will be presented at the annual AAEA awards program during the annual meeting at San Diego, California, 31 July–3 August 1977. Winners will be identified in the annual meeting awards program brochure and in the December proceedings issue of the *Journal*.

Personnel

Agricultural Development Council

Appointments: Shao-er Ong, former council associate, Bangkok, Thailand, is with the Department of Agricultural Economics, Michigan State University, for one year; **Donald C. Taylor,** former council associate, Kuala Lumpur, Malaysia, is with the Department of Agricultural Economics, University of Wisconsin—Madison, for one year; **Keizo Tsuchiya,** formerly with the Department of Agricultural Economics, Kyushu University, Fukuoka, Japan, is a visiting professor in the Department of Economics, Thammasat University, Thailand, Oct. 1976–March 1977.

University of Arizona

Appointments: Jimmye S. Hillman, head of the department, is a member of the Technology Assessment and Pollution Control Advisory Committee of the Environmental Protection Agency; **Gerald E. Korzan,** formerly with the Ford Foundation, is a visiting professor.

University of Arkansas

Appointments: Dewitt Jones, Ph.D. University of Missouri, is an assistant professor; **Frank T. Plafcan,** M.S. University of Arkansas, and **Thomas G. Sawyer,** M.S. University of Arkansas, are county extension agents with the Cooperative Extension Service.

University of California, Berkeley

Appointment: Michael Yokell, former assistant professor, Washington State University, is a National Science Foundation energy-related postdoctoral fellow.

University of California, Davis

Appointment: B. Delworth Gardner, former head of the department, Utah State University, is a professor and the director of the Giannini Foundation of Agricultural Economics.
Leave: Harold O. Carter, professor, is on sabbatical leave at the International Institute for Applied Systems Analysis, Vienna, Austria, Sept. 1976–Aug. 1977.

Clemson University

Appointment: Dennis L. Thomas, Ph.D. Iowa State University, is an assistant professor in farm management and production economics.
Leave: James C. Hite, associate professor, is with the Office of Regulatory Economics and Policy, U.S. Department of Commerce, during 1976; **Kenneth J. Roberts,** assistant professor, is an associate program director grants management, National Sea Grants Program, Washington, until 30 June 1977.
Retirements: Lehman M. Bauknight, Jr., and **Hooper C. Spurlock** received emeritus titles as professor and associate professor, respectively, May 1976.
Honor: Lehman M. Bauknight, Jr., former professor, received the Algernon Sidney Sullivan Award for outstanding service in recognition of his contributions to undergraduate teaching.

University of Connecticut

Leave: W. Davis Folsom, Ph.D. candidate, is a visiting assistant professor at Clemson University, Marine Resources Center, Charleston, South Carolina.
Return: Raymond O. P. Farrish is back as head of the department after spending a year as visiting professor at the University of Arizona.

Cornell University

Appointment: George J. Michalopoulos, professor, Athens College of Agriculture, Greece, is a visiting fellow.
Honors: Richard D. Aplin, professor of marketing, received the Professor of Merit Award for 1976 for excellence in classroom teaching, advising, and contribution to undergraduate programs; **Joseph B. Bugliari,** professor of agriculture and business law, received a $500 Chancellor's Award of Excellence in teaching.

University of Delaware

Leave: William R. Latham, III, assistant professor, is a visiting assistant professor at Clemson University.

University of Florida

Appointments: Jong-Ying Lee is a research economist with the Florida Department of Citrus; **Kary**

Mathis is the director of the Florida Agricultural Market Research Center.
Return: James A. Niles is back from teaching at the Agribusiness Institute of the Graduate School of Business, University of Santa Clara.

University of Georgia

Appointment: William Otha Mizelle, Jr., Ph.D. Clemson University, is an extension marketing economist, stationed in Tifton.

University of Guelph

Leave: Willem van Vuuren is in Europe on a Canada Council Grant to undertake a comparative land use study for one year beginning in September.

University of Hawaii

Appointment: Bryan W. Begley is a research associate.
Leaves: Robert A. Anderson, associate professor, is on sabbatical leave at the Western Rural Development Center, Oregon State University, Aug. 1976–Jan. 1977; **Salvatore Comitini,** associate professor, is on sabbatical leave as Food and Agriculture Organization advisor to the Fisheries Development and Management Project, Government of Indonesia, through 1976; **Chennat Gopalakrishnan,** professor, is on sabbatical leave as research associate at the Institute of Marine and Coastal Studies, University of Southern California, Sept. 1976–Aug. 1977; **Perry F. Philipp,** professor, is on sabbatical leave through November.
Resignations: Bertrand Renaud, former associate agricultural economist, is with the World Bank; **J. Louis Williams,** former associate extension specialist, is at Morningside College, Sioux City, Iowa.
Retirement: Jack T. Ishida, former professor and extension specialist.

University of Illinois

Appointments: Rabel J. Burdge, is an associate professor; **Dennis M. Conley** is an assistant professor.

Iowa State University

Appointment: Ronald E. Deiter is an assistant professor in economics.

Kansas State University

Appointment: David G. Barton, former assistant professor, Cornell University, is an assistant professor of agribusiness management in economics.

Louisiana State University

Appointments: Adolpho Martinez, Ph.D. Louisiana State University, is a research associate; **Stephen D. Reiling,** Ph.D. Oregon State University, is an associate professor of rural and community development resource economics.

University of Maine

Appointments: Johannes Delphendahl, professor, is chairman of the Department of Agricultural and Resource Economics; **Kenneth E. Wing** is the dean of the College of Life Sciences and Agriculture and the director of the Experiment Station.

University of Maryland

Retirement: George Max Beal, professor of agricultural and resource economics.

Michigan State University

Appointments: Ronald Cotterill, Ph.D. University of Wisconsin, is an assistant professor in food and agriculture policy, effective 1 Jan.; **Don Mitchell,** Ph.D. Iowa State University, is an assistant professor in food and agriculture policy.
Leaves: John Allen is on sabbatical leave to work and study in Massachusetts; **Carl Eicher** is on sabbatical leave to study as a fellow at the Woodrow Wilson International Center for Scholars, Washington, for one year; **Stephen Harsh** is on sabbatical leave to study and write an undergraduate textbook.

University of Minnesota

Appointments: Nariciso R. Deomampo, chairman of the Department of Agricultural Economics, University of the Philippines, is a visiting professor, Aug. 1976–July 1977; **Donald R. Newell,** M.S. University of Minnesota, is a research specialist in applied regional economics; **Delane E. Welsch,** Ph.D. Michigan State University, is a professor in farm management.
Resignations: Surjit S. Sidhu, former assistant professor, is an economist at the International Fertilizer Development Center, Florence, Alabama; **Stephen J. Ziegler,** former research specialist, is an instructor at the Bemidji Area Vo-Tech Institute, Bemidji, Minnesota.
Retirement: Truman R. Nodland is a professor emeritus of agricultural and applied economics after thirty-nine years of service.

Mississippi State University

Appointment: W. Lanny Bateman, former assistant professor, University of Georgia, is an associate professor and associate economist in marketing.

University of Missouri

Appointment: Richard Kenneth Rudel, former associate professor, South Dakota State University, is an associate professor.

University of Nebraska

Appointment: Raymond J. Supalla, formerly at New Mexico State University, is an associate professor.

University of North Dakota

Appointment: Arlen Leholm, former research associate, North Dakota State University, is a research associate.

North Dakota State University

Return: Roger G. Johnson, professor, is back from the Agricultural Research Institute, Dublin, Ireland.

Oklahoma State University

Appointment: James E. Casey, Jr., former instructor, Texas A&M University, is an assistant professor in production economics; **John Ikerd** is an associate professor.

Pennsylvania State University

Appointments: Theodore Alter is an assistant professor in extension public finance; **Walter W. Haessel** is an associate professor of econometrics in agricultural marketing and prices; **Richard D. Rodefeld** is an assistant professor in sociology of agriculture.
Retirements: Clare A. Becker, former professor of co-op organization, has left after twenty-nine years of service; **Kenneth R. Bennett,** former professor of statistics and econometrics, has left after twenty-six years of service.

Purdue University

Appointments: Timothy Baker is in research and teaching in farm management; **James Binkley** is in research and teaching in marketing and transportation; **Joseph Donnermeyer** is in extension and research in rural sociology and community development; **Mahlong Lang** is in research and teaching in agricultural marketing.
Leave: W. David Downey is a visiting professor at the School of Business, Indiana University, Sept. 1976–Aug. 1977.
Return: Ramon B. Wilson, professor of marketing and policy.
Resignation: John F. Marten is the executive director of Top Farmers of America, Milwaukee, Wisconsin.
Honor: J. B. Kohlmeyer was awarded the honorary degree of Doctor of Agriculture, May 1976.

Southern Illinois University

Return: Vincent Cusumano, assistant professor of agricultural industries, is back from a two-year assignment at the University FAO/UNDP Project, Federal University of Santa Maria Rio Grande do Sul, Brazil.

University of Tennessee

Appointments: John M. Devine is an instructor; **Dan L. McLemore** is an associate professor; **Robert H. Orr** is an assistant professor in rural sociology.

Texas A&M University

Appointments: Ray Sammons, former assistant professor, University of Arizona, is an area-economist-management, stationed in Amarillo; **Merritt J. Taylor,** former research associate, New Mexico State University, is a lecturer in farm and ranch management.
Retirement: Harold B. Sorenson, former professor.

U.S. Department of Agriculture

Appointments: Louise Arthur is with the environmental studies staff, NRED; **Jeff V. Conopask,** Ph.D. Virginia Polytechnic Institute and State University, is with the ERS; **Tom Stucker,** formerly at the University of Illinois, is in Agricultural Policy Analysis, CED.
Appointments in EDD: Signard Nilson, Ph.D. Cornell University, is a research economist in the Manpower Studies Program Area; **J. Norman Ried,** formerly with the Illinois Legislative Intergovernmental Cooperation Commission, is a social science analyst with the State and Local Government Program Area.
Appointments in NEAD: William B. Back is a project leader for the assessment of technology in the

food and fiber systems; **Dave Watt,** Ph.D. Michigan State University, is with the Economic Projections and Analytical Systems Program Area, Michigan State University.
Reassignments: Rodney Kite, formerly with CED, is with the Forecasting Support Group, Foreign Development Division; **Theodore Moriak,** formerly with the Agricultural Policy Analysis Program Area, CED, is with the Office of Management and Finance, ERS; **Ted Thornton,** formerly at Iowa State University, is with the Technology and Innovation Program Area, NEAD.
Reassignments in CED: William D. Givan is with the Georgia State Extension Service; **Ronald A. Gustafson,** formerly in Davis, California, is in Washington.
Reassignments in NRED: Gregory Gustafson, formerly in Washington, is with the Resource Organization and Control, Corvallis, Oregon; **James Johnson,** formerly with CED, is in East Lansing, Michigan; **Duane Marquis,** formerly with Agricultural Policy Analysis Program Area, CED, is in Houston, Texas; **Norman Starler,** formerly with the State University of New York, Fredonia, is with the Environmental Studies Group.
Returns: Walter G. Heid, Jr., CED, is back after acting as a consultant under a Kansas State University-Agency for International Development contract in Ecuador; **Harold Stults,** NRED, is back after eighteen months as a natural resource planner with the Development Assistance Organization, Riyadh, Saudi Arabia.
Resignations: Robert Golden, formerly with the Forecasting Support Group, CED, is with the Commodity Futures Trading Commission, Washington; **William C. Motes,** former director, EDD, is a legislative assistant for agriculture for Senator Dick Clark and a designee to the Senate Agriculture Committee Staff.
Retirement: Kenneth E. Ogren, former agricultural attache, Foreign Agricultural Service.
Retirements in CED: Charles Nauheim; Jim Vermeer; Charles Wilmot.
Honor in NEAD: Earl Gavett was presented the USDA Superior Service Award for outstanding research leadership in energy conservation and end use in agriculture.

Utah State University

Appointment: Jay C. Andersen, professor, is head of the Department of Economics.

University of Vermont

Appointment: Neil H. Pelsue, Jr., former associate professor, University of Maine, is an associate professor.

Virginia Polytechnic Institute and State University

Appointment: Jerry W. Looney, M.S., J. D. University of Missouri, is an assistant professor.

Washington State University

Appointments: Ron Faas, formerly at Michigan State University, is an extension CRD specialist; **Scott Matulich,** formerly at University of California, Davis, and **Douglas Young,** formerly at Oregon State University, are assistant professors.
Resignation: Dirck Ditwiler is at Murdoch University, West Australia.
Honor: Wallace Rehberg received the R. M. Wade Award for Outstanding Teacher in the College of Agriculture.

University of Wisconsin

Appointments: Wilmer A. Dahl is an assistant professor in agri-business management; **William Dobson** is chairman of the department; **Albert Nyberg,** on leave from the Rockefeller Foundation, is a visiting scholar; **H. Adedunmda Oluwasanmi,** vice chancellor, University of Ile-Ife, Nigeria, is a visiting professor, March–Aug.; **Russell Parker,** on leave from the Federal Trade Commission, is a visiting professor, May 1976–Oct. 1977; **Richard N. Weigle** is on the Agriculture Committee of the U.S. Chamber of Commerce, 1976–77.
Honor: Glen Pulver was elected president of the Community Development Society, 1977–78.

Other Appointments

Amir H. Baharuddin, Ph.D. University of Missouri, is an assistant professor at the School of Comparative Social Sciences, University of Sains, Minden, Penang, Malaysia.
Siddanaic Bisaliah, Ph.D. University of Minnesota, is with the Department of Sociology and Economics, University of Agricultural Sciences, Hebbal, Bangalore, Karnataka State, India.
James Bracht, M.S. University of Missouri, is a management trainee with the First National Bank and Trust Co., Joplin, Missouri.
Noel Devisch, Ph.D. University of Missouri, is a research economist with the Ministry of Agriculture, Belgium.
Harold L. Dickherber, M.S. University of Missouri, is with the U.S. Agency for International Development, Washington.
Rachel Doyle, Ph.D. University of Arkansas, is teaching at the College of Charleston, South Carolina.
J. Michael Gorham, Ph.D. University of Wisconsin,

is with the research department of the San Francisco Federal Reserve Bank.

Leonardo Green, M.S. University of Missouri, is the head of the Division of Project Evaluation, Ministry of Agriculture, Managua, Nicaragua.

Waldo Hooker, M.S. University of Missouri, is the head of the Production Economics Division, Ministry of Agriculture, Managua, Nicaragua.

Samuel W. McClure, M.S. University of Missouri, is a credit analyst for the Bank for Cooperatives, Omaha, Nebraska.

Stephen F. Mathis, M.S. University of Missouri, is a loan supervisor at Farmland Industries, Kansas City, Missouri.

Srilaorkul Somchai, M.S. University of Missouri, is an economist with the Division of Planning, Ministry of Agriculture, Thailand.

Alberto Valdés, formerly at the Centro Internacional de Agricultura Tropical, Cali, Columbia, is a research fellow at the International Food Policy Research Institute, Washington.

Billy R. Wynn, M.S. University of Arkansas, is a trainee with Arkansas Production Credit Associations.

Obituaries

Joseph Ackerman

Joseph Ackerman, former managing director of the Farm Foundation, died 3 May 1976 in Elmhurst, Illinois. Joe was a major force in the profession of agricultural economics, domestically and internationally for over three decades. Born on 20 July 1904 in Illinois, he received a B.S. in 1929, an M.S. in 1930, and a Ph.D. in 1938 from the University of Illinois. His professional life was intimately concerned with improving the effectiveness of agricultural economics extension, research, and teaching at all levels.

He worked as a professional farm manager after completing his M.S. degree, then spent a year in 1931–32 at Harvard on a research fellowship in agricultural economics. For much of the period up to 1939 he worked in Farm Management extension at the University of Illinois.

He joined the staff of the Farm Foundation in 1939, becoming managing director in 1955. Under his leadership the Foundation played a role almost without parallel in advancing agricultural economics through sponsorship of regional committees, seminars, and studies, as well as encouragement to the professional development of younger agricultural economists.

Ackermen filled many posts, undertaking every task with characteristic enthusiasm and energy. He served the American Farm Economic Association as vice president in 1949–50 and as president in 1954–55. He was constantly at the elbow of the organization, assisting it in numerous ways.

As secretary-treasurer of the International Association of Agricultural Economists, 1955–73, he played a key role in organizing and conducting its triennial conferences and in helping to insure its continuing effectiveness. He provided leadership in revitalizing the American Country Life Association in the postwar years, serving as president of the organization in 1947 and 1948, and was also the national president of Farm House Fraternity from 1948 to 1952. He was secretary-treasurer of the American Society of Farm Management and Rural Appraisers from 1939 to 1944. He participated actively in school affairs as a board member and officer at the local, state, and national levels. He served as president of the National School Board Association from 1966–67.

Ackerman was named a fellow of the American Agricultural Economics Association in 1964. His efforts in expending leadership training opportunities for extension personnel and in strengthening extension work in agricultural economics led to recognition in 1959 by Epsilon Sigma Phi, national honorary extension fraternity, for outstanding service to extension.

He is coauthor of the books, *Town and Country Churches* and *Family Farming*, and coeditor of two books, *Family Farm Policy* and *Agrarian Reform and Moral Responsibility*.

After retirement from the Farm Foundation, he spent three years with the Ford Foundation in New Delhi, India, applying the experience he had built up in the United States. On his return from India, he served the American Agricultural Economics Association as director of the National Employment Registry for Agricultural Economists.

His death brings sorrow to his many friends in the profession.

Glenn W. Hedlund

Glenn W. "Swede" Hedlund died on 24 June 1976 at age 67 following a brief illness. He had joined the staff of the New York State College of Agriculture and Life Sciences in 1933 and was associated with Cornell until retirement in 1974 except for five years, 1941–46, when he was professor and head of the Department of Agricultural Economics and Rural Sociology at Pennsylvania State University. During sixteen of the thirty-one years that he spent on the Cornell faculty, he was head of the Department of Agricultural Economics.

Hedlund received his B.S. degree from the University of Nebraska in 1930 and his Ph.D. from Cornell University in 1936. Reared on a wheat farm in Nebraska he had a deep interest in extension education essential to the growth and development of agriculture. At Cornell his teaching responsibilities were focused on agricultural cooperatives, farm finance, and marketing.

Hedlund's positive influence on agricultural cooperatives was one of his most important professional contributions. Over four decades his leadership directed cooperatives toward improved business management and was of importance in building the strong cooperative institutions that serve the agricultural economy. Instrumental in the formation of the New York State Council of Farmer Cooperatives, he provided program leadership for the organization from its inception. He served both as secretary of the Council during most of its existence until his retirement in 1974 and as a trustee of the American Institute of Cooperation for some years.

Hedlund served mankind and Cornell in many ways, acquiring an understanding of people, situations, and conditions far beyond the Cornell community. As an agricultural economist on the faculty of the University of Nanking, China, during 1936–

37, he traveled in the Near and Far East. Over the next sixteen years, Hedlund served on various committees, engaged in studying the agriculture of Bermuda for the Bermuda Government in 1939, studying and reporting on the organization and operation of the Farm Credit System for the Farm Credit Administration in the 1940s, and acting as chairman of a group studying cooperatives in relation to the Milk Marketing Orders during 1952–53.

During the academic year 1956–57, Hedlund worked on the University of the Philippines-Cornell contract toward the rehabilitation of the College of Agriculture at Los Banos. He served as chairman of Governor Nelson Rockefeller's Committee on Milk Marketing from 1961 until 1964, when he became a consultant for the Ford Foundation relative to education for employees of cooperatives in India. His sabbatical leave in 1972 was spent lecturing, consulting for the Agricultural Development Fund of Iran, and traveling in Europe and the mid-East. In the fall of 1975, Hedlund served as a member of a five-man team requested by the government of Bangladesh to evaluate the plant protection program of that country.

In 1953, Hedlund was cited by the Farm Credit Banks of the Northeast for his "outstanding service to agriculture in the Northeast." Upon his retirement from Cornell, the cooperative organizations concerned with agriculture in New York State initiated the establishment of the "Glenn W. Hedlund Scholarship Fund" in recognition of his contributions to agriculture in the state and nation.

Hedlund is survived by his wife Helen Howard Hedlund of Ithaca, N.Y., a son James Howard, two daughters, Mrs. John (Jean) Sullivan, and Mrs. Peter (Mary Beth) Marks, and three grandchildren.

FORTHCOMING FROM CAB

A DICTIONARY OF CHINA'S RURAL ECONOMY

BY KIERAN BROADBENT

The Dictionary and Glossary is expected to list approximately 10,000 terms in Chinese script with English equivalents. The main objective, however, will be to attempt to explain current variations in theory and practice. A special feature, therefore, will be a glossary of terminology which will explain differences between: (1) capitalist and socialist terms; (2) Soviet and Chinese terms, and (3) Chinese specific phraseology. A structured English/Chinese index will be included. The dictionary and glossary is expected to have a wide appeal not only to agricultural economists and rural sociologists interested in Chinese development, but also to government and international agencies as well as those working in certain cross-disciplinary subjects such as development studies, statistics, social anthropology and geography.

Trimmed size 246 × 189 mm

Details and orders to: CAB Central Sales, Farnham House, Farnham Royal, Slough, Bucks. SL2 3BN, U.K.

Price to be announced.

- AS PROFESSIONAL REFERENCES
- AS CLASSROOM TEXTS

Cooperative Business Enterprise
Martin A. Abrahamsen, University of Maryland

Reflecting the author's years of practical experience, this book covers all cooperatives but emphasizes the agricultural cooperative. It offers a critical evaluation of cooperative principles and practices and discusses the impact of government policy on cooperatives. Also included: strategies for growth, future opportunities, patronage refunds and retains, cooperative bargaining and pooling, and income tax treatment. Each chapter includes a summary, questions, and suggested readings. Available now, 528 pages, $15.00.

Food Policy for America
Harold G. Halcrow, University of Illinois, Urbana-Champaign

Offering a comprehensive yet specific analysis of food policy for the United States, this book outlines the costs and benefits associated with various food policies. Emphasis is on choices to be made in the future in regard to food pricing and trade, farmland use and development, national credit programs, taxation, farm labor, rural development, and nutrition policy. Chapter summaries, suggested readings, questions, and a bibliography are provided. Available January, 1977, 480 pages, $19.50 (tentative).

Market and Price Analysis
Dale C. Dahl and Jerome W. Hammond, both of the University of Minnesota

A comprehensive, analytic treatment of agricultural price analysis, marketing, and distribution. The authors concentrate on fundamental economic structures and methods of analysis, covering the entire web of interrelated industries that make up the food and fiber sector of the economy. Topics include analytic tools; the principles on consumption, demand, and supply; market information and market and price policy; and economic development. Available January, 1977, 448 pages, $13.95 (tentative).

ECONOMICS OF THE PRODUCT MARKETS OF AGRICULTURE

Harold F. Breimyer

Advanced agricultural economics with an emphasis on marketing is the general theme of this text. Breimyer offers students and researchers an accurate and nontraditional treatment of the subject. He dispenses with formal mathematical analysis or model building in his account of the economic forces at work in agriculture. Important points covered include: the sharp structural differences between the initial assembly markets for farmers' products and the giant merchandising systems, the efforts being made by farmers' organizations and in government policy to defend traditional markets or develop satisfactory replacements, and the dominant and distinctive role of multiproduct firms in processing and retailing.

1976. 210 pp., ill. $11.95. Order No. 1840–0

MARKETING FARM PRODUCTS–ECONOMIC ANALYSIS

Sixth Edition

Geoffrey S. Shepherd, Gene A. Futrell, and J. Robert Strain

The analytical approach to farm products has made this a successful text for many years. This new edition presents a theoretical framework for analyzing marketing farm products and applies the analytical approach to current agricultural marketing problems. The last half of the book prescribes solutions for marketing problems for each of the major farm products. The sixth edition features two new chapters on dairy marketing. Chapters on livestock, poultry, and grain marketing and seasonal price movements are extensively revised. Text, tables, and charts throughout the book have been updated. This is a proven text for undergraduate classes in agricultural marketing, applying economic theory to the solution of practical marketing situations.

1976. 485 pp., ill. $15.95 (tentative). Order No. 1080–9.

AGRICULTURAL DECISION ANALYSIS

Jock R. Anderson, John L. Dillon, and J. Brian Hardaker

An extensive study of decision analysis in agricultural management. Detailed coverage of farm and business decision making under risk, assessment of individual attitudes to risk, and the role of subjective probability judgments in making agricultural choices. Modern decision procedures are skillfully applied in introductory and advanced discussions of agricultural management. Excellent compilation of theories and references relating to decision analysis.

1976. 500 pp., ill. $25.00 (tentative). Order No. 0400–0.

A SURVEY OF AGRICULTURAL ECONOMICS LITERATURE

Volume 1, Traditional Fields of Agricultural Economics, 1940s to 1970s

edited by Lee R. Martin, Professor of Agricultural and Applied Economics, University of Minnesota

This is the first volume of a comprehensive three-volume survey of agricultural economics literature since World War II. This volume contains surveys of the literature in seven broad areas, prepared by ten outstanding authorities.

Subjects and authors of the reviews in Volume I:

Farm Management and Production Economics, 1946-1970. Harald R. Jensen, University of Minnesota.

The Analysis of Productive Efficiency in Agricultural Marketing: Models, Methods, and Progress. Ben C. French, University of California, Davis.

Policy for Commercial Agriculture, 1945-71. George E. Brandow, Pennsylvania State University.

Postwar Policies Relating to Trade in Agricultural Products. D. Gale Johnson, University of Chicago.

Agricultural Price Analysis and Outlook. William G. Tomek and Kenneth L. Robinson, both of Cornell University.

Agricultural Finance and Capital Markets. John R. Brake, Michigan State University, and Emanuel Melichar, Division of Research and Statistics, Board of Governors of the Federal Reserve System, Washington, D. C.

Technical Change in Agriculture. Willis Peterson, University of Minnesota, and Yujiro Hayami, International Rice Research Institute, Manila, Philippines.

Published for the American Agricultural Economics Association by the University of Minnesota Press.

The regular price of Volume 1 is $25.00. Members of the American Agricultural Economics Association may order copies at a special price of $18.00 ($20.00 outside the U.S.), postpaid. This special price offer is available to AAEA members for one year following publication of the book. Send your order now, using the order form below. Books will be shipped when ready.

Office use, leftover, inventory balance, etc.	(*a*) 1,482	(*b*) 1,482
Total	(*a*) 7,000	(*b*) 7,000

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Review by colleagues.** Authors are strongly urged to have their manuscripts critically reviewed by their colleagues prior to submission.
12. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
13. **Page Charge.** All published contributions, with certain specific exemptions, are subject to a charge of $40 per printed page or fraction thereof. Exemptions are granted for book reviews, papers invited by the editor, the presidential address, the fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. Authors who certify in writing that no financial support exists from an employer or granting agency to cover the page charge also will receive an exemption. Payment information and details on the financial exemption statement are provided with galley proofs. One hundred reprints (without covers) are provided if the charge is honored.

American Agricultural Economics Association

15 JUL 1977

President /Kenneth R. Farrell, Economic Research Service
President-Elect /R. James Hildreth, Farm Foundation
Secretary-Treasurer /John C. Redman, University of Kentucky
Past-President /James T. Bonnen, Michigan State University

Directors

Wallace Barr, Ohio State University
Richard T. Crowder, Pillsbury Co.
Sylvia Lane, University of California, Davis
Fred A. Mangum, North Carolina State University
Philip M. Raup, University of Minnesota
B. F. Stanton, Cornell University

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal,* changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices.

Copyright © 1976 by the American Agricultural Economics Association.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except that concerning "Books Reviewed" and "Books Received," should be addressed to the editor, William G. Tomek, Department of Agricultural Economics, Cornell University, Ithaca, New York 14853.

Communications concerning books for review and books submitted for announcement in the *Journal* should be sent to the book review editor, Francis E. Walker, Department of Agricultural Economics and Rural Sociology, Ohio State University, Columbus, Ohio 43210.

Emery N. Castle

1976 Fellow

Senior Vice President and Fellow of Resources for the Future, Inc.
Dean of the Graduate School, Oregon State University, 1972–75.
Distinguished Professor Award, Oregon State University, 1970.
President, American Agricultural Economics Association, 1972–73.
AAEA awards for excellence in published research, 1972 and 1973.
President, Western Farm Economics Association, 1962–63.

Emery N. Castle has achieved recognition from colleagues for his teaching, research, administration, public service activities, and for his leadership in natural resource economics and farm management. To those who have been privileged to be closely associated with him, his distinction lies not in what he has achieved as conventionally measured but in what he is—a man infinitely concerned with the intellectual and personal development of those with whom he works.

Born in Kansas in 1923, he completed a B.S. and an M.S. in agricultural economics at Kansas State University and a Ph.D. degree at Iowa State University (1952). He served for two years as an agricultural economist with the Federal Reserve Bank of Kansas City. In 1954, he joined the agricultural economics faculty at Oregon State University, where he distinguished himself as teacher, researcher, administrator, and public servant. While there Castle served first as dean of faculty, then as head of the Department of Agricultural Economics, and finally as dean of the Graduate School. He also was a member of the Presidential Committee on University Goals and served for a decade on the State Water Resources Board of Oregon and its successor agency, the Water Policy Review Board of Oregon. He and his associates in the Department of Agricultural and Resource Economics pioneered investigations, often with other disciplines, in environmental quality, marine resources, and outdoor recreation.

Emery Castle served his profession well and often, acting as president of the Western Farm Economics Association, vice-president and later president of the American Agricultural Economics Association, and serving on the editorial board of *Land Economics*. He was

the first chairman of the AAEA consolidated awards program and served for three years in that capacity. The excellence of his contributions was recognized through awards such as Oregon State University's Distinguished Professor Award, the AAEA's Award for Excellence in Published Research, and Kansas State University's Distinguished Service Award in Agriculture.

Since January 1976, Castle has been vice-president and senior fellow of Resources for the Future. In this capacity, he continues his dedicated service to individuals, the profession, and as a leader in agricultural and natural resource economics.

Arthur T. Mosher

1976 Fellow

President, Agricultural Development Council, 1967–73.
Member of the Consultative Group on International Agricultural Research, Advisory Panel on the Future of the International Agricultural Institutes.
Visiting Professor, University of Chicago, 1953–55, and Cornell University, 1955–57.
Author, *Technical Cooperation in Latin American Agriculture*, *Getting Agriculture Moving*, *To Create a Modern Agriculture*, and *Serving Agriculture as an Administrator*.

Arthur T. Mosher is one of the agricultural economics profession's pioneers in international economic development. He entered this arena forty-three years ago when few American agricultural economists were concerned with the developing world and has devoted most of his professional career to service in the field of international development, playing a major role in institutionalizing an international development dimension in the education of agricultural economists and other rural social scientists, both in the United States and abroad.

Mosher was born in Iowa in 1910, receiving his B.S. in general agriculture and his M.S. in agricultural economics (1941) from the University of Illinois and his Ph.D. in economics from the University of Chicago (1946).

He joined the staff of Allahabad Agricultural Institute in India as an instructor in agricultural engineering in 1933. In 1938–39, he lived with his wife and son in an Indian village, renting an eight-acre farm and farming it by prevailing village methods to gain experience in Indian agriculture. After finishing his graduate studies in economics, he designed and managed a three-year experimental program covering 400 villages to test extension methods and materials. His attention was directed to the agricultural development problems of Latin America while serving as a visiting research professor at the University of Chicago (1953–55).

Mosher has been with the Agricultural Development Council since 1957, serving as president from 1967 to 1973. Under his leadership, the Council has had a key role in supporting advanced education of rural social scientists from Asia and in strengthening professional relationships between rural social scientists in the developed and developing countries.

While his writings are directed primarily to

development practitioners, his publications have exerted a deep impact on both thought and practice in the field of agricultural development. His book, *Technical Cooperation in Latin American Agriculture;* monographs, *Getting Agriculture Moving, Creating a Progressive Rural Structure, To Create a Modern Agriculture, Serving Agriculture as an Administrator,* and bulletin, *Varieties of Extension Education and Community Development,* are included among his major publications.

This servant of international agriculture has found time to act as visiting professor of comparative extension education at Cornell University, panel member on world food supply for the President's Science Advisory Council, member of the Research Advisory Committee for the Agency for International Development, and member of the Consultative Group on International Agricultural Research, Advisory Panel on the Future of the International Agricultural Institutes. He continues to serve with the Agricultural Development Council in Asia where he began his distinguished career.

Willard F. Mueller

1976 Fellow

William F. Vilas Research Professor of Agricultural Economics, professor of economics, professor in the Law School, University of Wisconsin, 1969–present.
Chairman, Department of Agricultural Economics, University of Wisconsin, 1970–72.
Executive Director, President's Cabinet Committee on Price Stability, 1968–69.
Chief Economist and Director, Bureau of Economics, Federal Trade Commission, 1961–68.
Chief Economist, Select Committee on Small Business, House of Representatives, U.S. Congress, 1961.
President, Association for Evolutionary Economics, 1974.

Willard F. Mueller has achieved an international reputation as teacher, researcher, economic advisor, and public policy administrator. He has the unique ability to identify emerging problems and to incorporate successfully economic knowledge into workable public policies. While serving as chief economist of the Federal Trade Commission, he contributed to such innovative policies as developing merger guidelines in several food and other industries, creating the FTC's premerger notification program, and implementing affirmative disclosure requirements in advertising. His fierce intellectual independence coupled with an outstanding sense of fair play have created an ever widening demand for his counsel among public policy makers in agriculture, consumer affairs, business, the state government of Wisconsin, Congress, and the Executive Office of the President. Friends and adversaries agree that Mueller is unintimidated by special interests, unafraid of controversial issues, and dedicated to making the American economic system perform justly as well as efficiently.

Mueller's academic writings of 1959–61 and his collaborative work with colleagues and fellow researchers from the North Central region led to the subsequent adoption by agricultural economists of industrial organization theory as a framework for research. As chairman of the North Central Regional Research Committee, Organization and Control of the U.S. Food Production and Distribution System, he and his colleagues developed a highly innovative approach to regional research that has received wide support from state experiment stations, the U.S. Department of Agriculture, and congressional committees.

Born on a farm in western Minnesota, Mueller served in the Navy in World War II, received a B.S. in economics (1950) and an M.S. in agricultural economics (1951) from the University of Wisconsin, and a Ph.D. in economics from Vanderbilt University (1955). In addition to teaching at the University of

California, Davis, and the University of Wisconsin, Mueller has taught at the American University, University of Maryland, and as a visiting professor at Michigan State University. During 1958–59 he was associate editor of the *Journal of Farm Economics* and currently is on the editorial advisory board of the *Industrial Organization Review*. In 1973 he was vice-president and in 1974 president of the Association for Evolutionary Economics, an association of institutionalist-oriented economists.

Since returning to Wisconsin in 1969, Mueller has taught in the departments of agricultural economics and economics, as well as in the Law School. He has an ambitious research program with a large number of outstanding graduate students. In addition to numerous professional articles and several books, he includes among his most recent publications two extensive research monographs on multinational corporations prepared with his students for the Subcommittee on Multinational Corporations of the Foreign Relations Committee, U.S. Senate.

Mueller is also active in community affairs, particularly in working to enhance the opportunities of mentally retarded citizens.

Kenneth R. Farrell

1976–77 President

Deputy Administrator, Economic Research Service, U.S. Department of Agriculture, Washington, D.C., 1971–present.
Associate Director and Economist, Giannini Foundation of Agricultural Economics, University of California, Berkeley, 1969–71.
Director, American Agricultural Economics Association, 1972–74.
Member, International Association of Agricultural Economists; American Agricultural Economics Association; American Economic Association; American Association for Advancement of Science.

Kenneth R. Farrell was born in a rural community near Ottawa, Canada. As an undergraduate majoring in agricultural economics at the Ontario Agricultural College, Guelph, he was a member of several varsity sport teams and public speaking and debating teams of the College, receiving a B.S.A. with honors in 1950.

Following graduation, he spent two years in North Dakota as an agricultural instructor in a veteran's rehabilitation program. In 1953 he entered Iowa State University, Ames, where he received an M.S. and a Ph.D. in agricultural economics.

Farrell joined the staff of the Giannini Foundation of Agricultural Economics, Agricultural Extension Service, and the Department of Agricultural Economics, University of California, Berkeley in 1957, serving in various administrative, research, resident instruction, and extension posts including those of assistant director, Agricultural Extension Service; special assistant to the Dean of Agriculture; and associate director, Giannini Foundation. He was Fulbright Lecturer in Agricultural Economics at the University of Naples, Italy. The next four years were spent on leave from the University, first to the National Commission on Food Marketing to conduct a study of agricultural marketing order and agreement programs and then to the Economic Research Service, U.S. Department of Agriculture, where he served as director of the Marketing Economics Division and later as assistant administrator and chairman of the Outlook and Situation Board.

An author of numerous publications primarily in the fields of marketing, policy, and trade, Farrell has served as consultant to public and private organizations in the United States and

abroad. In addition to his present duties, he is the chairman of the Social and Behavioral Sciences Committee, USDA Graduate School; cochairman of the North Central Research Planning Committee; and chairman of the U.S.-Spain Project in Agricultural Economics, NSF-USDA. He has been active in the AAEA throughout his career, serving on various committees, the Editorial Council, and on the Executive Board as director and president-elect.

He, his wife Mary, and their youngest child reside in Reston, Virginia. He is an ardent gardener and golfer. He and his wife are active in local community affairs, church, and social action organizations.

Public Policy, The Public Interest, and Agricultural Economics

Kenneth R. Farrell

This is a particularly appropriate year for review of agricultural economics in relation to public policy. The quadrennial presidential election heightens our perceptions of major national public policy issues and the governmental process. It is a year of economic recovery and comparative stability, affording an opportunity to reflect upon the turbulent events of the past four years and longer-term economic and food policy issues. It is a year that foreshadows public debate on new farm commodity price legislation.

It also is a year of two bicentennials—the Declaration of Independence and the publication of the *Wealth of Nations*. The Declaration of Independence and the Bill of Rights set forth egalitarian social and political goals based upon principles of individual freedom, human dignity, and equality. Throughout the evolution of our society, from Jefferson's agrarian democracy to our current complex, industrial democracy, those principles have continued to influence pervasively the nature of national public goals and policies.

Smith's treatise expounded a self-regulating, open market economy in which social welfare was maximized by individual pursuit of economic self-interest. That treatise, later elaborated as a theory of perfect competition, provided a philosophic foundation for our capitalist market economy. It, too, has left a large imprint on national goals and policies.

But as we sometimes overlook, the *Wealth of Nations* was not written in the vein of narrow economic determinism. It was written in the tradition of political economy, incorporating philosophical and moral values compatible in many respects with the principles of our Declaration of Independence. That balance between philosophical and moral values that attain political status on the one hand and outcomes of a market economy on the other is at the heart of major public policy issues of our times. The late Kermit Gordon phrased the issue as follows: "Contemporary American society is, in a sense, a split-level structure. Its political and social institutions provide universally distributed rights and privileges that proclaim the equality of all citizens. But its economic institutions rely on market-determined incomes that generate substantial disparities among citizens in living standards and material welfare. . . . The resulting mixture of equal rights and unequal incomes creates tensions between the political principles of democracy and the economic principles of capitalism" (Okun, p. vii). Therein is the genesis of the increasing involvement of government in our society and the root of major public policy issues of the future, including many of those related to food and agriculture.

The theme of this address is normative and prescriptive. Stated simply, it is that the complexities and interdependencies of our society require of agricultural economists a more holistic, integral view of agriculture and public policies than is evident in our current agenda. We should broaden our professional perspectives, cultivate new clientele and professional alliances, recast and reorder our agenda, and experiment with modified and new institutional arrangements. In so doing we could better address emerging public policy issues and better serve the public interest concerning food and agriculture.

Beginning with an overview of the setting

Presidential address.

Kenneth R. Farrell is deputy administrator, Economic Research Service, U.S. Department of Agriculture.

The insightful, penetrating comments of James T. Bonnen and Harold F. Breimyer are acknowledged appreciatively. Other helpful comments on early versions of the paper were received from numerous readers in the U.S. Department of Agriculture, several land grant universities, and the Farm Foundation. The author is indebted to Geneva A. Riddle for her patience, dedication, and skill in typing numerous drafts.

for national public policy and some major national policy issues derived therefrom, I then review our past performance in policy analysis and conclude with a series of recommendations concerning reorientation of our agenda including supportive actions by the AAEA and the creation of a new public policy institute.

The Policy Setting

The most basic feature of the current policy setting is agriculture's growing social, economic, and political interdependence. Whatever insularity there once was in the sector is giving way inexorably to the pervasive integrating effects of extended markets and communities. The economics and politics of food and agriculture are no longer just those of the "farm bloc" or the agricultural establishment but also those of many diverse groups who lay joint, competitive claims upon resources used by agriculture or are impacted by economic performance of the food and agriculture complex. Our international interdependence includes but extends beyond immediate commerce to foreign economic development and food and technical assistance and comes wrapped in altruistic and moral as well as pecuniary and acquisitive terms.

In brief, U.S. agriculture and its role in world affairs has been transformed radically and irreversibly. The upshot of these circumstances, rooted deeply in the processes of economic development, changes in human aspirations and social goals, and new political realities, is to make it increasingly difficult—if not impossible—to analyze and understand agriculture and related public policies except as an integral part of national and world economic, social, and political systems.

An outgrowth of this increasing interdependence is heightened conflict between traditional agricultural and other interest groups in the affairs of food and agriculture. Examples abound: the clash between agricultural and environmental protection interests, between agricultural and urban interests in development and use of water and energy resources, the enactment of stringent standards related to food quality and safety, and export embargoes of agricultural commodities to control domestic food prices. Although we continue to rely principally upon market mechanisms to resolve such conflicts, at the same time we involve the government to alter outcomes or remedy deficiencies of the market. At the very heart of these issues are the economic questions: Who gains and who loses from government involvement in our economic system? What is the net benefit to society of that involvement? If there are positive net benefits, can losers be compensated such that benefits are not offset? What are appropriate measures of economic gains and losses and in what time frame?

These heightened conflicts are not transitory. They seem likely to broaden and intensify as policy trade-offs become more sharply defined in a context in which our capacity for economic growth at rates of recent decades, or even its desirability, is in question.

Schuh suggests that "the basic change in conditions of supply (of food) for the future involves a shift from factor supply conditions for primary inputs that are relatively elastic to a world of rising supply price for these inputs due to the need to bid them away from the nonfarm sector" (p. 5). Others find evidence of declining total factor productivity in farming and express concern about agriculture's future capacity to increase output without much higher real commodity and food prices than experienced in recent decades. With respect to energy sources and costs, we sit on a veritable "time-bomb" procrastinating in the development of realistic policies while growing steadily more dependent upon foreign energy sources. Yet almost any policy initiative involving the development of indigenous fossil fuel sources is likely to bring the interests of agriculture, rural communities, environmental interests, and energy-producing industries into sharp conflict.

The recent return to production of nearly 40 million acres of cropland held in reserve by government, the high cost of bringing additional land into production, the annual disappearance of 25,000 acres of cropland to sprawling urban development and other uses are bringing us gradually to the realization of the need for socially and economically rational long-term land use policies. Here, the interests of agriculture, rural and urban communities, environmentalists, and land developers seem certain to escalate in conflict.

With the trend of population growth having turned toward rural and small town areas since 1973 (Beale), the reliance of persons on 1.8 million farms for more than half their incomes from nonfarm employment, and a near equilibrium in the agricultural labor force (Schuh),

rural development has become a de facto part of overall national economic development.

Structural changes in the food and agriculture complex and the very uneven distribution of economic power within the complex pose other basic policy issues. Continued concentration in food marketing in farming and input supply industries gives rise to a series of fundamental policy issues involving tradeoffs between equity and efficiency. If, as recent projections suggest, 13% of all farms will control 70% of farm output by 1985, the very premise of traditional price and income guarantees and a wide array of other public programs predicated on the model of a purely competitive industry soon will be in question.

But the conflicts and necessities of public choice concerning food and agriculture can by no means be considered adequately within national economic, social, and political boundaries. We are inextricably involved in the fundamental problem of providing adequate diets for the burgeoning world population. Some agricultural economists believe that events in world food markets during the past four years were transitory, an aberration of the long-term condition of large supplies of commodities relative to effective market demand. They await return of surpluses and reincarnation of federal government supply management programs. Two generations of agricultural economists reared on the economics of surpluses, government-supply management programs, low commodity prices, and depressed farm incomes do not easily change their hypotheses and mind-sets.

Other economists believe that in the absence of serious economic dislocations, world demand for agricultural commodities will grow comparatively rapidly. They base their conclusions on the broad forces of population growth, rising affluence, consumer aspirations for, and political commitments to improved diets. The result would be relatively high levels of real farm product prices and incomes. Parenthetically, this outcome would present policy problems less familiar but no less perplexing to contemporary economists than the first one.

Even if "optimistic" projections were to be realized, they could hardly be termed favorable for many millions of persons in regions where food deficits seem likely to grow even as world food production increases. A recent analysis projects a total annual cereal deficit of about 100 million tons in developing market economies by 1985 compared with 45 million tons in 1974–75 and 28 million tons in the relatively good production period 1969–71 (Int. Food Policy Research Institute).

The starkness of such projections clearly poses fundamental economic and food policy issues for the developing market economy countries. For example, how do they acquire capital for agricultural development, and what policies are appropriate to induce increased food production while maintaining political stability and economic growth?

For the United States the issues are also numerous and important—issues that could well be exacerbated by instability in food production and political decisions in the centrally planned countries. Foremost in the immediate future may be the issue of the level and management of food reserves, nationally and internationally, to cope with short-term instability in production. But more generally, what type and mix of policies related to domestic agriculture, foreign trade, food aid, technical, and economic assistance should be pursued in the United States? What are the economic tradeoffs among related policy goals and instruments?

On the political side, any policy proposal centered on food and agriculture, even narrowly centered, must now run a broad gauntlet of special interests in the increasingly pluralistic, diffused national policy-making process. For example, in the 1975 hearings on a bill that would have adjusted target, loan, and purchase levels for major crops and the price support level for milk, testimony was submitted by representatives of ninety-two organizations ranging from the U.S. Labor Party to the American Beekeeping Association (Spitze).

Also to be reckoned with in the enactment of legislation is a multiplicity of institutions, new and old, in the legislative and executive branches and shifting balances of political power that condition the policy setting and the tone and scope of policy debate. Recent action in the executive branch consolidates food and agricultural policy review and formulation and restores an interdepartmental leadership role to the secretary of agriculture. Nevertheless, viewpoints and influence on policy issues continue to come from diverse quarters including the Departments of State, Treasury, and Commerce, the Office of Management and Budget, the Council of Economic Advisers, and a variety of other White House-created offices. Trade-offs among conflicting national

goals and perceived constituent and bureaucratic goals abound and manifest themselves in sometimes mysterious ways in the policy-making process. Clearly, agricultural policy is not being left to the agriculturists. In Paarlberg's terminology "the agricultural establishment has, in large measure, lost control of the farm policy agenda" (p. 96).

This overview of the policy setting implies that food and agricultural policy must be viewed in a much larger, more complex social, economic, and political matrix than was so even a few years ago. Even debate on new commodity price legislation in 1977 seems likely to go beyond the traditional agenda to include assessment of the relative merits of the proposed policy instruments within overall government spending ceilings: their impacts upon and distribution of benefits within and between commodity subsectors; the level and stability of food prices; the welfare of low-income consumers; their consistency with foreign trade, foreign aid, environmental quality, and nutrition goals.

Some observers of the policy scene suggest that not agricultural policy but food policy will be enacted henceforth. They use the term food policy to convey the need for a comprehensive, integrated set of national policies centered on food. Incorporated would be traditional agricultural price and income policy with elements of other national policies—foreign trade and aid, nutrition, environmental protection, and overall national economic policies, for example. Although it might be questioned where the boundaries of a comprehensive food policy could be logically and usefully drawn, we appear in some respects to be moving toward such a policy in an incremental, ad hoc, unplanned, even unconscious way. Elements of such a policy appear in the omnibus economic planning bill, the so-called Humphrey-Hawkins bill, and in the National Food Policy Act of 1976. Although neither bill seems likely to be enacted in the near future, they may well be precursors of the scope and setting of future policy debates involving food and agriculture.

Our Performance in Policy Analysis

Judgments of the performance of agricultural economists in policy analysis vary widely. In the spirit that constructive criticism can be salutary, the following observations are offered.

Output of the profession gives evidence of declining emphasis and effectiveness in dealing with policy issues faced by policy makers. In the formative years of the profession policy analysis was central to our activities. Much of the research of the period 1930–60 focused upon major commercial agricultural policy issues of that time and, in the early part of that era, dealt with creation of institutions to cope with those issues. Ideas and individuals moved freely between the colleges of agriculture, the U.S. Department of Agriculture (USDA), and policy-making forums. Brandow's agricultural policy review gives impressive evidence of the vitality and richness that once characterized commercial agricultural policy analysis.

But more recently the sense of excitement and involvement in those policy issues has wavered and waned. Ideas and individuals now seem to move less freely between Washington and other locations or even within Washington. To be sure, there is still some highly useful and timely policy analysis, a part of which never appears in professional outlets. But many of our analyses do not focus upon major policy issues of the type previously outlined. On very narrowly drawn issues, particularly those involving small incremental changes in commodity price programs, agricultural economists do quite well. But fewer and fewer policy issues can be bounded so narrowly. When we do address the big, complex, and controversial long-term issues—and that is not often—we do much less well. It is ironic, perhaps symptomatic, that this should be so at the very time our technical capacity to quantify economic relationships and handle large numbers of variables and masses of data has grown enormously.

Policy analysis is an integrative and adaptive process with respect to available knowledge and data, "a science of muddling through" (Lindblom). Thus, its quality is dependent upon the current stock of "research capital." Here, too, there has been deterioration. Too frequently we are forced to rely upon outdated estimates of important functional relationships and to find the results of past, more specialized research nonadditive in context of the policy issue at hand.

We are handicapped by inadequate knowledge of linkages between environmental quality and food production, of impacts of a host of institutional factors on foreign demand for U.S. commodities, and of linkages between macroeconomic variables such as employ-

ment, income, and domestic food demand. The currency and reliability of estimates of commodity supply, demand, and price relationships are in question. Coupled with obsolescent data systems (Bonnen 1975) and possible structural shifts in key economic relationships, even our preparedness for addressing conventional policy issues must be questioned.

Our analyses suffer from being excessively partial and insular. In an interdependent economic system in which horizontal, vertical, and feedback linkages abound, both conceptual and empirical models suggest commodity, functional, and sectoral independence. A great deficiency in recent years has been our failure to link foreign trade and domestic economic relationships to reflect their jointly determined nature. Linkage of the livestock and feed subsectors in the domestic economy needs strengthening. Despite large investments over the past thirty years under the Research and Marketing Act, we still have only very crude models linking the farm, input, and product markets. We have inadequate descriptors of the total food sector, its capacity, efficiency, and performance—only a set of fragmentary rough indicators predicated in part upon agriculture of the distant past. The subsector, systemwide, and worldwide models for policy purposes are generally inadequate (Fox, Johnson).

Policy-oriented research also is partial in the sense that many analyses stop short of tracing out full impacts of policy instruments. Too frequently analysis is limited to aggregate impacts on the farm sector, overlooking differential impacts among regions and upon the distribution of incomes within the sector and impacts upon consumers, government expenditures, and environmental quality. This condition limits our credibility and relevance for these are the interfaces at which crucial policy debate and trade-offs are occurring.

In part because of a fixation with neoclassical models of perfect competition, agricultural economists have embarrassingly little to offer on public policy issues centered on concentration of economic power in the food complex and in international trade. We seem more inclined to describe and document the past than to analyze the causes of changes and the full implications of current alternative market structures. We know much less than we should concerning the impacts of a plethora of government statutes and administrative procedures upon market structure, behavior, and performance, nationally and internationally. There is a paucity of research concerning international commodity agreements, marketing boards, and state trading devices. Despite their massive dimensions, little is known about the impacts of domestic food aid programs upon demand for food or the welfare of consumers.

Finally, we circumscribe ourselves too severely by our emphasis on production agriculture. At one time it was clear that public policies in the immediate economic interest of farmers were broadly consistent with the public interest in food and agriculture. The "farm problem," rooted in excess resources and chronically low personal incomes, was accepted as a national social and economic problem.

But today with improved personal incomes in agriculture, widening competition for resources between the farm and nonfarm sectors, and mounting public concern with externalities of farm production technology, that identity is much less clear and certain. To be sure, the maintenance of an efficient, productive agriculture is still in the public interest, however defined. But many other competing interests must be balanced against the economic interests of agriculture. Both because we purport to be social scientists and because of our public funding, we are obliged to include those interests on our research agenda and in policy analysis.

Further, I am convinced that the economics of agriculture cannot be analyzed and understood by looking only at agriculture. Our "charter" does not preclude us from beginning our inquiries well beyond the institutions of the farm sector or even the whole food and fiber complex. For example, I see nothing in our role as publicly funded agricultural economists that should preclude greater emphasis on household consumption economics as a means of better understanding consumer behavior in the interests of consumers. Similarly, with the economics of development and use of natural resources, rational public policies can be derived for a subpart only as we understand the whole. To paraphrase a social scientist from another discipline, it ought to be the primary professional commitment of social scientists, at least those whose work has some public resonance, to make their contribution to public life genuinely pluralist and thus make possible to all groups the enjoyment of equal benefits from their knowledge (Green).

From what sources do these alleged shortcomings in policy analysis derive? Certainly one of the external forces must be simply the complexity and interdependence of our social, economic, and political systems. How do we deal analytically with a process that has no beginning or end and whose boundaries are most uncertain, except to "muddle through?" Another force that led to decline in policy interest by economists is the lack of intellectual stimulation in the commercial policy issues of the 1960s. In a sense, commercial agricultural policy institutions matured between 1930 and 1960. Thereafter, until the early 1970s, we merely tinkered with and fine tuned those institutions—hardly a stimulating venture in an era of widespread alienation with public institutions of all type.

To derive a fuller explanation of our alleged shortcomings we also should look within the profession. I suggest four internal, interrelated determinants: our professional orientation, our methods of inquiry, institutional limitations, and inadequate delivery and feedback mechanisms. Some would add a fifth, the inherent limitation of received economic theory, particularly welfare theory, as an explanatory variable.

As for professional orientation, we may be party to what Lekachman dubs the "socialization" of economists—a process involving a system of education emphasizing belief, not reality. In any event we seem to have increasingly internalized the derivation of our research agenda and reinforced the process by the nature of our incentive systems and accreditation institutions.

Scholarship, it seems, is subject to singularity, to confinement in scope and method. One reason lies in our feeling more competent and therefore more secure in addressing narrowly defined problems.[1] By training and by desiring peer approval as scholars and scientists, we reinforce the singularity and confinement of our research. In the policy field we have tended to separate resource, development, trade, and marketing policies from agricultural policy and to embellish them with special pedagological and methodological mystiques. Much of the analyses of public policy issues that I have sketched, if it is to be done well, must be multidisciplinary, involving technical as well as economic relations and other social sciences (Hathaway). Yet we promote and perpetuate disciplinary and subdisciplinary independence by internalization of our research agenda and in the way we organize research and education institutions.

Internalization of our agenda is closely linked to our methods of inquiry. The view of economics as a science and the associated growth in application of statistics, mathematics, and econometrics to agricultural economic phenomena have elevated positive economics and quantitative methods to dominant positions in graduate school curricula and research. As the numbers of trained students increased, became professors and leaders in the profession, and in turn created more practitioners in their image, the design of a reward system giving emphasis to quantitative analysis completed the cycle. Unlike Adam Smith, contemporary economists pride themselves on their "value-free" analyses. If we aspire to deal realistically with the major policy issues of our time, we must inquire about societal goals and priorities, for it is from evolutionary, sometimes radical, change of those goals and priorities that major public policy issues arise.

Leontief's accolades of agricultural economics as a branch of economics in which scientific methods are applied to observable facts still ring fondly in our ears. Some of our research does blend quantitative methods with knowledge of institutions and observable facts to yield useful and believable results. But the question arises as to the extent to which means of analysis have become ends of analysis, whether demonstration of capacity to develop sophisticated quantitative models and publish in professional journals has become a goal in itself irrespective of whether the model or the data employed conform to reality or whether the results are useful to anyone. Getting the model "to run," as if it then assumed a life and purpose of its own, is an occasion of great accomplishment for some. But the test of accomplishment should be the reliability of its predictive powers and ultimately whether it assists in understanding any important economic relationship or in making any consequential economic decision, public or private. Perhaps it was similar concern that led one critic to decry "the spectacle of so many people refining the analysis of economic states which they give no reason to suppose will ever, or have ever, come about" (p. 2) and another to observe that economics

[1] The author is indebted to Harold Breimyer for statement of this idea.

has "a marvelous array of pretend tools which would perform wonders if ever a set of facts should turn up in the right form" (Heller, p. 2).

Such criticisms can easily be overdrawn. It seems to me that our excesses are not in the first place having sought to develop, refine, and apply such tools. Surely the justification for our discipline rests upon more than theory, intuition, and judgments based on personal experiences. If we are to be criticized it is in having become excessively reliant upon quantitative methods while failing to emphasize the inherent limitations of required assumptions and dependent data systems, to invest in development of those systems, and adapt imaginatively our methods to consequential economic questions. As for debate on the relative merits of institutional and positive economics in policy analysis, I find little that is productive. It seems obvious that a blend of the two is required by the very purpose of policy analysis and by the reality of public policy issues. But until we make a fuller commitment to apply economics to important public policy issues and strike a better balance in our agenda between the pluralist public interest and our internal professional interests, it matters little whether we are positivists, institutionalists, or some mixture of the two. To paraphrase Gordon, we should examine the trade-off between rigor and relevance of our research.

Much has been said recently on the limitations of the agricultural research establishments (National Academy of Science 1972, 1975; Hightower). Criticism centers on alleged lack of openness and responsiveness to needs of various nonagricultural interest groups—again the issue of special interest versus public interest and in turn the scope and focus of our research programs. We might question the extent to which we have become captives of old line institutions and thereby limited our capability to adjust to changing circumstances and policy issues, particularly those involving interests of nonagricultural groups. Bonnen points out "the institutions of agriculture have grown up as a closed, isolated system, and they are not well related to the new power centers of modern industrial society" (1974). Schultz worries about the possibility that we are becoming subservient to government, the result being that most agricultural economists find government actions in agriculture too controversial and too unsettled for analysis.

There are other features of our institutions that limit our ability to deploy resources sufficient to attain the scale, intensity, and direction of research effort needed to address complex policy issues. They include spatial diffusion of research organizations, ineffective coordinating mechanisms, the fractionated, episodic nature of research in most universities, and the short-run crisis orientation of much of the research in government. To that one might add the ingrained independence of researchers!

To some extent our inadequate performance is attributable to our poor communication skills and inadequate information delivery and feedback mechanisms in the pluralistic policy-making process. We need to invest more time and effort in two-way communication with policy makers and the general public. Some useful economic research never reaches relevant decision makers; some only reaches them in the obscurity of technical reports. This requires development of communication skills and more attention paid to "packaging" information for the particular needs of users. In this vein, the recent policy publications of extension are to be commended.

Conclusions and Recommendations

At this point you might ask, "What's right in agricultural economics?" To be sure, we have a professional heritage marked by pragmatic, useful application of economic theory and quantitative methods to the practical problems of American agriculture. We have a rich diversity of human capital in terms of technical training, accumulated knowledge, and professional experience and interests. The diffused and pluralistic structure of our research and extension programs provides a basis for "staying in touch with reality." They encourage individuality and diversity in viewpoints and methods. But institutions, if they are to survive, must adapt to changes in their environment and in the expectations of those who legitimize their roles and being in society.

Reorientation of our agenda and development of more effective research and education institutions are long-term processes requiring adjustments of several types. Some are as basic as altering curricula in graduate schools to provide greater diversity in training and exposure to institutional economics, welfare economics, and policy-allied disciplines such as political science and philosophy. Just as

basic is the need to instill a greater sense of commitment to analysis of public policy issues on the part of those already practicing. We could begin by raising our consciousness of policy issues, asking who is the intended recipient of our research, and asking what information is needed in the hierarchy of decision making within which public policy is formulated and implemented. In doing this we need to look through a much broader prism that includes the interests of many groups in addition to those directly associated with production and distribution of food and fiber. Basic to all of this is the redesign of the reward system in our institutions to encourage and support policy analysis and public service. It also is essential that administrators develop courage and willingness to protect those who choose to deal responsibly with conflicts inherent in major public policy issues.

Some resources could be gained for policy analysis by redirection from current activities of low social value. A part of our efforts is still of a service nature to firms and groups of firms, some of which could and should be provided by the firms themselves or acquired through private research organizations. Some research is so microcosmic and adds so little to knowledge that it would scarcely be missed. We could cease to collect, massage, and publish data that no longer conform to reality or are of use to only a few with vested self-interests. We could critically appraise the premises of some of our work lest in Bishop's terms we find ourselves further down the road to becoming publicly-subsidized consultants than we realize.

However distasteful, we also must find more effective mechanisms for joint planning and conduct of research and extension programs. Whether it be by modification of regional project approaches, by more extensive use of "competitive bidding" as opposed to formula grants of public funds, or by exertion of more positive, imaginative leadership and use of discretionary funds on the part of the larger, more strategically placed institutions, we must surely secure a higher degree of coordination and purpose than now prevails in our diffused research and extension establishments. The alternative may be a centralized, autocratic system imposed upon us, the embryo of which is present in proposals concerning federal funding of agricultural research.

Some rather simple initiatives could be taken within the research and extension establishments to stimulate interest in and improve the quality of policy analysis. The "apartheid" conditions separating research and extension in some universities should be eliminated, and researchers should understand that they have a responsibility for "packaging" and delivering their products to policy makers. It is simply too easy to report research in arcane, technical jargon, leaving others to translate for the wider audience. The reciprocal is that extension economists should become more deeply involved in the research process.

My own institution, the Economic Research Service (ERS), has not been as effective as it might be in bridging between universities and policy makers. More could be done by the ERS to improve the flow of information on policy issues arising at the national level; to assist university personnel in channeling their research to appropriate policy-making forums; to provide "clearinghouse" services for the profession by providing information on policy-oriented research in progress. Both universities and the ERS could benefit from a wider flow of ideas and personnel between the two. Some beginning efforts have been made to improve those linkage mechanisms.

We also could benefit from more formal research linkages with our counterparts in foreign countries. In this respect linkages with the developing countries seem more advanced than with the developed countries, although in both cases arrangements are episodic and rarely in the nature of the truly collaborative research on issues of mutual interest. We also need to vastly improve our data and knowledge bases concerning foreign agriculture, trade, and policy institutions.

Finally, there are initiatives that could be taken appropriately by the AAEA as the one institution that spans, or is capable of spanning, the whole profession. The dialogue we have twice yearly in large meetings is important but not sufficient to give impetus to expanded, more effective public policy analysis. I suggest for your consideration the following actions.

(*a*) Establish an annual award to recognize outstanding contributions in the profession to the advancement of public understanding of major policy issues with preference to contributions that are multiunit or multidisciplinary in nature.

(*b*) Invite or commission a series of papers

setting forth major public policy issues concerning food and agriculture and the implications of policy options related thereto. The forthcoming policy debates turning on expiration of the Act of 1973 provide an opportune setting for the latter set of papers.

(*c*) Over the next several years sponsor a series of seminars, workshops, and public forums to stimulate interest and understanding of contemporary policy issues within and outside the profession. Some of these ventures might be oriented toward methodology or curricula, some designed for problem identification, and others for planning purposes.

Although each of these adjustments and initiatives would be helpful, I believe we should go further. We should undertake serious discussion of the feasibility of creating a national food and agricultural policy institute endowed by public and/or philanthropic foundation funds. Its focus should be primarily national although obviously in an international context. It should concentrate on long-term, "basic" research, particularly that which is multidisciplinary by nature. A core staff could be augmented by visiting scholars, domestic and foreign, for terms of at least two years. Such an institute need not duplicate research in other endowed organizations, most of which have no singular focus on food and agriculture. Nor need it be highly competitive with publicly funded agricultural economic research institutions. It could very well complement those institutions while mitigating some of the deficiencies in current research approaches and institutions—the fractionated, episodic, and short-run nature of research and proximity of our institutions to traditional centers of power. The AAEA is the most appropriate forum for initiation of discussion of the merits of this suggestion.

In conclusion, we face as social scientists a great challenge and opportunity to serve a very broad and fundamental public interest in food and agriculture. We can best serve that interest by broadening our perspectives, cultivating new clientele and professional alliances, and recasting and reorienting our agenda and experimenting with modified and new institutional arrangements in the profession. In emphasizing public policy analysis and the application of economics in the interest of the many groups concerned with food and agriculture, we will be in the best tradition of the egalitarian principles of Jefferson and the humanistic principles of Adam Smith's political economy.

Agricultural Economists and Public Policy

Lauren Soth

In annual conclaves of scholarly associations, it is standing operating procedure for the members to ask themselves about their role in the workaday society. Being devoted to teaching the young and searching for new knowledge, living in semicloistered retreats, professors and researchers require mutual reassurance that they are doing things that are worthwhile in the real world.

Self-examination is healthy. I feel that I am following an honored tradition in this association by undertaking a discussion of the topic. But at the outset I must say that agricultural economists have less trouble with the deprecating question—what good are we?—than most people in the academic disciplines. They have had another hangup, as I shall explain.

Agricultural economics in the United States has been almost wholly a pursuit of the land grant agricultural colleges and the U.S. Department of Agriculture. It grew naturally out of the soil and climate of this public educational federation, where practicality was the watchword. Agricultural economics came out of dirt farming, as they say on the political campaign circuit, crops and soils technology, animal husbandry, farm management, and later marketing of farm products. Many of the early agricultural economists started their careers as teachers of animal husbandry or farm management. They did not first study economics and then turn to specialize in the economics of agriculture. By and large, it was the other way around.

The nature of the origins of the agricultural economics profession led to a feeling of inferiority among its early practitioners. I often sensed, when I was taking graduate work in economics and doing extension jobs in farm outlook and public policy questions, that agricultural economists at Iowa State and in the USDA were touchy about their lack of grounding in formal economics. Some of them flaunted their practical knowledge of farming or of agricultural markets and made light of the theories in textbooks. Others tried to prove themselves legitimate and worthy members of the profession of Adam Smith, David Ricardo, and Alfred Marshall.

The circumstances under which agricultural economics began to develop as a separate field of study gave the profession an advantage in the practical world of politics and business. Unlike the workers in most social sciences, including general business economics, the agricultural economists really knew their industry. Moreover, their innocence of theoretical economics enabled them to appreciate the power relationships of the market and to see the wide gap between the textbook principles and the way the economy actually functioned.

I

Agricultural economists have had more influence on the formulation and the carrying out of public policies for their industry, I should venture, than the economists specializing in any other single industry. In the 1920s, when agriculture was suffering from the plunge of prices after World War I, agricultural economists provided the intellectual leadership in designing plans for government action and for structural reforms of the marketing system. W. J. Spillman, Henry C. Taylor, M. L. Wilson, Henry A. Wallace, E. G. Nourse, and John D. Black are names that spring quickly to mind. These were the idea men behind the export debenture plan, the domestic allotment plan, the McNary-Haugen bill, the farm cooperative movement and other proposals for helping farmers contend with overproduction and low prices.

The prevailing diagnosis of the cause of the farm problem at this time was loss of foreign markets. Farmers had expanded production to sell abroad in the golden years of the early 1900s, so the reasoning went, and then increased output still more to meet the needs of

---

Fellow's lecture.

Lauren Soth is a journalist and economic consultant.

The author wishes to thank Jimmye S. Hillman, James T. Bonnen, Harold F. Breimyer, Emery N. Castle, John A. Schnittker, and Robert K. Buck for comments and suggestions in the writings of this paper.

World War I. The setbacks to foreign sales in the 1920s resulted in commodity surpluses. Farm relief plans generally focused on aspects of the foreign trade situation. Agricultural economists called for lower tariffs on manufactured goods to stimulate imports and furnish dollars to foreign customers for our farm products. They urged export subsidies for farm products, two-price plans such as the McNary-Haugen bill and the export-debenture scheme.

These early agricultural economists were unabashed political economists and partisans for farmers. They pushed the American development theme as espoused by the founding fathers and reflected in the Morrill Act, the Homestead Act, and throughout our public policy. In his *Agricultural Reform in the United States,* published in 1929, John D. Black defined the objectives of national agricultural policy as "first, to hasten the improvement in the rural scale of living; second, to check the present rapid rate of migration to cities; and third, to maintain a somewhat larger proportion of our population on the land than otherwise would be the case" (p. 60).

Black was the principal designer of what was then called the domestic allotment plan, a plan for retiring temporarily part of the land used for major crops. The aim was to reduce output and raise prices of farm products. When prices sagged drastically in 1930, 1931, and 1932, this plan became widely accepted among farm groups. In his one speech on agricultural policy in the 1932 presidential campaign, Franklin D. Roosevelt gave a fuzzy endorsement to the idea. After the election the New Deal Congress approved the first Agricultural Adjustment Act. That has been the fundamental system of supply management ever since, and though it is in abeyance at the moment and the political language has evolved to "set aside" instead of annual allotments, the essentials of the system are the same as forty-three years ago.

Black was advocating methods of supporting farm income that he thought would keep people on the farm and that he considered a desirable national objective. Two of his three objectives for farm policy had to do with maintaining a larger farm population than would prevail without a federal action program.

As it turned out, the domestic allotment plan had the opposite effect. It helped farmers who were in a strong financial position to acquire more land; price supports enabled the big farmer to gain substantially in competition with the small operator. Ironically, the allotment and price programs were criticized at first, by many agricultural economists as well as conservative politicians and business men for protecting the outdated, inefficient, small farmer and blocking modernization of the industry. Some naive urban critics of "farm subsidies," such as the *Wall Street Journal,* have continued even in recent times to charge that the farm programs inhibit efficient, large-scale farming.

It is true that, on its face, the legislation promises certain advantages to small farms, and all farm laws religiously proclaim their purpose of upholding the family farm. But the real effects were quite different, as became obvious to those who looked at the facts after World War II instead of basing their opinions on legislative preambles and theory.

II

There then arose a heresy within the professional agricultural fraternity of the land grant system, including some farm economists. The heretics repudiated the ancient Jeffersonian doctrine about the virtues of the family farm.

Even into the 1930s, farm policy reformers sought to preserve independent, small-scale farming and rural communities. They did not seek a change in structure of agriculture but mechanisms to improve its functioning. The philosophy of the Morrill Act, the Homestead Act, and the Country Life Commission of Theodore Roosevelt dominated the land grant colleges. The purpose of research and education was to raise the farm family to an urban living standard—not drive people off the farm but keep them there. Extolling the virtues of rural life was part of the ritual of extension work.

But the new technology was seen to be depopulating the farms as it reduced labor requirements. Making a virtue out of necessity, agriculturalists began to laud modernization and consolidation of farms and the "release" of farm workers for nonfarm work.

The family farm ideologists came in for condescending smiles if not contempt. It was time to recognize farming as a business and not a way of life. Agricultural economists began to talk about farm population adjust-

ment as a "final" solution of the farm surplus problem. It was not a problem of overproduction but of too many people sharing the national farm income. Instead of trying to restrain farm output so as to increase farm income, what was needed was continued reduction of farm population to increase the individual shares.

At the same time, after World War II, as Brandow has lucidly explained in his review of the literature on commercial agricultural policy, agricultural economists turned to the demand side as an explanation of the farm problem. The lesson of World War II had been that when the economy was in boom, with full employment, prices of farm products were high and farmers were prosperous. Most importantly, young people leaving farming areas could get jobs in the cities. The farm problem was not really a farm problem but a problem of general economic stabilization on a rising trend of growth.

This analysis was happily in harmony with the "permanent adjustment" theme. It also furnished timely justification of the conventional land grant doctrine that full-speed-ahead infusion of new technology was all to the benefit of farmers and the rest of us. The same rationale was comforting to those who wanted to "get the government out of agriculture" and let free markets reign.

The technological faith had come into question by a few farm radicals and a few dissident farm economists who made the logical connection between excess supply and new methods that increased production. So, it was nice for the true believers in science to hear other respected economists rebut this by arguing that the farm problem was caused by weak demand for farm products. The free marketeers were not disturbed by government financing and investment in new farm technology as an intervention in private business—only "artificial" meddling in what they regarded as natural markets.

Unfortunately for the final solution proponents, it soon became apparent that full employment and continued rapid reduction of the farm population were not enough to keep farm income high. The overproduction tendency seemed not just a matter of weak foreign and domestic demand; it seemed to be chronic, if irregular. Even with high employment, prices of farm products and the net incomes of farmers often were below satisfactory levels.

III

Agricultural economists attributed the farm problem first to loss of foreign markets, then to slack domestic demand. They were slow to appreciate the consequences of the technological revolution in farming. The application of science to agriculture was regarded as a "given" in the farm economics equation—beyond economic study. The land grant college-USDA system, in all its parts and roles, was based on the idea that technological efficiency is an ultimate good. There could not be too much or too fast a drive for getting more output per man, per acre, or per unit of capital.

Alone among the agricultural establishment scholars, a few economists braved the theologians of technology to ask whether the push for technical advance might be too impetuous. They asked whether the overcapacity of agriculture could be the result of letting technology get ahead of social adjustment. They suggested that priority in public expenditure for rural communities ought itself be subjected to scientific analysis.

Considering that these questioners of the dogma were themselves employees of the land grant system, they deserve praise for courage. Nearly all criticism of public agricultural research policies has come from within, not from agricultural economists in private educational, research, and business institutions, where you might expect it to originate. Instead, the outsiders mostly have beaten the drums for all out production research, that is, the development and application of new technology for agriculture, including the major farm organizations.

Agricultural economists inside the system were first to point out that farmers taken as a group did not benefit from the introduction of new methods; only the first users did. They dared to challenge the time-honored experiment station sales argument to legislatures that an increase in corn yields increased farmers' aggregate income. Public spending for agricultural improvements benefited the American consumer and the foreign buyer, not the farmer. Agricultural economists showed that the bypassed farm operators, hired workers, and small towns in rural areas benefited least of all or not at all from new farming technology. The discernible effects of these studies on public policy are small so far,

but I am confident that they will ultimately be substantial.

Agricultural economists have brought to bear on the intellectual front the nonfarm or nonagrarian concerns that are becoming apparent on the political front. The farmer in the last 200 years has felt that interests outside farming—the middlemen, bankers, railroads, and manufacturers—were making the main decisions about his business. He has had to take the other fellow's price, both as buyer and as seller.

Actually, in this century government farm policies have been largely left to the farmer and his organizations, including the land grant institutions; farm lobbyists have been able to get most of what they wanted. The decline of farmers in number and proportion of the voting population did not weaken their power in government, despite reapportionment. Yet the farmer's instinct about being at the mercy of outside interests is not far off the mark. Government policies have been beneficial to the elite of commercial agriculture and to the business interests selling to and buying from them but often not to the majority of people in farming.

The political atmosphere on food and agriculture has changed in the 1970s. The rise in food costs to consumers, the deterioration of rural community structure, the trend to industrial agriculture, and the migration of displaced rural people to cities have attracted a wider constituency for farm policy.

IV

Agricultural economists as partisans and political activists contributed heavily to the nation's farm policies of the first half of the twentieth century.[1] As "pure" economists, more segregated from the political scene today, their influence has diminished. Agricultural economics undoubtedly has become more scientific, more scholarly, and more knowledgeable about the farming business. The more you know, the more detached from politics, the less likely you are to attract attention and stir opinion. The more specialized you become, the less effective you are in the political economy. As our studies have become more intensive, more detailed, with greater use of mathematical techniques, inevitably they become narrower. The impact on public affairs is remote, long delayed, and indirect.

I do not say this is a bad thing; I do not belittle the mathematical tools merely because I do not understand them. I must admit, however, that the remark of Joan Robinson, who refuses to use equations, gave me some satisfaction. She said, "I don't know math, so I am obliged to think" (Golden, p. 42). If I were to criticize the budget of research in agricultural economics, I should be more inclined to adopt another criticism of American economists made by Joan Robinson. She said they are floundering because they still have an ideological bias toward the free market, which she says is a theoretical concept that does not exist.

Scientific, mathematical studies about the economic details of agriculture no doubt help us understand the industry. But to the extent that they rest on assumptions about pure economic science, they are illusionary and not helpful in the formation of public policy.

I read recently an interesting paper by Paul McCracken, professor at the University of Michigan and longtime member of the president's Council of Economic Advisers. McCracken believes an economic adviser ought to try to keep his own values and political judgments separate from his advice on economics. I guess everyone would agree with that. But it implies that there is such a thing as economic science that can be divorced from politics. That I doubt.

McCracken tells about an incident when he and other advisers were asked to report in 1961 about the domestic economy and the balance of payments. One of their recommendations was that the gold reserve requirement be reduced or removed while the issue was quiescent, rather than waiting until the Federal Reserve's gold holdings were on the verge of becoming deficient. Kennedy said he understood the economic logic and the economic cost of delaying a decision, but he would have to pass. He said such legislation would have to come before Senator Harry Byrd, and he did not want to start his administration by raising the gold issue with the senator.

McCracken said he and the other advisers performed correctly as advisers, but the president, looking at the larger domain for which he was responsible, chose not to take their advice. McCracken said he understood that pure

[1] Among the many good books recounting the impact of farmers' political movements on government policy that tell of the contributions of early agricultural economists are those by Salutos and Hicks, Benedict, and Hofstadter.

economics had been adulterated in Kennedy's decision, and he had no reason to think the president was wrong.

I agree on this kind of separation of economics and party politics. But in the larger meaning of political economy, McCracken and his associates took into account more than pure economics in their assessment of the gold reserve question. They had to consider the power factors in banking and government among others.

In dealing with agricultural policy, as with money or other economic policy, it is impossible to consider economics as a pure science. Economics itself is more complicated than any physical science. It deals with pesky human behavior. It embraces power of large organizations more and more. We deceive ourselves and our clientele when we claim to be only "humble technicians" bringing to bear an antiseptic economic analysis on a public policy question.[2]

On the whole, agricultural economists have been broad enough to see beyond economics in public policy and to see that economics is more than demand and supply curves.[3] I could provide a long list of current AAEA members who have made large contributions to the agricultural policies of this country. But I'm a coward. I'm afraid I'd leave out a deserving stalwart or two and offend them, while offending others by including certain names. So I won't give you my list. Anyway, you all know the people who have served as economic policy advisers in the executive departments, directors of policy studies for Congress, members and directors of presidential commissions, and the authors of influential books and articles. It should be easy, at least in this instance, to support without documentation my claim that agricultural economists have been more influential in economic policies for their industry than other specialized economists have been for theirs.

V

In his 1967 presidential address to the AAEA, Bishop, who was then director of the National Advisory Commission on Rural Poverty, said, "those of us who work in the rural social sciences have not perceived the significance of the growing urbanization of rural America" (p. 999). He said farm economists had been preoccupied with the problems of the farm firm and had given little or no attention to economic problems much more important to the majority of the rural population.

Bishop asked that economists study the effects of farm programs on income distribution in agriculture and the effects of technology on the structure of rural communities. He said, "In order to increase our usefulness in coping with problems of economic structure and public policy, we must break the bonds of pure competition and extend our analysis to problems that transcend market phenomena" (p. 1007).

Nine years later I think one can say that the agricultural economists have been shifting in the direction Bishop advised. With consumer organizations becoming more vocal, with environmental concerns becoming imperative, and foreign policy once again rising to the forefront of agricultural policy, the trend toward a broader approach to public policy will continue. The public has awakened to the connections between farm policy and foreign policy, food prices, protecting the environment, and the rural-urban structure of society. The public says, in effect, that farm policy is too important to be left to the farmers, since that means in practice the big farmers and agribusiness.

The public is no longer willing to accept without question the assertions of the agricultural establishment that the United States has the purest and most nutritious food supply in the world. Nor is it ready to leave soil and water management to the establishment. Even the issues in rural areas of crime prevention, public welfare, education, the rights of minorities, and collective bargaining of farm workers will not be left to rural areas. As Bishop said, the rural society is becoming urbanized; its

---

[2] Randall discussed "Information, Power and Academic Responsibility" perceptively in this *Journal:* "Conceiving the economy as a system of mutual coercion, it becomes impossible to avoid the moral dilemmas which confront anybody involved in the public sector or in social decision making. If an action taken in any public agency tends to increase the power of some people while reducing the power of others (i.e., to make some people better off and others worse off), its distributional consequences cannot be attributed to some inevitable and inexorable economic law. Rather, these consequences are the result of a decision of which that agency should be conscious and for which it must take responsibility" (p. 229).

[3] Randall asked, "What, then, is the normative significance of a supply curve, a demand curve, a price? Very little, I suggest, since all of these things are very largely dependent on the structure of power within an economy, and the structure of power can be changed by political action as well as by what we have come to think of as economic changes. Economic data such as prices and supply and demand curves can be used in a normative context only if the current structure of power is assumed optimal" (p. 229, note 9).

isolation is ending. The farmer and his community have been brought into the mainstream of the nation.

Paarlberg said, "The biggest issue of agricultural policy is . . . who is going to control the agenda. . . . The old agenda is concerned primarily with commodities and specifically with influencing supplies and prices in the farmer's interest. . . . The new agenda differs radically . . . : Food prices and specifically how to hold them down . . . ecological questions . . . rural development, primarily a program of the 80 percent of the rural people who are nonfarmers . . . civil rights . . . collective bargaining." Paarlberg also said the agricultural establishment should not just "repeat the honored rhetoric" but should recognize that the new constituency would have to be served.

I agree with him. Moreover, I think the nonfarm pressures on agricultural policy will be beneficial to independent family farming and to a healthier rural society.

Agriculture's own institutions, developed for an earlier time and for a different farming structure, are incapable of meeting the requirements for public policy on rural affairs today. The very success of the scientific advances in farming tended to freeze the institutions in place. The fact that the benefits of scientific advance were not being shared equally within agriculture and between agriculture and the urban sector tended to be ignored by the land grant system, the commercial farm organizations, and agribusiness.

There seems to be a law of nature that successful human organizations resist change until they have lost effectiveness and are replaced. Bonnen, our honored president, has frequently alerted us to what he has called "The Decline of the Agricultural Establishment." Ten years ago Bonnen said in a speech that "the commercial agricultural power structure has reached a state of extreme organizational fragmentation . . . and these fragmented elements are themselves contributing greatly to a general erosion of the political power which together they exert."

The politics of farming in the 1920s and 1930s had to do with a fairly homogeneous farming community. That community has been splitting apart from the effect of the technological revolution. Farmers' organizations have been splitting into agribusiness firms and into commodity groups. The colleges of agriculture and the USDA have tended to become more associated with larg farming interests and the suppliers of farm ir puts and the buyers of farm products. Th close association of the USDA with the pe ticide industry and the international grai companies has been notorious. Regulation ‹ pesticides has been taken away from USD/ and the regulation of grain inspection is bein reformed.

Agricultural economists have been the lea ers in calling to public attention the neglect ‹ low-income farm families and hired far labor, the effects of government farm pro rams on the farming structure, and the impa of technology on rural America. But the cha lenge laid down by Bishop is still pertinent one judges the profession by what appears i the *Journal of Agricultural Economics*. Publi policy issues till receive secondary effor especially those policies which affect the ge eral public.

For half a century the principal public po icy question concerning food and agricultur was how to deal with production overcapa ity; in the next half century the central pro lem could well be scarcity. High food cost and instability of prices will be public polic targets. Agricultural economists will fin themselves in a different position with respec to farm policy formation than in the past. W need more work on food and nutritio policies, foreign policy, national energy, an environment policies and the structure of a riculture and rural communities.

Perhaps I could be accused of bias, but I a confident that the members of the AAEA wi rise to the needs of the occasion as they hav in the past.

The New Macroeconomics of Agriculture

G. Edward Schuh

Most of the literature on the macroeconomics of U.S. agriculture is cast in the context of a closed economy. Moreover, it considers a world in which there is rapid technological change and focuses on the problems involved in the so-called agricultural transformation—the process whereby an important share of the agricultural labor force is transferred out of agriculture and new modern inputs produced in the nonfarm sector are introduced. (For a survey of the literature on the agricultural transformation, see Johnston.) Consequently, it tends to ignore linkages to an international economy and focuses instead on the secular income problems that agriculture faces as it is subjected to the processes of economic growth.

This perspective no longer seems relevant to the major problems now facing U.S. agriculture. Outmigration from agriculture has declined markedly, long-sustained growth in factor productivity appears to be leveling out, and major shocks to the U.S. food and agriculture sector have come from abroad as a result of the American economy having become more open. At the same time, the rules governing the trade and exchange relations among countries have changed, and there is pressure for even further change as the less developed countries push their demands for a new international economic order.

This paper addresses these new conditions and the implications they have for us, both as a nation and as a profession. What perhaps most differentiates this paper from previous treatments of the macroeconomics of agriculture is an attempt to examine the agricultural sector in the context of an open world economy. Looking ahead, the major analytical and policy problems agricultural economists face will have to do with how U.S. agriculture and the economy as a whole fit into a rapidly changing, interdependent world economy. Those problems have to be understood in the context of our present stage of development and the major forces impinging on agriculture. Hence, part of my paper will be concerned with these issues as well.

The Setting

The contribution that agriculture makes to the economic growth of the larger economy is undergoing marked changes. In the past, its contribution consisted primarily of furnishing abundant supplies of food to the domestic economy at constant or declining real prices, the release of large numbers of workers to man an ever expanding nonfarm sector, and the supplying of large amounts of capital—both human and nonhuman—for the development of the rest of the economy. From the present perspective, the capital flow may now well be the other way; the outflow of labor has slowed in the aggregate, and food prices have recently risen relative to the price of other goods and services. Moreover, agriculture is a major source of export earnings and thereby provides the means to purchase the growing amounts of petroleum, raw materials, and finished products imported from abroad.

Agriculture continues to be an important market for goods from the nonfarm sector and in the recent recession was an important point of strength as farm incomes were sustained while the rest of the economy was in serious trouble. This was probably the first time in our modern history that a severe recession in the general economy had little effect on agriculture and was due in no small part to a strong export demand as well as the continual broadening of our welfare programs.

The early 1970s have seen major shocks to U.S. agriculture and economy. After a long secular decline in the real price of agricultural products, food and agricultural prices were in

Invited address.

Journal Article No. 6494. The author has benefited from helpful comments on an earlier draft by Lowell Hardin, Dale Hathaway, Jerry Sharples, George Tolley, Larry Witt, and his Purdue University colleagues.

the vanguard of an unusual peacetime inflationary spiral. Rather than subsidizing exports, as was done in the past, some form of export controls was imposed in each of the last three years. Food aid on concessional terms was reduced dramatically as commercial sales abroad burgeoned. Average per capita incomes of farm people rose above those in the nonfarm sector. From a chronic problem of low relative incomes for farm people, a shift has occurred to what many believe will be a chronic problem of instability.

The question that emerges is whether these recent events reflect changes in the macroeconomics of agriculture. In my view they do. Some of the changes have important implications for the welfare of U.S. citizens and for policy makers as they attempt to devise policies that are in the best interests of the nation.

Changes in the Economic Environment of U.S. Agriculture

The U.S. economy experienced unprecedented growth in the decade of the 1960s. There was also unusual growth in other parts of the world, including some of the LDC's. The regime of fixed exchange rates established at Bretton-Woods broke down, and the world has fitfully moved to a system of floating exchange rates. Population growth around the world continues to press hard against the stock of land, despite technological breakthroughs in birth control, concentrated efforts by at least some countries to reduce their growth rates, and technological breakthroughs in agriculture that were prematurely labeled a green revolution.

I turn now to a brief look at the more specific changes relevant to agriculture.

Reduced Outmigration from Agriculture

It is generally recognized that the chronic farm problem of the 1950s and 1960s was a result of the inability to transfer labor out of agriculture at a sufficiently rapid rate. The United States had persistently underinvested in the education of its rural people, with the result that farm people often did not have the skills and talents required for nonfarm employment. The agricultural labor market naturally tends to be rather imperfect, in part due to its geographic dispersion. During the 1950s and early 1960s, fiscal and monetary policy caused the level of unemployment in the general economy to be relatively high, constituting an important barrier to the outmigration of labor.[1]

As we entered the decade of the 1970s, the agricultural labor market was approaching an equilibrium. Employment in agriculture has remained about stable since 1970, the real agricultural wage rate rose relative to the wage rate in the private nonagricultural sector from 1965 through 1974, and average per capita incomes in the agricultural sector were larger than those in the nonfarm sector in both 1973 and 1974.[2] Median family incomes of farm people, while still less than those of nonfarm families, have risen dramatically relative to those in the nonfarm sector.[3]

There will undoubtedly be a continued outflow of human resources from agriculture, particularly from the Northeast and Southeast. On the other hand, there may well be some return flows in other regions, and the aggregate outflow will most likely be greatly reduced compared to the past. Average annual net outmigration during the 1950s and 1960s was 741,000 and 592,000, respectively. From 1970 through 1974, the average net outmigration was only slightly over 110,000 per year, in a total labor force of some 90 million (Council of Economic Advisers 1975).

Stagnating Productivity Growth

Increases in total factor productivity have been an important source of output expansion in the past. From 1940 to 1970 total measured physical inputs in agriculture increased only 4%, while output increased 58%. Clearly, the major source of output expansion was an increase in factor productivity.

More recently, there has been a marked and little understood decline in the rate of measured productivity growth in agriculture. During the decade of the 1950s, total factor productivity grew by 27%. In the decade of the

---

[1] Evidence on the role of unemployment in reducing the outflow of labor from agriculture can be found in Hathaway, Schuh (1968), and Sjaastad. For an explanation of why tight monetary and fiscal policies were pursued in the 1950s and early 1960s, see Schuh (1974).

[2] Supporting data for these assertions are readily available from public sources such as the *Economic Report of the President*. They will be provided by the author on request.

[3] From 1970 to 1973 median family income of the farm population increased by 30% in real terms, compared to 6% in the nonfarm sector (Council of Economic Advisers).

1960s it grew by only 11%, or at a rate only slightly more than a third as large as in the previous decade. This stagnation in productivity growth first emerged in the period following 1965 after a continued and sustained rise in the previous fifteen years. Total factor productivity grew by some 10% in 1971 but has again stagnated since then.

The National Academy of Science in May 1971 organized a Committee on Agricultural Production Efficiency to evaluate the adequacy of this nation's policies, knowledge, and technology relative to agricultural research and educational efforts. Although far from being a prognostication of doom, the committee's report is indeed sobering. Their data show rather strong diminishing returns from the application of fertilizer to land, with the rate of increase in crop yields per pound of fertilizer added tapering off since 1965. The number of eggs laid per hen is apparently leveling off at near 230 per year, and a similar biological limit is expected to emerge with respect to the production of broilers per pound of feed. In addition, the number of people fed per farmer and the number of people fed per acre are also leveling off.

In looking ahead, the committee indicated that no major scientific breakthrough comparable to hybrid corn or DDT can be reasonably predicted for the next one or two decades, although they believe promising potentials remain for improving productivity from the application of known technology and from new technology now in the research and development phases. On balance, however, they indicate that the biological realities suggest a slowing in the rate of productivity growth for most crops in the future and express similar concerns about productivity in the livestock sector.

Peterson has pointed out that total factor productivity in U.S. agriculture did not start growing in a substantial way until the 1940s, despite the fact that our research, teaching, and extension infrastructure was put in place in the late nineteenth century. The petering out of productivity growth in recent years suggests that a technological "epoch" is playing itself out until (and if) a new burst of innovations come on the scene. The truth of the matter is that we have only a weak conceptual and empirical understanding of the technological transformation through which U.S. agriculture has passed. Hence, little basis exists for knowing what to expect in the future.

The Shift to Floating Exchange Rates

The rules that have governed trade relations among nations in the post-World War II period were largely established by the Bretton-Woods Conference of 1944. At this conference the industrialized western countries under U.S. leadership established an elaborate system of trade, tariff, and financial arrangements that in its broad outlines lasted through the early 1970s. Central features of the system included reliance on fixed exchange rates and a number of reserve currencies, the most important of which became the U.S. dollar. In its role as supplier of the major reserve currency, the United States ran a persistent deficit in its balance of payments, collecting seigniorage in the process (Grubel).

This system encountered periodic difficulties as one country or another got out of adjustment, but for the most part it served the developed countries of the world reasonably well. World trade grew at a faster rate than world gross national product (GNP), and a growing interdependence among countries evolved, especially among those of the industrialized West.

As inflation picked up in the U.S. economy during the late 1960s and early 1970s, the U.S. dollar became increasingly out of line with the currencies of its major trading partners, and the deficit in the balance of payments grew increasingly larger. In August 1971 the dollar was devalued in relation to gold by 8% and again in February 1973 by another 10%. In the process the United States closed its gold window. De facto generalized floating among the industrialized countries was adopted in March 1973.

These successive devaluations of the U.S. dollar and the shift to floating exchange rates ended a rather long period of discrimination in economic policy against the agricultural sector (Schuh 1974). An overvalued currency is in effect an implicit export tax that, depending on the elasticity of foreign import demand and the elasticity of domestic factor supplies, has its incidence on the exporting sector. When combined with the tight monetary and fiscal policies designed to stem the gold outflow and control the balance of payments deficit, the result was a severe squeeze on agriculture, at the very time it was already experiencing a considerable adjustment problem due to the adoption of new production technology and substantial investments in nonhuman capital.

Changes in Our International Environment

In addition to the shift from fixed to a system of floating exchange rates, there have been a number of other important changes in the way the United States relates to the world economy. In the first place, the United States has become a great deal more dependent on its external sector. The share of exports in the total economy has doubled in the last fifteen years, and the share of imports has doubled in just seven years. U.S. exports and imports are each currently about 7% of total GNP and are still rising, putting them only slightly below the same ratios in Japan and in the European Common Market as a group, which are about 9% and fairly stable (Bergsten and Cline). In addition, about one-third of the profits of U.S. corporations now derive from overseas activities, primarily from foreign direct investments. Bergsten and Cline argue that if these profits are taken into account along with trade, the U.S. economy has probably become more open in quantitative terms than Japan or than western Europe as a unit. Moreover, the United States already imports more than 50% of nine of the thirteen industrial raw materials required by the domestic economy.

As one aspect of this general opening of the economy, U.S. agriculture has become more closely integrated with the world economy, especially on the export side. The export coefficient for agriculture doubled between 1950–53 and 1970–74 (Brandao and Schuh). At the same time, other countries have become increasingly dependent on the United States as a source of supply for grains. Although the United States has been an important and growing source of supply throughout the post-World War II period, it became of major significance in the early 1970s (Brandao and Schuh).

A third, and perhaps the most important, respect in which U.S. agriculture has become more strongly linked to the world economy is through the increased importance of agriculture in the trade balance. Although little recognized in contemporary discussions of trade and trade problems, there has been a major shift in the structure of U.S. trade, with the result that agriculture now makes a major contribution to the trade balance. The United States was a net importer of agricultural products in 1920–62; only in the mid-1960s did the trade balance for agricultural products turn positive and now has grown successively larger. On the other hand, a deficit in the trade accounts in nonagricultural products began to emerge in 1968 for the first time since 1930 (USDA).

The deficit in the trade balance of nonagricultural products literally burgeoned in the period 1971–74. At the same time, the surplus on the agricultural trade account also burgeoned. In 1973 that surplus was more than sufficient to offset an $8 billion deficit in U.S. trade in nonagricultural products. In 1974, it was just $3 billion short of offsetting an almost $15 billion deficit in trade in nonagricultural products, and in 1975, the $12.4 billion surplus in the agricultural trade accounts contributed mightily to the record $11.1 billion surplus in total trade accounts.

This change in structure of U.S. trade is of major significance to the U.S. economy. It imposes an important constraint on our economic policy vis-à-vis agriculture, while at the same time making both the agricultural sector and the general economy subject to shocks from the agricultural sectors of other countries.

The final significant change in the international environment is the increasing demand by the LDC's for a new international economic order. Encouraged by the success of the Organization of Petroleum Exporting Countries, these demands constitute a program for structural change in the system of trade and international relations among countries that was originally designed by the West. The argument of third world leaders is that the prevailing system is exploitative, functions to preserve the economic dominion of the West, and has prevented the nonindustrialized countries from developing. Their desire is to use trade to attain political objectives and to redistribute the world's income and resources in their favor.

Implications

There are six major implications of these changes that I would now like to address.

(*a*) The secular income problem in agriculture is now largely behind us. The emerging equilibrium in the labor market is of major significance in this respect. When this equilibrium is combined with the decline in the rate of productivity growth, the release of most of the idled land back to production, and the shift to the right in the demand for agricultural pro-

ducts as a result of devaluation, the result is an almost total disappearance of the excess capacity that existed at prevailing price ratios for such a long period of time. (For a more detailed discussion of this development, see Council of Economic Advisers 1975, chap. 6.)

The conditions of product supply have also undergone important changes, determined in part by changed conditions in the factor markets. With labor dammed up in agriculture and up to one-sixth of farm land withheld from production by agricultural policies, output was in the past fairly elastic in response to rising prices. Land could be released to production, labor could be more effectively utilized, and output could be expanded fairly easily. This is in part what happened on the occasion of the first post-World War II food scare in the mid-1960s.

That degree of flexibility on the up side no longer exists. The land in retirement under government programs has all been released to production except for that under long-term contracts. To the surprise of many, only about 37 million of the 60 million acres in retirement actually came back into production. In addition, agriculture now has to bid against the nonfarm sector to bring forth a larger supply of labor services, in contrast to just slowing down the rate of outmigration, as was the case in the past. This combination of a positively sloping supply curve for the two primary inputs, land and labor, suggests that sudden shifts to the right in the demand for agricultural output will be reflected in higher product prices. Much of the previous flexibility on the upside has been lost, at least when evaluated in terms of current input use.

On the down side, however, flexibility has probably been gained. A larger share of total farm inputs now comes from the nonfarm sector. Farmers are particularly responsive to the relative price of these inputs, with the result that declines in farm prices will result in a reduction in their use. Similarly, at least in nonrecession periods, it will probably be easier to shift labor out of agriculture in response to a decline in relative prices. The agricultural labor force makes up a smaller proportion of the total labor force than it once did and has also become more closely integrated into the nonfarm labor market.[4]

[4] The real income per capita from nonfarm sources increased markedly for farm operators after 1960 (see Gardner).

Overall, there has probably been an increase in the short-run supply elasticity of U.S. agriculture due to the increased importance of purchased inputs and the higher level of education of the labor force that increases farmers' ability to deal with disequilibria (Schultz). To the extent that asymmetry exists in supply response, the rigidity may now be on the up side rather than on the down side.

None of this is to deny that there still might be income problems in agriculture in response to short-term imbalances. However, it would appear that these would be of a transitory nature, and not the secular problems experienced in the past.

(*b*) The management of agricultural policy will be more complex. The evolution to a more open economy and the shift to floating exchange rates makes the management of economic policy a great deal more complex, if for no other reason than that there are more variables to keep track of and more policy instruments to manage. With floating exchange rates there are rather complex interactions among domestic monetary policy, the exchange rate, and the competitive potential abroad. An increasing tightness in monetary policy, for example, will attract a larger capital inflow, other things being equal, due to the rise in interest rates that it implies. The larger capital inflow, other things being equal, will raise the value of the dollar and in turn reduce the competitive potential on the trade account.

Similar considerations apply to the monetary and trade policies of other countries, especially those of major U.S. trading partners such as Japan and Germany. If they should pursue tighter monetary policies, the result will be to weaken the dollar relative to their respective currencies, thereby putting U.S. export products such as grains in a stronger competitive advantage vis-à-vis domestic production.

These interdependencies mean that agricultural economists have to give greater attention to monetary and fiscal policy if they want to understand developments in the agricultural sector and to make useful forecasts of trade and other variables in the economy. Moreover, being sensitive to domestic monetary and fiscal policy is not enough; concern about policies in other countries is needed.

A further complication arises from the importance of agricultural trade in balance of payments. The exchange rate now has to be treated as endogenous with agricultural trade.

Weather-induced fluctuations in foreign import demand can affect the exchange rate and, in turn, influence the allocation of exports among alternative markets. Equally as important, if controls should be imposed on agricultural exports, the value of the dollar may decline in international markets. This will raise the prices of U.S. imports. If such import controls are imposed under the guise of controlling domestic inflation, they will be shortsighted, although that does not deny the validity of such interventions under certain circumstances. Obviously, both the distributional and growth consequences of a decline in U.S. food prices are very different than those from a rise in prices of import goods.

The increased complexity in the management of economic policy is not necessarily a disadvantage, although it obviously increases the scope and magnitude of information and research needs for decision making. The obvious corollary of the increased complexity is an increase in the degrees of freedom in the management of policy, since there are more variables to do the adjusting. Moreover, the consequence of an increase in the number of variables that can adjust is that a given shock to the system is diffused on a much wider basis. For example, if world trade was free and all exchange rates were floating, a short fall in grain output in another part of the world that led to a large increase in demand for U.S. exports would bid up the value of the dollar on international exchange markets. This would make U.S. exports more expensive to other countries, causing a reduction in the quantity demanded.[5] In that way the cost of the short fall would be spread more widely around the world and not be limited to just a small number of exporting and low income countries, as in the recent past.

The problem is that we are far from having completely free trade and generally floating exchange rates. As Johnson has pointed out, much of the instability in international markets in recent years was due to barriers to trade and rigidities in domestic agricultural policies. But that only points up the importance of the current round of multilateral trade negotiations in which the United States is attempting to have agriculture included in the next round of trade liberalization. It also points up the importance of engaging the LDC's in a constructive dialogue so that they can be induced into more liberal trade policies. Without such developments, the U.S. food and agriculture sector will continue to be buffeted by shocks from the international economy unless we go back to a costly program of grain reserves.

(*c*) The price of food to the U.S. consumer will be determined in part in international markets. The increased openness of the U.S. economy, especially for agriculture, means that the price of food at home will be determined in part by international markets. No longer will a major share of the benefits of technical change in agriculture redound directly to consumers in the form of lower food prices due to an inelastic aggregate demand for food. Although the foreign demand for output is not perfectly elastic, it does appear to be on the order of -5.0 or -6.0 (Tweeten). The growing share of U.S. output going abroad makes the aggregate price elasticity of demand for U.S. output larger. Hence, domestic consumers will tend to benefit more from the increased export capability that technological change in agriculture represents than from an immediate decline in relative food prices.

Similarly, to the extent that there is a world food problem, consumers will share in it in the form of higher food prices, just as in recent years. Export controls and other trade interventions could keep consumers from bearing the costs directly in the form of higher food costs. But such interventions would raise the price of U.S. imports through their effect on the exchange rate, so the income loss would be experienced in any case, although as mentioned above with quite different income distribution consequences.

(*d*) U.S. consumers now have a vested interest in agricultural research and development abroad. Food prices in the United States, to the extent they are determined by the price of raw agricultural products, will decline only as the world supply of agricultural output increases relative to demand, with the important caveat about trade restrictions noted above. Despite the size of U.S. agricultural exports and technological superiority, the United States alone cannot lower world food prices. Hence, U.S. consumers now have an interest in improving world agriculture and in bringing world population growth into balance with potential food supplies. This interest should no longer derive solely from a feeling of benevolence toward the world's

[5] It would also lower the domestic price of imports, thereby helping to offset the rise in food costs that might result from such a shock.

poor, but because it is in the best interest of consumer groups.

The technological gap between U.S. agriculture and that in the LDC's is sizable, so there is much potential to be exploited in increasing world food output. Investments in agricultural research in other lands will be the key, but activities should not be limited to that. We also have a vested interest in training the people required to develop the indigenous institutional capability in other lands and in improving international capital markets and the flow of capital to agricultural development in the LDC's.

(*e*) Domestic agricultural research policy needs to be revamped. Two aspects of domestic agricultural research policy appear to be in need of change. The first is the balance between basic and applied research. With the apparent realization of much of the potential from existing scientific and technological know-how, the obvious need is to put a greater emphasis on basic research. Yet the current emphasis on accountability and the financial pressures on educational and research institutions puts greater emphasis on applied research. This emphasis needs to be changed.

Equally as important, new means of financing agricultural research need to be devised. The more elastic demand for agricultural products that the increasingly open economy brings with it confers on land owners and other resources that are inelastic in supply a larger share of the benefits from domestic research and development (R&D). Under these conditions, it is not likely that a consumer-dominated body politic will be willing to support domestic R&D as they have in the past.

Given that agricultural land owners and producers will now receive a larger share of the benefits of domestic R&D, a case can be made that they bear a larger share of the costs. The long-used check-off system used to finance cotton research is one means of solving this problem, as is the recent legislation on poultry and egg promotion and beef promotion. Alternatively, a land tax might be devised for this purpose, since an important share of the benefits of technical change will be realized in the form of higher land values. Still another means would be by way of an export tax, although at the present time the Constitution prohibits such a tax.

(*f*) New sources of productivity growth for labor need to be identified. Increases in labor productivity in agriculture are important if wage rates and the income of farm people are to continue to increase. Similarly, increases in productivity in the economy at large are important if aggregate growth rates of the past are to be sustained. The decline in outmigration from agriculture has implications for both of these.

For agriculture, it implies a decline in the rate of productivity growth for that sector. Growth in labor productivity in U.S. agriculture has been unusually high throughout most of the post-World War II period. It is not difficult to understand why. Output has been expanding steadily, the labor force has been declining, and other nonlabor inputs such as fertilizers have increased substantially. As a result, factor proportions have shifted markedly. The land-labor ratio has risen; the physical capital-labor ratio has risen, the fertilizer-labor ratio has risen; and society has imbedded more human capital in labor in the form of higher levels of education. It is little wonder that labor productivity has grown so rapidly.

The consequences of a decline in the rate of outmigration will be equally multifaceted. In the first place, the land-labor ratio should change more slowly. Additional mechanization can and undoubtedly will take place, although it is important to note that agriculture is already one of the most capital-intensive industries in the economy. The use of other inputs, such as fertilizer, can also be increased, but in this case the factor proportions will probably change at a slower rate in the future. As noted above, there is evidence of diminishing returns against land in the application of fertilizer. In summary, the expectation is that there would be a decline in the rate of growth of labor productivity as the rate of outmigration declined.

The data suggest that there has been a marked decline in the rate of productivity growth over the years, just as the analysis suggested (table 1). The time periods were chosen so as to coincide with observed changes in the labor market. The rate of outmigration started to decline in 1965; by 1971 it began to flatten out even more.

This decline in the growth rate of labor productivity is one explanation for the leveling out of the growth rate in total factor productivity in agriculture. It has been reinforced, however, by the decline in the growth rate of crop production per acre—or land productivity, a decline even more pronounced than

Table 1. Growth Rates (%) in Productivity of Land and Labor, Selected Periods, 1950–75

Period	Farm Output per Unit of Total Labor	Crop Production per Acre
1950–65	10.8	3.7
1965–71	6.9	2.0
1971–75	2.0	0.4

Source: Synthesized from data in Council of Economic Advisers 1976, tables B-84 and B-87.

the decline in labor productivity growth. Together, these data give one cause for concern about the potential for productivity growth as a source of output expansion in the future, unless there should be a major breakthrough in production technology.

The decline in outmigration from agriculture also has implications for the economy at large. In the past, an important source of aggregate growth in the economy has been the reallocation of labor from the low productivity agricultural sector to the higher productivity industrial and nonfarm sector (Denison). Given the magnitudes of the labor transfer during the post-World War II period, the gains from this source have been sizable. With the transfer process apparently nearing an end, this source of productivity growth for the economy at large declines or disappears.

This development points up the importance of productivity growth in other sectors of the economy if aggregate growth rates are to be sustained. The service sector, where some 60% of the labor force is now employed, is a strong candidate, and the growing government sector is especially important. The payoff to society of reducing the high level of unemployment among blacks in the 16- to 24-year old age group also promises to have a high social payoff.

Of more direct relevance to food and agriculture, productivity in the processing and distribution sector can be an important source of growth and a means of lowering food prices to consumers. Sixty percent of the food bill is provided for goods and services from this sector. Labor practices now impede the adoption of such technologies as the central boxing of meat, and consumers resist computerized checkout at supermarkets, both of which can be important sources of productivity growth.

As these examples indicate, the sources of growth are not lacking. They just will be different in the future than they have been in the past. But society does need to seek them out, and when changes in labor practices and other rigidities are needed to bring them about, those changes need to be made.

Emerging Institutional Challenges

The new macroeconomics of U.S. agriculture involves a decline in the outmigration from agriculture, a leveling out of productivity growth, the evolution of the U.S. economy into a more open world economy, and changes in the international environment. The institutional challenges to us as a nation and to us as agricultural economists are great.

The first challenge is to be successful in negotiations for freer world trade. The current Tokyo round of multilateral trade negotiations is potentially more important to us than the previous Kennedy round, especially if progress is made in liberalizing trade in agricultural products. If we can sustain the past movement towards freer world trade and at the same time extend the domain in which exchange rates float freely against one another, large steps will have been taken towards the much sought-after goal of world food security and without the political problems of a government-managed grain reserve.

Under such a system exports on the margin should shift sharply from one country to another in response to changes in exchange rates and in internal prices in countries around the world. Therefore, a major challenge in such a system will be to maintain confidence so that individual countries can depend on having open access to markets, either as buyers or sellers.

The evolution of such a system requires the introduction and development of new institutions that provide a means of making the emerging world economy work more efficiently. A more efficient system of monitoring world agriculture and diffusing the resulting information to the world economy is needed, as are improved marketing arrangements. Steps also should be taken to improve the functioning of the international capital markets, with all the political difficulties that that entails.

Clearly, the thrust of these suggestions is in the direction of strengthening an international market system to better serve the world economy. To some that may sound utopian; to others it will sound imperialistic. The truth of

the matter, however, is that important strides have already been taken towards an international market economy.

Domestically, we face challenges in both research and teaching programs. On the research side, there is not an adequate institutional capability to do the research necessary to understand world agriculture. Researching and understanding international trade per se will not be sufficient. To shape and reshape a continuously rational policy more understanding is needed about world agriculture and the forces that shape it, how foreign economic policies are shaped, and how changes in those policies influence international commodity and capital markets and in turn U.S. agriculture.

Changes are also needed in the educational program. Students need to be given stronger training in macroeconomics and in the aggregate aspects of agriculture. Their training also needs to be strengthened in trade and in the economics of an open economy. Finally, they need some familiarity with world agriculture and with the economic and other forces that shape foreign agriculture.

Our task in public education is no less great. The educational needs of the adult population are very similar to those of the students. In addition, some of the major policy choices to face in the years ahead have to do with the U.S. role in the world economy and how we relate to it. Rational policy will evolve only through an informed body politic.

Some Concluding Comments

Agricultural economics is by definition a sectoral discipline, which is both a source of strength and a source of one of the major weaknesses. The former is so because it has caused specialization in understanding the problems of a single sector of the economy. Our initial start in dealing with the art and science of farm management gave a strong underpinning in the microeconomics of the sector. The close association with correlary disciplines in the various schools of agriculture, which have for the most part been our academic homes, gave a perspective that few fields in economics have had.

At the same time, a sectoral emphasis has caused neglect of the linkages of agriculture with the rest of the economy and underestimation (or underemphasization) of the interrelationships between agriculture and the larger economy. Agricultural economics earned its spurs and has made most of its contributions to science and knowledge with its work at the microlevel. If there has been one major failing over the years, it has been this failure to grasp fully the macroeconomics of agriculture.

Agricultural economists have made important contributions to economic theory. For example, they have contributed as much to development economics as has any other subdiscipline of economics. They have contributed to methodological improvements and have also played an important role at the national policy-making level.

We are now faced with new challenges. The domestic structure of agriculture is changing, especially in the way that agriculture is linked to the nonfarm sector and in the contribution that agriculture makes to the larger economy. At the same time the U.S. is increasingly linked to a large and rapidly changing world economy. Events in the rest of the world are now as important to the strength and vitality of the food and agriculture sector as are developments in the domestic economy.

It is now almost an imperative that we give strong macroeconomic training to students, that we challenge them to know more about world agriculture and world economic development, and that we develop a research capability that will enable us to provide useful analytical and empirical inputs into the policy-making process and to effectively discharge larger educational responsibilities to U.S. citizens. Our challenge will be to do this without weakening the microeconomic work that is so much a part of tradition and that can serve so well in developing the macroeconomic theory and in doing the macroeconomic work that is before us.

A Contemporary Political Economy of Family Farming

Paul W. Barkley

Making sense of two ill-defined concepts is not an easy task. It must be undertaken, however, because people inside and outside of agriculture are asking about the family farm and how it relates to the political economy. The source of confusion centers on the changing organization of agriculture and changes in the control of resources traditionally used by North American farmers to produce crops and livestock products. It is suspected that this changing control is bringing considerable change in output, efficiency, and the distribution of spoils in the industry, but no one yet knows if this is so.

The fundamental changes in U.S. farming need not be recounted. Farm numbers have dropped, nonfarm capital has substituted for home-grown capital, the use of stock resources has replaced the use of flow resources, and formal information-gathering techniques have substituted for informal gossip. All this is known; some is only partially understood.

Similarly, the increased centralization of economic activity, the increased interdependence between the agricultural and the nonagricultural sectors, the resurgence of world trade, and the apparent worldwide fuel crisis are familiar attributes of the contemporary political economy. They impinge upon agriculture, but they need not be described here. It seems appropriate to turn directly to the main problem. How is the family farm related to the contemporary political economy and what relationships exist between economic society and the agricultural industry? This question is addressed by elaborating some definitions, commenting on production, exchange, and distribution within agriculture, and discussing agriculture's place in the political economy.

The Family Farm

Although there were family units producing agricultural products in antiquity, the family farm as we know it likely traces its origins to the enclosures. The enclosures broke the small fiefdoms of Europe, played a necessary role in releasing laborers for industrial pursuits, and gave land to individuals who could till it as they wished without subservience to the will or needs of the ruling class. In the eighteenth century, Thomas Jefferson developed ideas about the virtue and importance of men working land that they themselves possessed. Such orgaization brought incentive to produce, allowed individual freedom, and was expected to yield better husbandmen and citizens.

Like the world around it, the family farm has changed. A century ago, it was a place where a family utilized its own resources to produce the products needed to maintain itself and the farm firm. If surpluses were produced, the farmer entered into exchange agreements by selling crops and buying capital equipment, staples, and other consumer goods. With the advent of mechanized equipment and the subsequent demise of the horse, the family had extra labor—labor that either fled to the city or was utilized through expanded farm operations.

Even two decades ago, a family farm was a place where a multigenerational family could utilize its own resources to initiate and complete a production cycle. The family controlled the resources, made the decisions, and enjoyed or suffered the consequences. Decisions about producing the nation's food were dispersed among millions of small family units. Now the farm family is not expected to own the farm's resources nor is it expected to

Invited address.

Paul W. Barkley is a professor of agricultural economics, Washington State University.

The author is indebted to A. H. Harrington and L. F. Rogers for helpful critiques of a near-final draft. Early discussions with D. W. Holland, M. E. Wirth, and C. F. Feise also contributed to the substance of the paper.

supply the labor needed to operate the farm. In a recent, highly overdramatized article appearing in the revived *Saturday Evening Post,* Paarlberg defined the family farm as one "on which the greater part of the labor and decision making is supplied by the farmer and his family" (pp. 42–43). When accompanied by data saying 95% of U.S. farms qualify as family farms and that these account for two-thirds of the nation's total agricultural output, a comforting picture of families working together on independent units appears.

Paarlberg's definition, though somewhat standard in technical as well as popular writing, is extremely deceiving. It makes no provision for income goals or efficiency in resource use. There is room for suspicion that defining family farms as good, then declaring that 95% of the nation's farms are in this class, imputes goodness to a situation that includes much that is bad. Indeed, there is poverty, inefficiency, illiteracy, and immobility among Paarlberg's 95%. His definition draws attention away from this. The family farm as defined is apparently desirable but only on ethical, moral, and romantic grounds—issues that have been systematically trained out of agricultural economists and left in the realm of politics, literature, and poetry.

Political Economy

The definition of political economy is less romantic but no more secure than that of the family farm.[1] Agricultural economists are asking for a return to this branch of the discipline, but what do they have in mind? Are they asking for a return to the political economics of the classical economists, or are they asking for a return to the 1930s and 1940s when agricultural economics and agricultural economists had a stronger hand in determining the nation's agricultural policy? One must presume the former since only through it can much discipline be brought to the latter.[2]

What is the traditional political economy? The common feeling suggests that political economy is broader than just economics. It includes some notion of how policies affect economic affairs and how, in turn, economic affairs bring about changes in policy.[3] In the early nineteenth century, Ricardo was practicing political economy when he observed the effects of the Corn Laws on the incomes of people, their employment status, and the value of land. Ricardo used this observation as a springboard to clarify the theory of rent. In this case, a public policy led to elaboration and explication of economic theory.

A century later, the farm policies of the New Deal would have qualified as political economics on the same grounds. These were policies born of privation in the agricultural industry. The economists who worked with them came to understand the theory of the firm and eventually saw the need for an intensive modern study of farm management. They, no less than Ricardo, were practicing political economy when they extended theory after observing the consequences of a policy problem.[4]

The massive sales of wheat to communist nations, the public interest in private land, the world food shortage, and the distressingly high fuel costs may also bring the need for inquiring how exogenous influences affect agriculture and how happenings within the industry can impinge upon the outside world. If political economy is this broader view, surely it is a good thing.

However, political economy as seen by Ricardo, Malthus, Senior, Say, and Mill was more than a two-way inquiry regarding the causes and effects of economic policy. It was the general study of production, exchange, and distribution conducted in a society characterized by three distinct classes of people. With boldness that few of us would dare, Adam Smith divided economic society into classes of workers, capitalists, and landlords. Ricardo accepted this division and went on to say that "to determine the laws which regulate distribution among these classes is the principal problem of Political Economy" (p. 5).

The mainstream of economic thought that led from Smith through the classicals then on

[1] Contemporary definitions of "political economy" are hard to find. Reflective comments on the theme can be found in Jalladeau, G. Schultz, and Heilbroner.

[2] One of the more urgent pleas was made by Breimyer.

[3] Interestingly, Alfred Marshall took the opposite view. After defining economics to be "a study of the economic aspects and conditions of man's political, social and private life; but more especially of his social life" (pp. 42–43), Marshall suggests that economics "shuns many political issues which the practical man cannot ignore: and it is therefore a science, pure and applied. . . ." From this, Marshall draws the conclusion that the discipline "is better described by the broad term 'Economics' than by the *narrower term* 'Political Economy' " (emphasis added).

[4] Perhaps the best example of this was provided by T. W. Schultz.

through Marshall, Pigou, and into various U.S. traditions developed a revulsion for classes in society, so these were hidden behind a transparent veil called "factors of production." Class distinctions are still avoided by depending upon the categorization of factor inputs, and questions of how income is divided among people are almost always avoided by asking only how income is divided among factors. Had the discipline retained the class distinctions of the classical definition, the makeup of our profession and our collective inputs into policy formulation would be considerably different.

Production, Exchange, and Distribution

If political economy does dictate that economic analysis be conducted on a three-way basis, it makes sense to examine agriculture in each of three contexts: production, exchange, and distribution. Most could be said about production because the dramatic changes in agriculture have stemmed from changes in production practices, most having come in response to major changes in technology. The three-field system, the steel plow, the internal combustion engine, and the mechanical cotton picker each revolutionized at least a part of the industry.

Agricultural economists have done a capable job of inquiring into production. They have consistently recommended that inexpensive inputs be substituted for expensive ones and have stressed the trade-off between high variable incomes and low stable incomes.

Family farmers, no less than corporate farmers or subsistence farmers, have been apt students for and of economists' efforts. They have substituted capital for labor and have fine tuned along a continuum that stretches from complete specialization to extravagant diversification. U.S. farmers are to be congratulated for behaving as economists suggest they should in always searching for new and inexpensive ways to do old and expensive chores; they have learned to substitute science for art. In the present context, little needs to be said about the production process, political economy, and family farming. Production is interesting primarily because changes in it have a demonstrable effect on the process of exchange and on the institutions surrounding the distribution of income among factor owners.

All farmers enter into exchange relationships on either side of their production activities. Exchanges on the input side have increased in number and have become more complicated as various forms of productive capital have left the direct control of the family farmer and now reach him only through organized markets. Changes on the product side are no less intense because farmers have become increasingly remote from final consumers and have relinquished control over several productive activities. A class of intermediaries has sprung up to perform low-level processing functions that alter the form of agricultural commodities to fit consumer preferences. Farm operators, especially those in the family farm class, have continually heaped wrath on these processors, but clearly processors perform functions that the consumer is willing to pay for and that the farmer is unable to perform. The wrath is surely unwarranted, but it has become a part of the propaganda used to justify the family farm.

Processors of agricultural products can be used as a vehicle to point out one of the many paradoxical asymmetries evinced by farm operators as they consummate exchanges. The farmer has insisted upon high quality standards for purchased inputs. While noncertified seed can be purchased in voluntary exchanges among neighboring farms, certified seed must be of a specific high quality, and this quality must be guaranteed by the seller. Similarly, mixed feedstuffs for animals must be clearly and honestly labeled, and the chemical analysis of fertilizers must be shown on containers in which these inputs are sold. Since individual farmers have little market power, they have banded together to obtain legislation insuring the quality of inputs. In cooperating, the individuals have abdicated some of their independence. They have paid for it in the form of higher input prices, but the uniformity of the input coming with mandated quality requirements has apparently been worth the price.

Similar forces have motivated the purchasers of many farm products. Processors, like farmers, can be more efficient if they have regular streams of uniform raw materials (inputs) coming into their plants. About twenty-five years ago, many processors of farm products began to reach back to the farms in an attempt to make the flow of farm products regular and to insure that the products were uniform in size, shape, color, and quality. This

made as much sense for the processor as input quality control had made for the farmer. In order to achieve certain gains in efficiency, processors had to insinuate themselves into production processes carried out on individual farms and insist that inputs of certain kinds be applied at certain times and that certain quantities of crops be delivered on certain days. The processor had to assume control of production. This was done in the era of vertical integration that swept through the vegetable, fruit, poultry, and livestock enterprises in the 1950s.

Vertical integration was unpopular with farmers. They apparently resented the encroachment on their capacity to make decisions and, ostensibly at least, would rather have maintained the capability of using the wrong inputs to produce an inferior product for sale on a day when it could not be processed. At the time it was happening, the erosion of this opportunity to err was viewed as precursor to the demise of the family farm. The response was clamorous with major farm groups as well as individual operators castigating processors for doing what farmers themselves had already done: taking steps to insure the quality and quantity of a factor input.

The concept of the family farm did not vanish with the advent of vertical integration. Instead, it adjusted to accommodate the new form of business organization. After vertical integration took hold, the farm family became a labor pool using resources controlled by nonfarm decision makers. Rather than threatening the family farm, integration of production and sale activities seems to have benefited those who at first condemned it. Successful farm operators accepted the superior managerial skills of the processors' fieldmen as part of the integration process. Now, the contract that allows involvement in a vertically integrated production process is almost a property right and has taken its place along with land ownership, water rights, peanut allotments and the conservation reserve as part of the farmer's bundle of rights.

But the asymmetry of these essentially bargained exchanges on either side of the production process has escaped attention. The psyche of the farmer says that he is free to exist as a small unit and to make his own decisions. Society has indulged him in this fancy. Apparently this ideological bent allows the farmer to impose rules on the suppliers of his inputs, but it does not allow the purchasers of his products to similarly impose on him. Here, perhaps, is the making of a noteworthy study of the farmer's role, his self-image, and how these characteristics affect his behavior in exchange.

The third dimension of classical political economy relates to distribution. Of all the themes treated by economists, this is surely the most evasive and consequently it has received very little analytic attention. Robbins' modern definition of economics contains no hint about distribution, and the marginal conditions of maximum welfare abstract from the issue to the point of threatening their own internal compatibility. Marginal analysis when conducted in a partial equilibrium framework is strict: distribution is determined by factor rewards determined by a factor's contribution to the production process. Under this scheme, the distribution of family income depends on the number of factors a family controls. This view of distribution is comforting to an analyst. It is objective, rigorous, free of value judgment, and provides access to numerous analytic hypotheses; however, it has a serious flaw. While it can lead to determining when distribution is not in accord with the rules of the margin, it cannot lead to prescriptions about what incomes should be. The same market mechanism that capably allocates resources does nothing to insure that a resource in its highest and best use will receive sufficient rewards to maintain itself.

For a time in the late 1960s, economics and agricultural economics came out of the distributional reverie supplied by the marginal analysis and began to describe poverty in agriculture; the conclusions were not highly rewarding. These agricultural economists proved only that the poor in agriculture were poor because they could not command sufficient resources to be wealthy.

Many agricultural and farm programs began as income programs intended to buoy the returns to an economically beleaguered industry. However, given the peculiar institutional relationship that exists between the farm family and its resources, the labor share has seldom been the residual claimant of record. Net returns in the short run—quasi rents in the parlance of rent theory—have been imputed into the value of fixed resources. Moreover, family labor has likely been dreadfully underpriced, exaggerating the claims other resources have on the farm's returns. The truly skilled manager who has been able to keep a

small family farm solvent only through ingenious manipulations of factors may find that when external forces impinging on the farm's economy finally require liquidation, the skill that kept the farm running is not rewarded. The net returns to the operation—operator and all—are imputed to land and other fixed factors. The only access the farmer has to rewards for his flow of skill is to sell the stock resources that have been the object of that skill. The problem is especially distressing in cases where the land is not owned by the operator. The superior skills of the operator become high land prices that eventually accrue to the nonfarming landlord.

In sum, political economy, as traditionally construed, is a discussion of production, exchange, and distribution. While the field of study has many interesting facets, and these form interesting interfaces with the family farm, a discussion of the contemporary political economy of family farming is not a particularly fruitful exercise when carried out on a farm-by-farm basis. The real value of studying the two in the same context comes from society's point of view.

The Social Significance of Family Farms

Examining the social significance of family farms requires a modification in approach. Instead of concentrating on the family as a labor pool and decision-making unit for a single farm, the focus changes to the way in which factors are held—the property rights possessed by the farmer. This nation has always placed high regard on private ownership of land and other natural resources. The private ownership of land, however, opens considerable opportunity for society to exploit the owner of the resource. Contemporary writers are quick to point out that the family farm is "resilient" and able to withstand low prices, poor weather, and inferior inputs. While it is true that individual farms and U.S. agriculture as a whole weathered the economic catastrophe of the 1930s without significant reductions in output, it is misleading to credit the industry for this occurrence. More accurately, society found it easy to exploit the people and resources committed to farming.

In contemporary society, the small holder who uses his family's labor in conjunction with his fixed capital and land is in an ideal position to be exploited. His variable costs are low and, once a crop is in and a biological process started, the costs of continuing the process until harvest are extremely low. Low variable costs provide an incentive to maintain output even if product prices fall to disastrously low levels. After harvest, fixed costs must be paid, but even they are subject to deferral. Thus, the nation's family farmers consume the depreciation on all forms of capital, pay themselves extremely low wages, and even defer payment of taxes knowing that this deferral can be continued for two or more years before the threat of foreclosure emerges. During this time, production continues, the family farm appears to prosper, and the nation has its food.

This elementary point regarding continuation of production is made in all basic textbooks. The more important relationship between the economic organization of the agricultural industry and the economic performance of the society is too frequently ignored. Stability in the general economy is not insured by keeping agriculture resilient. However, reasonable stability in the food supply is. To date, agriculture has been kept resilient by maintaining or encouraging small units on which operators have relatively high equities and relatively low variable costs. The family farm is the ideal form of organization for providing this combination of resource control and resilience. An agriculture organized in this fashion becomes a perfect shock absorber for not only its own errors but also for those imposed upon it through other forces in the economy.

Resource control in agriculture is changing. Vertical integration changed the control of inputs on (usually) small parcels of land. Land ownership patterns are changing, the threat of corporate management has been growing in intensity, and control of credit has become awesome both through its concentration and its archaic rules designed to protect the banker rather than his customer. With all these forces operating to fragment control of agriculture's productive resources, the legitimate question becomes: who is in charge? Like the farmer's relationship with the processor, his relationship with the fragmented controllers of factor inputs is asymmetrical. Any one "controller" can order production stopped, but no one controller can order production to start. The farmer becomes more than risk taker and laborer; he is the initiator who must poll various resource controllers and solicit their coopera-

tion in an increasingly joint venture. This role of the farmer as a multidimensional negotiator is not understood nor is it, I think, being investigated with any degree of intensity.

The Consequences

Bringing these diverse themes together into a cohesive lesson for agricultural economists requires mixing economics with folklore and these in turn with an important part of the American political and agricultural traditions. It is relatively easy to comment on definitions. The definition of the family farm has changed in the past and is certain to continue to change in the future. Families will continue to work together and make decisions. The political economy of the decision-making process will also change as added segments of the agricultural industry are standardized, vertical integration continues to expand on the product side, and supply cooperatives continue to usurp farmers' decision-making power on the factor side of the production process. Even though negotiated and bargained exchanges will become fewer in number, those left will become more difficult to make. If agricultural economists continue to be involved in decision making, it will become necessary to learn whether twenty easy, daily decisions are, in aggregate, more difficult than a single decision that allows avoidance of the twenty! This sounds like a trivial exercise, but it has the makings of a fascinating riddle and may pave the way for extremely useful research regarding the relationship between the decision-making process and the allocation of resources on family farms.

But other problems intervene. Power is clearly being concentrated within the agricultural industry and the ancillary industries that supply agriculture with inputs and purchase its products. The Lorenz curve that results from plotting land holdings against farm size is creeping away from the diagonal as is the curve plotting farm receipts against farm numbers. Bigness is emerging. This nation indulges in another of its fantasies when forced to ponder the effects of this concentration of power on the organization of agriculture and the relationship between agriculture and the remainder of the economic system.

But the concentration of control raises legitimate fears. In concentrating, those who make decisions are removed from the resources and are likely to be motivated by the economic forces that influence firm behavior—product prices, profits, internal rates of return, and pay-off periods. If agriculture is organized on these lines, the great loss will not be the loss of moral and cultural virtues of family farms but the loss of the capacity of the small-holder system to maintain production in a time of economic adversity. An agriculture in which resource control is centralized may be more efficient, more productive, and more responsive to the demands of food consumers and may provide higher incomes to persons involved in the ownership of resources used in the production process. However, it does not have that most desirable of all characteristics: guaranteed stability in output.

In this setting it is legitimate to ask whether the family farm should survive with any more than a rhetorical dimension. It should because the social consequences of not having an exploitable food producing class are too high. If the institution is to be preserved, it will have to be preserved on noneconomic grounds.

One way to preserve the family farm is to make it the object of religious-like veneration among all citizens. Some careful distinctions will need to be made in such a movement. The object of veneration should not be the stolid simplicity of the man, woman, and pitchfork as in Grant Wood's painting "American Gothic," which gives virtue to the people who run the farm. The object in a present-day context will be the farm as a farm. Moreover, the adulation will need to be accorded the sole proprietorship in agriculture rather than just any sole proprietorship. Although the small farmer has much in common with the small restauranteur, the independent corner grocer, and the independent fuel dealer, society must concentrate with special attention on the farmer. He must plant and harvest each year, and society's stake in this process must not be confused with society's stake in the record shop, the back country lawyer, or the local Hallmark card dealer.

A Program of Work for Agricultural Economists

It would be foolish to recommend that agricultural economists, either individually or as a professional association, ignore the family farm or treat it as only a political or romantic

construct. If indeed 95% of all U.S. farms are family farms, the sheer force of their numbers dictates that members of this profession become aware of their existence and build them into research, teaching, and policy programs. This can be done in many ways, but some themes appear more important than others. The most important centers on the generality of the family farm. It is general in location (all parts of the United States have them) and quite often general in the sense that it produces a mixture of crops and livestock. The plea to inquire into family farms is a plea for generality among researchers. Researchers in agricultural economics have become extremely specialized, so much so that in pursuit of specialty many have lost sight of all but a few characteristics of agriculture or the role of agriculture in the economy as a whole. Our extremely awkward agricultural policy of the past decade is an outward manifestation of this loss of integration and purview. Four lines of research can be suggested to correct this problem.

First, the economic role of the family farm in U.S. economic society must be better understood. While intuition and the deductive logic of production, efficiency, and welfare economics tell us that the family farm is a good thing in terms of its ability to absorb adversity, there is no hard evidence showing how much adversity can be absorbed. Looking ahead to a world with high possibilities for unrest and instability, this kind of information would be more than just useful. The adversity absorption coefficient for U.S. agriculture could be found by close inquiry into cost structures, alternative sources of income, tax delinquency laws, bankruptcy provisions, and family income plans. Such studies should concentrate on the farms rather than on the individual enterprises. Society needs to know when its farms will shut down.

Accompanying this inquiry is a second theme, related to Ricardo's prime interest in political economy. How will income be distributed among those in agriculture as various shut-down points are approached? Although much economic research is related to and depends upon specific classes of resources, knowing the functional shares among those classes are not particularly revealing in the case of agriculture. The farmer, especially if he is made in the classic mold of the family farmer, is at once capitalist, land owner, and laborer. It does little good to know that two-thirds of the product (income) goes to labor if it is not known how an individual himself is distributed among the classes. What happens when returns to family labor drop to intolerably low levels while returns to capital remain high? What kind of income maintenance programs will need to be designed to keep appropriate sets of resources from being broken apart? Answering these questions will require extremely innovative research.

Third, the problem of asset control in agriculture is a pressing one. It is somewhat interesting to know whether assets controlled by the Boeing Company, the Coca-Cola Company, or Mutual of Omaha are any more or any less productive than those controlled in blocks suitable for 160-acre implements. It is more essential to learn about the institutions that govern the acquisition and the abandonment of control. These institutions will become important regardless of how resources are controlled or who controls them. Research into institutions affecting agricultural production is very tedious because only a few agricultural economists have the training or the patience to undertake it. The main body of institutional research in agricultural economics has emphasized the institutions surrounding natural resources, especially land and water. It will take some effort to transfer this skill to studies of institutions that affect labor, credit, managerial skill, and the exercise of power in market exchanges.

Finally, the agricultural economist must recognize that the family farm exists in a context that impinges upon the decisions made within the farm and the industry. Some agricultural economists should be asked to study this context and to inquire into the public benfits of the essentially private firm. The latter will be broadening if a handful of scholars are able to make progress in understanding the publicness of private enterprise. Perhaps the overextended specialization among us will weaken, and we will find ways to put our research to good use.

In this study of context there will be the utmost temptation to call in other disciplines to inquire into decision making, social significance, and the political acceptability of various family farm themes. At some point these temptations must be honored. For now, the economist has ample work within his own discipline. The economic problems should be understood before we submit to the difficulties of interdisciplinary research.

In sum, the family farm exists as an economic, political, and romantic entity in the U.S. economy. It will continue to exist in a political economy, and professional agricultural economists will be well served by looking at the whole farm from the point of view of the classical attributes of political economy. Moreover, these activities regarding production, exchange, and distribution will need to be addressed from some point of view other than that held by the individual farm operator, which is too specialized, too narrow, and does not lead to an adequate policy base. The social importance of family farms needs to be addressed. Society has a large stake in the institution and has maintained the institution by turning public vice into private virtue. The terms of this coexistence need explication. It is our job to bring substance to that view so that the family farm becomes recognized for its ability to absorb miscalculation and adversity and for its role in a confusing and fast-moving political economy.

Agriculture in International Economic Relations

Thorald K. Warley

The systematic study of international economic relations has commanded increased attention in recent years among both economists and political scientists as the economic relations between nation states and groups of countries have intensified, changed in character, and generated a weighty set of new and complex problems. Matters pertaining to foodstuffs and other primary commodities are the subject of both unparalleled cooperation and dangerous frictions between members of the international community. Those involved in the conduct and the study of international affairs attach great weight to commodity policy issues in international economic relationships. Equally, a range of "external" considerations have been elevated in importance in national policy formulation for the agricultural and food sector. Thus, it is appropriate and timely that the American Agricultural Economics Association (AAEA) consider the subject of agriculture in international economic relations.

In a paper of tolerable length one can touch on only some of the more salient features of a subject of enormous scope and infinite complexity. I omit entirely any comments on the topics of world hunger and food insecurity, on the manifold interdependencies between energy pricing and world agriculture, and on the subject of "food power." My purposes are modest. First, I provide a short inventory of some of the more prominent characteristics of contemporary international economic relations. This serves as an introduction for some observations on the agricultural matters that are of importance in the economic and political relations between major groups of countries. Finally, I share with you some of my concerns about the participation of members of our profession in international commodity policy formulation and in conducting research and teaching in this area.

The Changing Character of International Economic Relations

Even the most casual observer of international affairs must have a sense that the world is in the midst of a vast historical transformation in security, diplomatic, and economic relations. Five characteristics of the changes that are afoot seem to have particular import for understanding the place of agriculture in international economic affairs.

First, as Cooper has noted, whereas strategic balance, territorial integrity, and ideological competition once constituted the main stuff of higher foreign policy, now foreign economic policy is the core of foreign policy. The world *problematique* is increasingly defined in terms of the economic relations between states, and its content is heavily weighted with such specific matters as trade and monetary arrangements, economic development and stability, supplies of food stuffs and raw materials, transnational production, claims on the resources of oceans, and the like.

Second, there is a markedly greater degree of pluralism in world political and economic relationships than hitherto. It was once appropriate to view the world as a bipolar system dominated by the two nuclear super powers. Now the world is shaped by the actions of a larger number of actors, including the European Community, Japan, Organization of Petroleum Exporting Countries (OPEC), the Group of 77, multinational corporations, transnational elites, and the secretariats of intergovernmental organizations. Power itself is no longer primarily military. New sources and types of political power can be found for instance in command over key resources such as food and energy and in voting coalitions in

multilateral institutions. The use of power has become more complex in a multipolar world of shifting alliances in which different coalitions of countries face each other on different issues (Hoffman).

Third, the influence of the United States on international economic affairs has diminished. The "architecture" of the postwar international economic order was conceived by the United States, and the operation of its monetary, trade, and development subsystems was secured and nurtured by this country. Now the Bretton-Woods monetary system has been discarded; the tenets of the General Agreement on Tariffs and Trade (GATT) centered trade system (liberalism, nondiscrimination, and observance of a multilateral code of fair commercial practice) are under assault; and the developing countries have rejected the core assumptions upon which the old economic order was founded. International economic relations must be reconstructed, but the United States does not now have the hegemonic power to shape international relations according to its philosophy and preferences. Indeed, the impulse of the United States to recoil from a leadership role is strengthened by its past experience of having had to bear a disproportionate share of the costs of sustaining the old economic systems—money, trade, aid, and world food security—and by the lack of appeal it now encounters internationally for its conception of a liberal world economic order.

Fourth, international economic problems have increased in scale and complexity and the linkages between them have multiplied. This has had two important consequences. There is a growing lack of congruence between the span of problems that afflict nations and the reach of the authority and the competence of the nation state. Furthermore, interdependencies between problems have proliferated to the point where it is increasingly difficult to identify discrete problems and apply discrete solutions to them. Necessary conditions for accommodating to this aspect of international economic relations include the willingness of nations to pool their sovereignty in the attack on shared problems; agreement on the nature of solutions and modes of cooperation; and the creation of intergovernmental institutions that are structured and equipped to address present-day issues of common concern. Reality it somewhat different. Nation states are loath to surrender their autonomy. Sharp differences in the analysis of the causes of problems and in preferred solutions are the essence of international economic disharmony. Most of our postwar multilateral institutions are vertically structured, narrowly compartmentalized, and provided with mandates that are not coincident with either discrete contemporary problems or clusters of interrelated issues. Their membership spans countries at such disparate stages of economic development and with such divergent economic and political ideologies and objectives as to impede their effective functioning.

It is now commonplace to observe that functional economic interdependence is an important part of our material prosperity and that this interdependence is leading to a genuine world economy and an embryonic global polity. However, a fifth characteristic of evolving international economic relationships is a growing perception that economic interdependence has its costs as well as its benefits. For instance, while U.S. advocacy of an open world economy is partially posited on the conviction that economic interdependence fosters peaceful political relations between nations, it is quite clear that deepening economic interactions breed political frictions and resented asymmetries as well as amity. Additionally, the corollary of international interdependence is increased national vulnerability to instabilities and dislocations of external origin. Multiplication of transnational attachments erodes the authority of sovereign states by widening the area of conflict between national objectives and international obligations and by narrowing the range of national policy choices. Awareness that few countries see interdependence as a goal, and most are sensitive to its costs, can help clarify our understanding of the economic behavior of nations. Thus, the concept that states seek an optimum degree of interdependence that is normally less than the maximum is helpful in accounting for the tenacity of economically irrational protectionist policies with respect to agriculture and other sensitive industries. Furthermore, the enduring conflict between those who advocate a "market-oriented" regime for trade in farm products and those who counter with a demand for a "market-organization" approach to commodity production and trade through international agreements is really a clash between a prescription for a degree of interdependence that knows no bounds other than the uncertain dictates of market forces on

the one hand and a determination that the degree of interdependence should be limited, codified, and collectively managed on the other.

I am persuaded that these characteristics of international economic relations are to be found in the agricultural issues that currently lie between groups of states and, further, that these issues can be better understood if they are viewed against this conceptual backdrop.

Interregional Relations in Agriculture

Developed Country Relations

Discussions on the future shape of trading arrangements for temperate zone agricultural products among the advanced countries are centered in the multilateral trade negotiations currently in progress under the GATT. The matter of establishing an internationally coordinated system of nationally held grain reserves now being explored in the International Wheat Council in London will likely move to Geneva if anything of substance can be agreed on that nettlesome subject.

The trade negotiations are concerned with the traditional objective of securing freer access to international markets by further lowering tariff and nontariff trade barriers. But, in addition, the current negotiations are distinguished from the six previous GATT rounds insofar as an important part of their purpose is to strengthen the rules on fair trade by extending the articles of the agreement on such matters as national subsidy practices, access to supplies, and the use of safeguard procedures.

The United States has insisted that the negotiations must yield both freer and fairer trade conditions for her agricultural exports. The reasons are well understood. As a study by the Congressional Budget Office concluded, multilateral liberalization of trading arrangements for farm products is an optimum trade strategy for the United States in terms of the attainment of a mix of goals including enhancing domestic price and income stability, maximizing farm income, sustaining balance in external payments, and minimizing the need for government intervention in and budgetary expenditures on the agricultural sector. Improved access to foreign markets for U.S. farm products will be crucial if the recent gains in export earnings, farm incomes, and farm asset values should prove to be due to the congruence of unusual and transient events. But beyond the immediate national economic interest is a broader purpose. Agricultural trade arrangements are characterized by neomercantilist national policies, discriminatory regionalism and bilateralism, and the widespread use of national interventions that distort trade but are largely unfettered by the international rules of commercial practice embodied in the GATT. Hence, bringing this aberrant sector more surely within the framework of an open nondiscriminatory trading system governed by rules of acceptable conduct has implications for the continuing viability of the liberal international economic order that the United States has sought so long to create and sustain.

By contrast, the conviction of the member countries of the European Community (EC) is that the creation of further opportunities for expansion of trade in agricultural products must occur within the framework of a regulated international trading regime. The community has therefore proposed that international agreements be negotiated for a range of commodities, with the specific provisions of such agreements being tailored to the needs of each product. In the all-important grains sector the community has proposed that an international commodity agreement be established providing for minimum and maximum prices, implemented by the manipulation of reserve stock levels, and with reciprocal supply and purchase commitments. Japan, while exhibiting its characteristic passivity in international forums, is known also to favor trade arrangements for agricultural products that would assure her access to supplies at stable prices that might be provided by formal intergovernmental commodity agreements, multilateral stocking arrangements, and tighter rules governing the national use of export controls.

It has been customary in the United States to describe the EC's and Japan's stance on agricultural trade arrangements in both the Kennedy round and the current negotiations as camouflage for an unwillingness to expose their inefficient agricultural industries to international competition. Certainly, the political influence of the farm lobbies in Europe and Japan is real enough, and the importance of the French-German bargain and of the Common Agricultural Policy as foundation and cement respectively of the union are still central political equations in the European experiment. However, the conventional "protec-

tionist" argument does not sufficiently explain the gulf that separates the United States and other advanced countries on agricultural trade policies. The impasse on agricultural trade policy is deeply rooted in differing national economic systems and contrasting derivative views of the appropriate configurations of international economic relations.

In the United States the ascendent assumption about the national economy is that economic activity should be governed to the maximum degree possible by market mechanisms. As Shonfield has pointed out (part I), this economic philosophy carries over directly into international economic affairs. U.S. commercial diplomacy is primarily motivated by the desire to expand the area of influence of competitive markets and aimed at securing changes in the domestic economic policies and frontier measures of other governments that distort international production and trade. Additionally, the United States regards detailed commercial codes as important because they enshrine the rules of fair trade practice, provide an objective basis for determining when the rules have been transgressed, and provide a quasi-judicial process for dealing out measured penalites for infractions.

This mixture of laissez faire and legalism does not mold the behavior of other countries. Both the EC and Japan conduct their national economic affairs with a much greater degree of *dirigisme* than does the United States. More especially to our purpose, they regard their domestic agricultural policies as components of a set of integrated industrial, regional, and social policies designed to secure, at a measured pace and by government guidance, the kinds of societies they are trying to build. This philosophy and practice carries over into their international economic relations also. External relationships must be managed in such a way as not to jeopardize the attainment of broad national sectoral and regional development goals, to force an intolerable pace of industrial restructuring and social adjustment on particular groups, or to lead to an unplanned degree of dependence on external sources or excessive exposure to externally generated instabilities. Furthermore, since internal goals are constantly being redefined, the preferred style of conducting commercial relations with other countries favors pragmatic marginal adjustment through continuous negotiations and conciliation of disputes by mediation rather than the satisfaction of judicial rights embodied in binding international codes.

With such profound differences in economic philosophies and diplomatic styles, it is small wonder that exchanges between the United States, Europe, and Japan on that most sensitive of areas, agriculture, often appear to be a dialogue of the deaf.

One looks to the future with some pessimism. The time has long since passed when the United States could impose its preferences on its friends, let alone its antagonists, and the drift of the times seems to be away from both the unmanaged interdependence characteristic of open systems and the codification of interdependence in enforceable laws. Furthermore, forecasts of a rising supply price for U.S. agricultural output (Schuh 1976) and the instabilities experienced in world agriculture in the past few years have manifestly not disposed Europe and Japan to either accept a lower degree of agricultural self-sufficiency or to further expose their economies to the vicissitudes of unregulated world food markets.

One fears that the response of the United States to a failure to have its way on agricultural trade matters might be a refusal to complete the negotiations, vigorous use of the retaliatory provisions of the 1974 Trade Act, and a disinclination to cooperate in other areas of economic policy. Such a reaction would be a grievous disproportion, and perverse. Within the multinational trade negotiations there are important mutual gains to be had in liberalizing trade in manufactures and in selective strengthening of the GATT code. Beyond that, there is a host of intragroup matters requiring attention, great urgency in coordinating the developed countries' response to the demands of the third world and working out how best to conduct economic exchanges with socialist countries, and a variety of global systems problems that will only yield to cooperative solutions initiated by the advanced countries.

Meantime, Diebold's judgment seems sound when he suggests that the way agricultural trade issues between the developed countries will be resolved is not by a "catching up" to the more liberal arrangements achieved for other products "but a leap into a kind of cooperation which has not yet been established in other fields" (p. 299). However, Miriam Camps's observation that "the advanced countries are not yet ready—intellectually,

psychologically, bureaucratically—for the radical course of far more integration of their economies, far more coordination of policy, and far more collective management" (p. 43) seems *a fortiori* and ominously true of their relations on matters pertaining to agriculture.

East-West Relations

Only the most mindless optimist would suppose that military security and ideological competition will soon cease to dominate the relationship between the western democracies and the socialist countries. Nonetheless, expanding economic exchanges offer immediate and mutual economic gains, and one hopes that expanding economic interdependencies will raise the economic cost of a retreat from the process of mutual restraint we term detente.

There are a number of enduring lessons about the character of international economic relations between capitalist and centrally planned economies to be learned from the experience of selling grains to the U.S.S.R. over the past few years. I identify four.

First, the very method by which centrally planned economies conduct their economic transactions with market economies poses problems. In particular, the skillful exploitation of unequal access to information between monopsonistic procurement agencies and uncoordinated sellers can result in an asymmetrical distribution of the benefits of economic exchanges. Indeed, because central planners can consider the totality of the implications of their external transactions while externalities and secondary effects are not perceived in advance—or cannot readily be internalized—in market economies, there is perhaps an inherent propensity for socialist countries to capture a disproportionate share of the gains from foreign commerce. This view has been disputed (CIEP, p. 53), but I am not persuaded that it is without substance.

Second, permitting Russia free access to western food supplies impedes the smooth functioning of the food system in the rest of the world. In particular, so long as the Russians gear their production and consumption targets for livestock products to the peaks of their variable indigenous grain supplies, prevent rationing of consumption and resource reallocation by price variation, and make up their deficits by sporadic forays into world grain markets, they are bound to be a significant destabilizing influence. As we have witnessed, the variability of Russian import demand for grains can dislocate livestock production and consumption, destabilize prices, redistribute incomes, and complicate commercial relations between exporters and regular customers. These disturbances reach into the furthest corners of national societies and the world economy.

The U.S.S.R. is not the only source of variation in export demand. As Paalberg has noted, what distinguishes this component of world trade is that, while imposing substantial burdens on other parties by their incursions into foreign markets, the Russians have been able to avoid sharing the costs of improving the performance of the world food system—improving information, creating security and stabilization reserves, and providing balance of payment support, food aid, and agricultural development assistance to developing countries facing inflated bills for food imports. The "free-rider" feature is objectionable enough. What is worse is that the U.S.S.R.'s nonparticipation may impede the attainment of improvements that those who are willing to work together are seeking to create. For instance, it is questionable whether a durable multilateral system of grain reserves could be effectively operated—and hence negotiated—in the absence of a major trader and a prime source of the instabilities the reserves are designed to attenuate.

Finally, ad hoc accommodations to the problems caused by unstable and unpredictable export demand can force international economic relations in directions that lead away from preferred goals. Thus, while the political necessity and the economic advantages of the 1975 U.S.-U.S.S.R. agreement on grains are well understood, still and all it extended bilateralism, discrimination, and government intervention in international transactions, which are precisely the features of trade in agricultural products that U.S. commercial diplomacy has long been bent on eliminating. Indeed, the conclusion I draw is that whereas the reshaping of international economic relations between advanced countries with predominantly market economies may well be directed towards expanding the scope for market forces and reducing the influence of government interventions, this is unlikely to be feasible in dealings between groups of countries with radically different economic systems. This trade is in part politically moti-

vated, and it would appear that its conduct will require a high degree of political direction, too. This requirement in turn may necessitate changes in domestic marketing institutions and demand a multilateral code of trade rules that differ substantially from those embodied in the GATT.

North-South Relations

One of the more dramatic changes that has occurred in world economic and political relationships in the past two years is the success of the developing countries in shifting the subject of their poverty from the periphery of world affairs to the center. Their accomplishment has many causes including the use of their numerical preponderance and voting solidarity to ensure that their cause heads the agenda of all intergovernmental meetings, the success of OPEC as an examplar of their expectations and supporter of their objectives, and the growing awareness of the advanced societies that economic growth and political stability in the world is dependent upon reaching an accommodation with the two-thirds of mankind who now constitute the "down-and-ins."

The objective of the less developed countries (LDC's) is to crown their political freedom with their economic emancipation. They are seeking to achieve the latter by having international economic relations changed in ways that will place a floor under their present poverty and assure their accelerated economic development for the future.

Those who have followed the debates in the sixth and seventh special sessions of the U.N. General Assembly, the north-south dialogue in the Conference on International Economic Cooperation, and the course of the fourth United Nations Conference on Trade and Development (UNCTAD) will be aware that the concept of "a new international economic order" that the LDC's have demanded encompasses every facet of the relationship between the industrialized countries and the developing world—aid, trade, monetary arrangements, private foreign investment, control over resources, access to technology, the location of production activities, shared responsibility in decision making, and adaptations in the structure and functions of multilateral institutions. In each of these areas the LDC's are demanding not marginal tinkering but fundamental changes, the cumulative result of which would be to make their accelerated development a prime purpose of international economic relationships.

The new international economic order calls for the establishment of a comprehensive global policy for commodities (UN 1974). The so-called "integrated program for commodities" as articulated by the UNCTAD secretariat has seven principal elements (UN 1976): an expanding set of intergovernmental commodity agreements for an open-ended list of products, a common financing facility for those agreements with provisions for buffer stocks, a network of intergovernmental purchase and supply commitments, index-linking of the prices of LDC commodity exports to the prices of their imports, compensatory financial arrangements to guarantee the total value of their exports in real terms, improved conditions of access to advanced country markets, and the deliberate transfer of primary processing activities from rich to poor countries.

These measures are designed to serve two ends. The first is to improve the performance of commodity markets in economic terms by enhancing market stability and thereby the allocative function of prices and by allowing greater scope for comparative advantage to determine the location of production and processing activities. The second goal is to improve the performance of world commodity systems in political terms by effecting an international redistribution of income in favor of the poorer countries via a comprehensive, politically directed, regulatory regime governing commodity production, pricing, and trade.

These proposals constitute a truly revolutionary challenge to the existing economic order and to at least three of its central assumptions. Among these assumptions were, first, that with temporary derogations and special assistance, the LDC's would progressively adopt the predominantly market-oriented system of international exchanges employed by the advanced countries and characterized by "arms length" trading by private individuals responding to market signals. Second, trade in commodities would fit for the most part into the same kind of international economic regime as trade in manufactured products. Selective concerted interventions by governments in commodity markets might be necessary on occasion, but these were to be regarded as aberrant and transient, to be contemplated only where exceptional

economic wastes could be demonstrated, and to be implemented only when very favorable ratios between the benefits and costs of interventions were assured. A third assumption was that the international trading system was agnostic with regard to income distribution. The system's central concern was efficiency in resource use and thereby the growth of world product, not its distribution. If the international distribution of income resulting from competitive trade was politically unacceptable, presumably redistribution should be effected by direct transfers and not by the manipulation of the terms of trade and market output and shares, since such manipulations were prone to widen international inequalities in income and cause inefficiencies in world resource use.

It is apparent that the demands of the LDC's for the creation of a comprehensive, continuous, regulatory regime for commodities, in which income redistribution would be a prime goal, and in which the levels, shares and directions of production and trade, and the terms of trade would be established by political decision rather than market mechanisms, are a profoundly important development in international economic relations.

Characteristically, the main burden of making a response to these far-reaching proposals has fallen to the United States. The U.S. initial position was to maintain that the old economic order had served advanced and developing countries well, to deny that a new economic order was in the making, to stress that the primary concern must be with ensuring the growth of world output rather than with its distribution, and to emphasize that adjustments in economic relations must confer mutual benefits on both rich and poor countries to be acceptable. Subsequently, however, the United States has advanced some forty specific proposals for changes in world economic systems that would favor the developing countries and particularly the poorest among them (Kissinger 1975, 1976). All of these proposals are consistent with a liberal and a more just economic order. Many of them are coincident with the LDC's aspirations, e.g., expanded aid, easier access to western capital and technology, accelerated trade liberalization, more liberal compensatory finance provisions, and a willingness to consider on a case-by-case basis the merits of commodity arrangements with short-run stabilization objectives. Other U.S. proposals offer constructive alternatives to LDC positions. However, to the elements that the LDC's regard as central—the use of commodity policy to transfer resources to the LDC's, agreement that intergovernment commodity arrangements should be a permanent and widespread feature of world commodity systems, a prior commitment to common funding of buffer stocks, indexation of commodity prices and export receipts, and the contrived redistribution of production and processing activities—the United States has been resolute in its opposition.

How these matters will be resolved cannot be known at this time. What is certain is that the first real dialogue of mankind has now been joined and that international commodity policy is its focal point.

If we accept that relieving the present plight and improving the future prospects of poor people in poor countries is important to the kind of world our children will inherit, then the technical task is to find efficient means by which a more equitable distribution of a growing world product can be effected. There is much in this area to engage and test our profession. However, a sterner test is to decide whether our sense of belonging to a global society is sufficiently well developed to convince us that the concept of social equity should extend beyond national boundaries and exist between nations as within them.

Implications for National Policy Making

Policy making in an open economy is infinitely more complex and difficult than in one that is closed. As Tumlir has observed, the very concepts that have traditionally guided policy making—national sovereignty, national interest, and national power—are not easily defined for a country deeply involved in an interdependent world of interrelated issues. National policy makers in such a setting need to give systematic and simultaneous consideration to the domestic effects of changes in the external environment and to the external effects of changes in national policies. In a situation where "everything is related to everything else" the numbers of groups with a claim to participate in the policy formulation process multiplies and so, too, it would appear, does the scope for disputes over priorities and authority.

All this is obvious enough. The substantive point is that the fractionated existing structure of government may not be well suited to deci-

sion making and the conduct of supportive research in a situation where domestic and international issues are increasingly intertwined. Jaenke has noted that we are experiencing serious difficulties in making the adaptations in governmental structures necessitated by the perceived need to reach beyond "farm" policies to consideration of the issues of national "food" policy, i.e., a movement towards adapting sectoral policies to the wider needs of macroeconomic policy. The problems are even more complex when decision processes must find an accommodation between domestic agricultural policy requirements and goals in the wider areas of foreign trade policy, foreign economic policy, and foreign policy. The structural response to date—adding "internationalists" to the U.S Department of Agriculture and bringing people with some knowledge of agricultural matters into other branches of government; creating a mess of coordinating committees, councils, and boards; and shifting final decision authority to higher levels—may not be functionally or politically the best solution. Manning has suggested that the problems of decision making on foreign economic policy issues in the United States have already grown to the point where a radical restructuring of government has become necessary.

Implications for the Profession

International agricultural trade policy and the broader topic of international commodity policy is an area where our profession should be more heavily engaged than is presently the case. This is particularly true for a country like the United States, which is preeminent in international exchanges in farm products and which will continue to play a decisive role in determining the arrangements and rules governing global interdependence in primary commodities.

Over the years individual members of the AAEA have made many distinguished contributions to the analysis of international agricultural trade issues. But, looking at the picture in the round, it is a cause for both surprise and concern that so few agricultural economists have chosen to make a sustained commitment to the study of the international dimensions of national agricultural policy or of international commodity policy, that so much of the best work on international trade in agricultural products is being done by persons who would not claim to be agricultural economists, and that our profession at present is making such a minimal contribution to whole areas of the great contemporary debate on the future world order governing the production and exchange of primary commodities.

This is an unfortunate situation because we as a profession have so much to offer. I am not thinking only of our great tradition of addressing practical problems, of accomplishments in blending theory and empirical analysis, and of skills in systems analysis and construction of models that allow policy makers to anticipate potential future events and examine the trade-offs between policy alternatives. These are durable strengths of the profession of agricultural economics that will be required as the debate on international economic relations in agricultural products and other commodities moves from ideological confrontation to the search for practical measures of wide political acceptability. Rather, I have in mind that the course of world trade policy is beginning to move along paths we have already traveled. For instance, the subject of nontariff trade barriers, which is one of the more vibrant fields of study in international commercial policy, is only a generalization of a problem with which we in agriculture have long experience, i.e., the causal linkage between the growing involvement of national governments in industrial or sectoral policies and the adoption of neomercantilist trade policies.

Further, agriculture provides thirty years of experience—little of it encouraging but all of it illuminating—of international attempts to attenuate the adverse trade effects of domestic policies by policy harmonization, multilateral codes and agreements, and a diverse array of ad hoc cooperative measures that others now see as important instrumentalities in the collective management of interdependence (Warley). There is absolutely nothing in the perceptions and analyses of the LDC's of the nature of their commodity problems—and in the limitations of the solutions they propose—that is not instantly familiar to anyone who has spent his time working on price and marketing policies for farmers in advanced societies. Thus, our skills are required; the insights we have acquired in a domestic context are adaptable to a wider canvas; and our experimentation in international agricultural trade problem resolution contains lessons of wide applicability to international economic policy.

However, there are also some limitations on the ability of our profession to work effectively in the broad problems of agriculture in international economic relations. I mention but three items of what could be a lengthy bill of particulars.

First, we are paying a price for our overwhelming preoccupation with domestic agricultural affairs. Too many people for too long have thought about American agriculture as though it operated in a closed economy, with trade a marginal activity and even an optional extra. The result is that there does not appear to be a large number of people in the profession who are familiar with the content of the contemporary international dialogue on agricultural trade arrangements and future international commodity policy and the linkages between these matters and other aspects of international economic policy. This deficiency is magnified by the process whereby the center of gravity of national decision making on agricultural trade and commodity policy matters seems to be shifting away from the USDA, in which many of our profession are employed, and which is the principal institutional channel through which the rest of us who work outside government maintain some contact with policy priorities and policy formulation. The issues of foreign economic policy with which agricultural matters are linked and which increasingly mold national "agricultural" decisions lie entirely outside the USDA and are largely beyond our ken. Thus, the narrowness of our interests, of our setting, and of our contacts is an inheritance that bears heavily upon us.

Second, even in our role as economists qua economists, some weaknesses exist in the triad of our professional equipage of theory, methods, and data, and in work habits that impede effective functioning. Most economists have a solid in training microeconomics and quantitative analysis. If we were exposed to macroeconomics, it was likely taught primarily in terms of a closed economy. If we took a course in international trade (normally an elective), it probably did not deal with commercial policy nor was it integrated with international monetary economics or the economics of growth and development. Thus, compartmentalized curricula prepare us poorly for work on multifaceted international economic issues. I suspect that there is still truth to the ancient charge that we are "economic imperialists" in the sense that problems are defined as being primarily economic when they are not and that we are unwitting ideologues to the degree that efficiency is elevated to the status of a goal of economic activity rather an instrumental variable.

Economists are now less guilty than previously of neglecting to measure distributional effects of policy alternatives but, as Rivlin has chided us, we are convinced that we cannot say anything useful to policy makers about the welfare implications of alternative distributions of income. The assumption that the redistribution of income (even if effected by the first-best method of direct transfers) necessarily entails some sacrifice of product is probably at variance with the truth. These matters are not unimportant, for the considerations of security, stability, autonomy, equity, and status that are neglected in our received theory are the very mainsprings of national policy behavior and the core issues of international economic policy. On methods, the complaint of Krause and Nye about economists' reliance on comparative statics methodology is telling, since the scale, pace, and cost of adjustment necessitated by changes in trading arrangements are key matters for policy makers everywhere. The gaps in the data needed to adequately parameterize the external environment are so well known as to be scarcely worth remarking. But our inability to handle the realities of noncompetitive market structures, disequibria in exchange rates, and other factors that cause differences between market prices and social costs should be particularly worrisome to a profession that seems to venerate freer trade arrangements. As to work habits, one notes the paucity of genuine multidisciplinary work (although all would agree that it is desirable) in a situation where the domain of problems is rarely purely economic. Schuh has cautioned us against a professional proclivity for looking backwards in an attempt to understand the troubled present and foretell the perplexing future (1975). This is a particularly dangerous practice in studying agricultural trade and international commodity policy since in these areas of international economic relations the players, the rules and, indeed, the game itself have all changed.

Third, the institutional settings in which most economists work are not well adapted to functioning in this field. As suggested above, the structure of government is not congruent with emerging problem areas, nor ideally

suited to either decision making or the conduct of associated supportive research on linked issues. However, I am most particularly and personally aware of the constraints on the ability of agricultural economics faculty in the land grant colleges to make a contribution commensurate with our numbers and our talents. We have already been reminded by President Farrell that our research contribution is circumscribed by our being organized as a cottage industry, by too much of our work being episodic and noncumulative, by our entrepreneurial style, and by the research apprenticeship requirements of our graduate students having too large an influence on the research we choose to do, the way in which we do it, and the time taken to bring our inquiries to fruition. In our teaching function, the learning environment provided may also not be conducive to equipping students to function as policy makers, researchers, and opinion molders on the complex issues of agriculture in international economic relations. Few of the land grant colleges having agricultural economists who specialize in international agricultural trade policy also have significant numbers of faculty in related disciplines who are concerned with other aspects of international economic relations and international affairs with whom breadth and synergism in training might be achieved.

Conclusion

I have suggested in this paper that the problems of evolving international economic relations in agriculture are important and complex and further that some obstacles may exist to the successful participation of our profession in their resolution. While I am not required to provide a detailed plan for the cleansing of the Augean stable, let me end with three observations.

First, economists need to reexamine the intellectual foundations that condition the way we think about international economic relations, mold the analytical work we do and—particularly in the United States—guide national commercial diplomacy. We need to disenthral ourselves of theories that distort our perception of reality. Might it be, for instance, that the paradigm of the "objective optimality and moral neutrality of the perfectly competitive market" is less useful to us in looking at the world than the alternative of the "stabilized mixed economy" in which, as in our national economies, international economic activity is part market determined and part politically directed and which is concerned simultaneously with efficiency, stability, and equity. To illustrate I would venture that it is abundantly clear that in addressing the proposals of the LDC's on international commodity policy the three are inseparably linked, for the LDC's will not cooperate in the reform of the international economic system unless the subjects of equity and stability are addressed, and their cooperation is required if the world economy is to function effectively.

Second, our profession should be less tunnel visioned and isolationist in its work on international agricultural and commodity policy issues. Of course, the problems of trade in primary commodities have their distinctive features but for the most part issues pertaining to agriculture in international economic relations do not constitute a discrete problem set, and they are not so perceived by higher-level policy makers. We have much to gain by consciously striving to meld our work into the broader stream of international economic studies and much to offer by using our agricultural case material to illuminate the tasks, problems, and possible solutions to managing the world's deepening economic interdependence.

Finally, I deem it important that the AAEA arrange for systematic consideration to be given to alternative institutional modalities by which the contribution of agricultural economists to the study and resolution of problems of agriculture in international economic relations can be extended and enhanced in value. The "mix" of institutional arrangements through which we can function includes intergovernmental organizations, agencies of national governments, non-governmental agencies with large in-house research capabilities like the Brookings Institution, research catalysts such as the Atlantic Council in Washington and the Trade Policy Research Centre in London, universities with a commitment to international economic affairs and established multidisciplinary research and teaching programs in the area (e.g., Johns Hopkins, Chicago, Harvard, and the Fletcher School of Law and Diplomacy), research networks with multiagency involvement and central funding and direction, programs to foster professional mobility between the international organizations, government

and academe, and, not least, the honored institution of the isolated cerebrating scholar. What is the comparative advantage of each of these settings and arrangements in the conduct of what types of research? Are selective strengthening and improved coordination necessary, and if so how might these be wrought? I am not able to answer these questions. But I do have a sense that the problems of agriculture in international economic relations are so important and pressing that muddling on will not necessarily ensure that we muddle through to new policies that will avert the dangers to the world economy and to world society that lurk in the unresolved issues of international agricultural trade and commodity policy.

Specific Sessions

The Economics of the Farm Family
(T. W. Schultz, University of Chicago, Chairman)

The Efficiency of Women as Farm Managers: Kenya

Peter R. Moock

The purpose of the study on which this paper is based is to investigate possible differences between male and female farm managers in the possession of, and means of acquiring, technical information relevant to agricultural production of maize (*Zea mays* or corn), the staple commodity of the area. Technical information is taken to mean knowledge relating to the manner in which inputs are combined. Producers are said to differ in technical efficiency when they experience systematic differences in the output produced from a given combination of inputs.[1] Allocative decision making, which has to do with the quantities of inputs used as distinct from the techniques of input use (cf. Shapiro, p. 2), is excluded from the analysis because of the absence of farm-specific price data.

The section that follows describes the geographic area, giving an explanation of the high proportion of female farm managers (relative to the ratios found in most farming communities, in Africa and elsewhere). Next, the data are described, and the model is set out in general terms. The empirical analysis follows, and finally, some conclusions.

The discussants for this session were Bruce E. Gardner of the Council of Economic Advisors and G. Edward Schuh of Purdue University.

Peter R. Moock is an assistant professor of economics and education at Teachers College, Columbia University.

The collection and early analysis of the data were supported by the Rockefeller Foundation and the U.S. Agency for International Development. During this period the author was affiliated with the Institute for Development Studies, University of Nairobi, and the Center for Research on Economic Development, University of Michigan. Appreciation is owed Wallace Huffman and T. W. Schultz for many helpful insights and Victor Levine and Kenneth Shapiro for commenting on an earlier draft of the paper.

[1] In addition to systematic differences, output may be subject to random disturbances.

Women as Farm Managers in Vihiga Division

The sample (described more completely by Moock 1973) consists of 152 maize farmers in Vihiga, an administrative division of roughly 200 square miles and 300,000 people in western Kenya. Reflecting the high average population density, the typical holding consists of seven resident members and 2.5 acres.[2] The area's response to population pressure is a pattern of circular labor migration, especially by male household heads. In a random survey conducted in 1971, one-third of farm heads were found to be currently away from the family farm, engaged in or searching for work. The typical farm head has spent nearly a quarter of his total years away. The mean cumulative migration period is eleven years.

In the head's absence, farm management is relegated to another farm family member, usually the wife of the farm head. Vihiga is a notable farm community for its extent of female management. In 1971, 38% of the division's farms were managed by women. Whereas women perform a substantial portion of the physical work on farms throughout Africa, as farm managers the women of Vihiga have assumed considerably more decision-making responsibility than is generally the case.

The Model

The variable list appears in table 1. Wherever meaningful, variables are expressed as area

[2] These are median estimates derived from an earlier probability sample of farms in the division (P. Moock 1971).

Table 1. Variable List and Summary Statistics

Name	Description	Sample	Male	Female
DV-YIELD	maize output per acre (200-lb bags)	17.6 (5.7)	17.8 (6.1)	17.1 (4.9)
Physical inputs and natural factors				
1. *SCALE*	area planted in maize (acres)	1.6 (1.1)	1.8 (1.2)	1.2 (0.7)
2. *PLNTP*	plant population per acre (1,000 plants)	9.6 (2.3)	9.8 (2.3)	9.2 (2.2)
3. *LABOR*	labor input per acre (hours)	983 (339)	974 (336)	1,002 (346)
4. *CFERT*	chemical fertilizer applied per acre (lbs.)	72.6 (57.8)	79.8 (59.1)	58.5 (52.9)
5. *HYBRD*	planted any of hybrid varieties (0,1)	0.89	0.92	0.84
6. *INSEC*	used insecticide (0,1)	0.31	0.39	0.16
7. *INTER*	interplanted legume among maize (0,1)	0.57	0.51	0.67
8. *SOIL*	Applied fertilizer or left field fallow previous season (0,1)	0.36	0.43	0.24
9. *HAIL*	hailfall damage (0,1)	0.82	0.80	0.84
10. *DAMG1*	moderate damage from erosion or striga weed (0,1)	0.22	0.25	0.18
11. *DAMG2*	severe damage from erosion or striga weed (0,1)	0.09	0.10	0.08
Information proxy variables				
12. *WOMAN*	manager a woman (0,1)	0.34	0	1
13. *SCHL1*	schooling, 1 to 3 years (0,1)	0.34	0.34	0.33
14. *SCHL2*	schooling, 4 years or more (0,1)	0.34	0.43	0.16
15. *MIGR*	migration experience (years)	9.4 (10.8)	12.6 (11.2)	3.0 (5.9)
16. *AGE*	age (years)	48.8 (12.3)	51.8 (12.6)	42.9 (9.3)
17. *XTNSN*	extension contact (index)	178 (92)	191 (98)	152 (72)
18. *LOAN*	loan recipient—special extension services (0,1)	0.43	0.50	0.29

Note: The summary statistics reported are means and, in parentheses, standard deviations. The full sample consists of 152 farm observations, of which 101 are managed by men and 51 by women.

rates, a procedure that reduces collinearity among inputs and transforms X_1 (area planted) into a measure of production scale. An estimate of *YIELD* (shelled and dried maize per acre) was obtained on each farm by sampling the stand and hand harvesting the selected parts of the crop. The mean was 17.6 "bags," which translates approximately as 63 bushels, per acre. All data were recorded during the principal planting season of 1971.

As a first approximation, the production model consists of the single multiplicative equation

$$(1)\ YIELD = aX_1^{b_1} \ldots X_4^{b_4} e^{(b_5 X_5 + \ldots + b_{11} X_{11} + u)},$$

where e is the base of natural logarithms and u is a random disturbance variable. The tractable inputs, i.e., those affected by farmer decisions ($X_1, \ldots, X_8$), and three indicators of natural phenomena (X_9, X_{10}, X_{11}) are defined in table 1.

This model is incorrectly specified if knowledge can be assumed to enter into the production process. If farm managers hold different levels of technical information, and the correlations are nonzero between information and variables X_1 through X_{11}, then the estimates of b_1 through b_{11} are biased. The variables specified as the direct and indirect sources of technical information are formal schooling (X_{13} and X_{14}), experience (X_{15} and X_{16}), and extension contact (X_{17} and X_{18}).[3] In general these are factors found to affect the allocative ability of farmers.[4]

The final information proxy (X_{12}) is the focus of this paper. The right-hand columns in

[3] The appropriate algebraic specification of these variables, in the model "corrected for management bias," is by no means obvious. The equations reported in the empirical section below are the "best performing" of many that were estimated.

[4] See the midwestern U.S. studies by Huffman and by Fane and the general review by Schultz. The effect of educational factors on technical efficiency has been called the "worker effect" of education, as distinct from the "allocative effect" (Welch).

table 1 allow comparison of means (and standard deviations) for the male and female subsamples. On the average, output per acre is smaller for women (17.1) than for men (17.8), but the difference is not significant even at the 0.10 probability level.[5] The absence of a significant difference is provocative when we observe that in general the women use smaller bundles of physical inputs, especially store-purchased inputs, than their male counterparts. They use noticeably less chemical fertilizer (X_4) on average and are less likely to plant one of the hybrid seed varieties (X_5) or to use insecticide (X_6), although the mean labor input (X_3) is marginally higher on female-managed farms than on male-managed ones.

The proof of the pudding, should anyone doubt that these women were more technically efficient maize farmers than the men, is the positive coefficient on X_{12} in a regression equation (not shown) that controls for physical inputs and natural factors, i.e., in the estimation of model (1), with the term $b_{12}X_{12}$ added to the expression in parentheses. The b_{12} estimate is 0.066, suggesting that a woman obtains 6.6% more output at the mean levels of input use than does a man. This coefficient is significant at the 0.10 level.[6]

[5] Geometric means were even closer numerically—16.4 and 16.7.

[6] It falls just outside the critical region for rejection of the null hypothesis at the 0.05 level; the t-statistic is 1.63, and the critical value, 1.66.

The empirical section to follow is an analysis of the male-female efficiency difference. Two questions are explored. (*a*) Do the men and women of Vihiga benefit differentially from schooling, experience, and extension contact? (*b*) Do we observe input-specific productivity differences in the production relationships, for the male and female subsamples, when we have accounted for information sources that shift the relationship neutrally?

Empirical Analysis

The analysis begins with three estimations of a production model in which information sources ($X_{13}, \ldots, X_{18}$) are assumed to affect inputs ($X_1, \ldots, X_{11}$) neutrally. The estimated equations are given in table 2. Equation (*a*) is based on observations of male management only; equations (*b*) and (*c*), on female.[7]

Comparisons of the regression coefficients in equation (*a*) with those in equation (*b*) or (*c*) suggest several intriguing interactions between variables in the equations and the manager's sex, the criterion used in partitioning the sample. Some of these interactions are "tested" in the following equation based on the full sample of 152 farms (a prime indicates

[7] In equation (*c*), the school-extension interaction term is omitted, since the correlation between *SCHL2* and the product variable is 0.998 for women (cf. 0.881 for men).

Table 2. Regression Estimates for Examining Male-Female Differences in Technical Efficiency

Variable	(a) Male (n = 101)		(b) Female (n = 51)		(c) Female (n = 51)

$$

Whereas a little schooling (one to three years) is associated with higher yields for the women in our sample, this does not apply to the males. In the men's case the relationship appears to be an inverse one between some schooling and technical efficiency. On the other hand, those who have attained four or more years in the formal system, men and women alike, do obtain more output per unit of input on average than do farmers who have not been to school.[9]

Equations (*b*) and (*c*) in table 2 suggest that migration experience (years away from home) is a detriment to a woman's technical skills as a farmer, though the coefficients on *MIGR'* are not significant in two-tailed tests.[10] There is no indication in equation (*a*) that prior absence affects a male manager's skills in one direction or the other. A reasonable interpretation of this is that men, when they "go to town," typically leave the family at home and, through visits and correspondence, manage to keep informed about the farm. Women who migrate are usually accompanied by husband and children. With no immediate family left on the farm, they do not learn of new techniques in farming. The equations in table 2 indicate that the manager's age correlates positively with technical efficiency, as predicated, but only for women.[11] The correlation does not exist for men. These interactions, while interesting, are weak and do not hold up in any equation based on the full sample. Thus, the experience variables are left out of equation (2).

Equation (2) indicates that exposure to the Ministry of Agriculture is associated with greater technical efficiency, provided the farmer is male and not too well educated. The elasticity with respect to *XTNSN* is 0.03 for males with three years or less of schooling, but the effect vanishes for men with four or more years attainment and is not present in the case of women.[12] All else being equal, the possession of a government loan for the purchase of maize inputs (seed, fertilizer, and insecticide) is associated, in table 2, with smaller yields for female managers—a paradox since loan recipients were to be given close supervision.

In table 2 there are some apparent differences between the male and female subsamples in the size of the effects of various inputs on the output measure. Two of the differences are significant, and one nearly so; these appear in equation (2). The women seem to have made better use of labor in the production of maize than the men; they benefited less from

[8] The dummy variable *WOMAN* does not appear by itself in equation (2). When added, its coefficient, while positive, is not significant, nor is the coefficient on the female-labor product variable (the two are correlated at 0.997).

[9] Taking the partial derivative of equation (2) with respect to *SCHL2* and using the mean value of *XTNSN'* (4.348) yields $\partial YIELD'/\partial SCHL2 = 0.177 - 0.033(4.348) = 0.034$. Judging from table 2, this estimate probably understates the effect of *SCHL2* for women, though not for men.

[10] The sign of b_{11} could not be predicted a priori, since the content of migration experience is nowhere indicated in the data set although this dimension is known to vary substantially across farm managers.

[11] Age (migration time held constant) serves as a measure of experience on the family farm and, at least as such, should be a direct indicator of production knowledge.

[12] The index *XTNSN* is based on five binary indicators of extension contact: "Since this time last year, have you . . ." (*a*) been to consult a Ministry of Agriculture (MOA) instructor? (*b*) been visited by a MOA instructor? (*c*) attended a MOA crop demonstration? (*d*) attended a MOA animal demonstration? (*e*) attended a course at a Farm Training Center? The procedure used to weight indicators is described elsewhere (P. Moock 1973, pp. 160–65).

the density of the maize stand (*PLNTP*). The returns to production scale appear positive for women and negative for men, although in neither case is the effect significantly different from zero. *Ex post* explanations of these differences are highly speculative and are not attempted in this paper.

Conclusions

This paper has looked at sex-linked differences in production knowledge on the part of small-scale maize farmers in an area of Kenya. If such differences do exist, they are likely to be quite local and transitory. The hypotheses tested here relating to male-female differences in technical efficiency are nondirectional ones. To conclude, the findings are summarized and some interpretations are advanced.

First, the impact of schooling on output, other factors remaining the same, is greater for the women than for the men. The men who had been to school for just a few years performed worse on the efficiency criterion than those who had never been to school. The author concludes that literacy and numeracy, skills emphasized in primary education, are applicable to the acquisition of information used in small-scale farming, as evidenced by the schooling-output relationship for women.

The men who advance further in school are more likely to participate in the search for off-farm employment. Generally, it is only the more able individuals who find and keep jobs. Thus, men found managing farms despite educational credentials may have lower than average ability. This selection mechanism biases the male subsample with respect to the overall ability distribution but probably does not apply to the women, who are seldom expected to find work off the farm. It may also not apply to men with four or more years of school. These very educated men often find off-farm employment locally (e.g., as shopkeepers or primary teachers), which allows them to look after their farms at the same time (J. Moock).

Another striking finding has to do with the impact of the extension services on farming. The women seem not to benefit, as the men do, from extension contact, perhaps due to the marked male orientation of the services as provided by Kenya's Ministry of Agriculture. The staff consists almost entirely of men, the few exceptions dealing exclusively with "home economics" (nutrition and health). Moreover, much of the ministry's agricultural instruction takes place at the chiefs' *barazas* (regularly held meetings), attendance at which is seen particularly as the prerogative of male elders. Although women do attend, their participation is limited. The ministry makes scant use for instructional purposes of the churches, in which women play a much more active role.

Some farmers in the sample received maize input loans in 1971, granted through the ministry in conjunction with Kenya's Agricultural Finance Corporation. As credit recipients they qualified for special extension services. The loans were extended that year as part of an experimental rural development program. In planning the program, the government staff was divided, a vocal minority arguing against the inclusion of women, whose farming skills and whose obligation to repay debts (under existing laws) were considered dubious. Although this view did not prevail, and some women received credit, this skepticism may have exacted its toll, since the women with loans got smaller yields on average than did the women without them.

The Value of the Productive Time of Farm Wives: Iowa, North Carolina, and Oklahoma

Wallace E. Huffman

Farm wives allocate their time outside of the household to two work activities, farm and off-farm work. Although few studies have attempted to determine the value of the time of farm wives devoted to farm production, the value of their time is important for understanding the level and fluctuation of farm household income and the changing time allocation of farm wives.

The study on which this paper is based focuses on assessing the value of time spent by U.S. farm wives at farm work. The data on wives' farm work were derived from the 1964 *Census of Agriculture* (U.S. Dep. Commerce 1967, 1968). These data have deficiencies, but until surveys are revised to better measure the working time of farm wives, these and similar data are the best available. The results of this study show that farm work by farm wives contributes significantly to farm output and that the marginal product of their time at farm work compares favorably with their nonfarm wage.

The paper is organized as follows. First, participation of farm wives in farm work is discussed. Next, the empirical analysis describes the data, empirical model, and the results. The last section presents the implications.

Participation of Farm Wives in Farm Work

Much of U.S. agriculture continues to be organized around the institutional structure of the family farm, and husband-wife families are the predominant family type. Modern economic growth and the accompanying adjustments have, however, brought significant changes in farms and farm families. During the past fifty years, growth in the demand for nonagricultural products relative to agricultural products and concommitant adoption of labor-saving agricultural technology have created economic incentives for large numbers of people to leave farming; those farms that remain have become larger and more mechanized.

In both farm and nonfarm households birth rates have fallen during the past two decades, and households have purchased many new durable goods, some of which are labor saving. Both factors have contributed to a reduction in the demand for wives' household time, thereby releasing additional time for work outside of the household and/or for "leisure" time. Furthermore, evidence shows a rising participation of farm wives in work outside of the household. This pattern is similar to the rising labor force participation of nonfarm wives (U.S. Dep. Labor).

Farm wives are indeed an important source of labor on farms. But the magnitude and change in this labor input is difficult to assess because of a paucity of data and deficiencies in data that are collected. In the *Census of Agriculture,* except for 1964, neither the number of wives working on farms nor their hours (or days) of farm work are collected. In other data, many working farm wives are not counted as being employed in agriculture. The primary reason is that most wives working on family farms are classified in the occupation of unpaid family workers. The Bureau of Labor Statistics (BLS) (U.S. Dep. Labor 1960, 1972), Bureau of the Census (U.S. Dep. Commerce 1972), and U.S. Department of Agriculture (1965) fail to count as being employed the unpaid family workers who work less than 15 hours during the survey

---

Wallace E. Huffman is an assistant professor of economics, Iowa State University.

Journal Paper No. J-8585 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa. Project 2078. T. W. Schultz and John Miranowski provided helpful comments on an earlier draft. G. Wozniak provided computational assistance.

week. A secondary reason is the timing of surveys, given the seasonality of farm work. For example, the BLS labor force participation rate survey is taken in mid-March, clearly a slack time on most farms. A third reason is that multiple job holders are classified by the BLS and the Bureau of the Census as working in the industry where the largest number of hours are worked. Thus, farm wives with both farm and nonfarm work may be counted as working only in the nonfarm sector.

The special farm labor report of the 1964 *Census of Agriculture* does provide comprehensive national estimates of farm work by farm wives (U.S. Dep. Commerce 1968, tables 3 and 4). This report uses a broad definition of farm work and contains data on hours of farm work for fifty-two survey weeks of a year for all farm household members.[1] These data show an annual average participation rate in farm work by farm wives of 42.8%, varying from 37.1% in January to 48% in June (see table 1).[2] Wives reporting farm work devoted an annual average of 19.9 hours to it per week, varying from 17 hours in January and March to 22.3 hours in July. (Farm operators, who reported farm work, worked an annual average of 41 hours per week.) Thus, although these data show a relatively high rate of participation by farm wives in farm work, the average number of hours of work per week is significant but not large.

Data on the participation of farm wives in farm work for other years are unavailable. Thus, a trend cannot be established. But one could hypothesize that the long-term trend in wives' participation in farm work has been upward, although not as rapid as the labor force participation rate for all women, with cycles about the trend caused by disturbances—major wars, business cycles, and cycles in farm profits—in the farm and nonfarm labor markets. The increasing mechanization of agriculture—especially size, versatility, and power accessories of tractors—and mechanization of livestock feeding have made physical strength less important for many farming activities. Tractors with radios and air-conditioned cabs have improved the quality of working conditions, especially in crop production. The steadily falling number of hired workers and teenage children in farm households leaves only wives on many farms to provide human assistance with two-person farming activities. The generally increasing size of farm businesses and the dynamic economic environment facing farmers have increased the expected return from accurate and complete business records, and farm wives do much of the farm-business record keeping.[3] Also, as more farm husbands take full- or part-time off-farm jobs (U.S. Dep. Commerce 1967, pp. 514–18; 1973, p. 178), wives are left to supervise and do the farming.

We cannot forget that the off-farm labor force participation rate of farm wives has risen significantly from 16% in March 1959 to 26% in March 1971 (U.S. Dep. Labor). Thus, increasing hours of off-farm work may account for all the increase in hours of nonhousehold work by farm wives.

Table 1. Labor Force Participation by Farm Wives on Family Farm

Month	Rate[a] (%)	Hours/Week for Wives Working
April 1965	41.2	18.7
May	46.9	20.1
June	48.0	21.9
July	47.4	22.3
August	45.7	21.9
September	44.2	20.6
October	43.9	21.0
November	42.1	20.2
December	38.4	17.4
January 1966	37.1	17.1
February	36.8	17.2
March	37.8	17.1
Average, annual	42.8	19.9

The Empirical Analysis

The productive value of farm wives' time in farm work is to be assessed by estimating an aggregate production function. The data, empirical specification of the model, and the empirical results are presented and discussed.

[1] Farm work is defined as farm work or chores, work in fields, milking, care and feeding of livestock and poultry, care and repair of equipment and buildings, keeping farm records, and planning and supervising farm work.

[2] The labor force participation rate is calculated as the ratio of the number of farm wives working to the number of farm operators working during the survey week for farm operators and wives who worked on their own farm and were not paid a wage. This is not a conventional definition of labor force participation, but it seems appropriate here.

[3] This conclusion is from a report prepared for a different purpose (Schreier).

The Data

The observations are per farm county averages for all 276 Iowa, North Carolina, and Oklahoma counties. These observations were chosen because in these states agriculture continues to be an important industry, the family farm continues to be the predominant institutional structure, and the states represent different geographic regions of the United States—Midwest, Southwest, and Southeast—that have different on-farm and off-farm work opportunities for farm wives.

County tables from the 1964 *Census of Agriculture* are the primary data (U.S. Dep. Commerce 1967, 1968). Farm outputs and inputs are measured as flows. Output by final product type is gross product and is measured as value of sales, home consumption, rental value of farm dwellings, government farm program payments, and net increase in farm inventories. The inputs of husband, wife, and hired labor are derived from flow data on actual numbers of days worked on farms.[4] Man-(woman-) days of farm work per year are derived from adjusted weekly hours of farm work by farm operators (nonoperator household members) and from annual expenditures on hired labor.[5] Education of farm husbands (wives) is an index derived as an income weighted average of the number of farm operators (wives of farm operators) in seven different schooling completion classes.

The land-and-building input is measured as the rental on the current value of farm land and buildings; the fertilizer and seed input is measured as price weighted primary plant nutrients plus expenditures on seed. Machinery services are the rental on an inventory of a selected group of machines on farms in 1964 plus expenditures on petroleum products. The livestock input is measured as the rental on the inventory of breeding stock plus expenditures on purchased livestock and feed. An agricultural extension input is derived from unpublished Federal Extension Service data for 1960 as the annual average number of one-tenth man-days spent on crop and livestock activities by agricultural extension agents (USDA 1961).

The arithmetic mean value of annual days worked by Iowa wives of 105 is much larger than for wives of North Carolina (40) and Oklahoma (64).

The Empirical Specification

The empirical specification of the production function is

$$(1)\quad \ln Y_{ij} = \alpha_{IA}D_1 + \alpha_{NC}D_2 + \alpha_{OK}D_3 + \sum_{l=1}^{k=3} \alpha_l \ln X_{ijl} + \sum_{l=1}^{k=3} \beta_l \rho \ln X_{ijl} + \mu_{ij},$$

where ρ is the share of final livestock output in total output, $E\mu_{ij}^2 = \sigma_i^2$, and D_i is a 1-0 state dummy variable. The specification permits the input-output relationship to vary by product mix of output and the intercept and variance of the disturbance of the function to differ across states. The appropriate estimation procedure for equation (1) is weighted (generalized) least squares. (See Huffman 1976b for more detail.)

The Empirical Results

The results from fitting equation (1) to the 276 observations of per farm county averages are reported in table 2. All the estimated α's are positive and significantly different from zero, except for the coefficient of fertilizer and seed input. The input coefficients, $\alpha_l + \rho\beta_l$, (and partial elasticity of output with respect to X_l) for wife labor and three of the other inputs differ significantly by product mix of output. For wife labor, the input coefficient declines as ρ increases. By assuming that variable factors are paid proportionally to their marginal product and total payments just exhaust output, the estimate implies that the factor cost share of wife labor is largest on crop farms and declines as the relative importance of livestock output increases. The results also yield implications on factor ratios. As ρ increases, the cost-minimizing ratio of wife to hired labor increases, but the ratios of wife labor to other inputs decline.[6]

The three right-hand columns of table 2 provide estimates of an agricultural produc-

[4] Estimates of the partial elasticity of substitution between these labor inputs are not particularly large (Huffman 1976b).

[5] The variables are defined the same as in Huffman (1976b), except for land-and-buildings input and the grouping of fertilizer, seed, and livestock into two input classes. See Huffman for more details (1976a).

[6] Setting marginal rate of substitution of X_i for X_j in production and exchange equal, the sign of $\frac{\partial(X_i/X_j)}{\partial\rho}$ is determined by the sign of $\beta_i\alpha_j - \alpha_i\beta_j$.

Table 2. Estimate of an Aggregate Agricultural Production Function for Iowa, North Carolina, and Oklahoma, 1964

Input	Regression Coefficient (t-ratios)	Implied Coefficients (t-ratios)		
		$\bar{\rho}_{IA} = 0.66$	$\bar{\rho}_{NC} = 0.33$	$\bar{\rho}_{OK} = 0.53$

	(−11.15)			
ρ × wife woman-days × wife education	−0.161			
	(−11.15)			
D_1	−4.462	−4.462		
	(−4.11)			
D_2	−4.226		−4.226	
	(−4.11)			
D_3	−4.429			−4.429
	(−4.19)			
R^2	0.999			
$\hat{h}_j$		1.472	1.485	1.477
(s.e.)		(0.075)	(0.076)	(0.075)
$\hat{\sigma}_i^2$		0.0045	0.0186	0.0080
$\hat{\hat{\sigma}}_i^2$		0.0037	0.0217	0.0075

Note: These weighted least squares estimates of the parameters of the production function are based on averages for 276 counties of Iowa, North Carolina, and Oklahoma. β's that had small t-values when all coefficients were estimated were constrained to being zero, and the two-stage weighted least squares estimation procedure was repeated. Weights are the $\hat{\sigma}_i^2$'s.

[a] Variables are in natural logarithms, except for extension and ρ, which are in level form.

tion function for Iowa, North Carolina, and Oklahoma, respectively. The coefficients of each function are evaluated at the mean value of ρ for each state subsample. The estimates of the scale parameter (h_j) for the functions are significantly larger than unity. Thus, for all three states, the results imply economies of scale in agricultural production. The scale parameter is largest for North Carolina and smallest for Iowa, but none of the differences is statistically significant. Differences in the intercepts for the three functions do not imply efficiency differences; they are largely the result of procedures used in deriving the variables.

Implications

A major postwar change in the U.S. economy has been the rising labor force participation rate of married women. An immediate consequence is larger household incomes and larger quantities of goods and services produced and consumed. For farm households, increased hours of work by wives requires allocative decisions on working time. Additional hours could be used to increase the total quantity of available farm resources to permit a substitution of wife for hired labor and other inputs. Alternatively, additional hours of work could be devoted to nonfarm wage work. A

Table 3. Mean Marginal Products for Representative Farms, 1964

[a] Marginal products are calculated from the minimum variance unbiased estimate of conditional mean output (Goldberger) using geometric means of inputs and $\hat{\sigma}_j$'s (table 2). Standard errors are calculated using the equation for exact variance of products (Goodman).
[b] The numbers in brackets are cost per day in 1964 of respective type of labor. For hired labor the cost is the state average daily wage rate (USDA 1965), and for husbands and wives, the cost is the geometric average daily wage rate for off-farm work by farm husbands and wives, respectively (U.S. Dep. Commerce 1967).
[c] Arithmetic mean for input.

comparison of the implied marginal products from this study of wives' time, adjusted for economies of scale of about 1.5, with the nonfarm wage rate of farm wives (table 3) shows that farm family incomes in Iowa and Oklahoma (North Carolina) would have been larger in 1964 if additional hours of wives' time had been allocated to nonfarm work (farm work).[7] None of the differences between marginal products and wage rates are statistically significant. One does puzzle at the reasons for the large differences across the three states in the marginal product of wives' time.

Even if mean changes in family income are the same for additional hours of farm and nonfarm work of wives, other effects will differ. The return from added farm work is more difficult to identify than regular wage payments for nonfarm work because it is obtained as net farm income (a residual), which is a return to several "unpaid" factors and is subject to large annual variation due to abnormal weather conditions and output prices. Because variation in nonfarm wage income and net farm income are not highly correlated, additional hours of nonfarm work by wives opposed to farm work reduce the variance in farm household income. If households face significant credit rationing or are risk averse to variation of income, they may prefer added nonfarm work for wives even when the expected nonfarm wage is less than the expected marginal product of wife's time from farm work.

Although the labor force participation of wives is increasing, wives continue to allocate large numbers of hours to work in the house-

[7] The off-farm wage rate (table 3) is the opportunity cost of wife's time only when she works at nonfarm jobs and when hours of off-farm work are flexible. If the wife does not work at off-farm work, the opportunity cost of time is the value of the marginal household utility of her time in household activities.

hold, complicating decisions on skill acquisition through formal training. Wives who work both outside and inside the household are "multiple" job holders and should invest in skills that raise the productivity of their time in both activities. For example, when outside work is nonfarm work, skills for nursing and elementary school teaching are useful in both the household and market. When outside work is farm work, overlapping skills seem less likely.

The results of this study do permit a comparison between the marginal product of education of farm wives at farm and nonfarm work. The average education index gives the income that the average education mix of wives in a state would generate in nonfarm labor income in 1959. If nonfarm wage rates rose 10% between 1959 and 1964, then the marginal product of education in 1964 should be about 1.1. The relatively small marginal products of wives' education suggest that investment in wives' formal education raises their productivity more rapidly at nonfarm than at farm work. However, for wives with low levels of education, the effect of expanded coverage of minimum wage legislation probably has increased their quantity of farm work. Being self-employed or working as an "unpaid" family worker are ways of circumventing the unemployment effects of minimum wage legislation. But as education levels of farm wives rise, this effect should diminish.

In conclusion, it is clear that farm wives participate in and are productive at farm work. However, I challenge others to obtain new and better data and to attempt to determine the value of the productive time of farm wives so that we may gain a better understanding of the level and fluctuation of farm household income and allocation of time of farm wives.

The Demand of Farm Families for the Quantity and Quality of Schooling for Their Children in the United States

Mark R. Rosenzweig

In recent years economists have become increasingly interested in the roles of education in the agricultural sector. The pioneering studies by Gisser and Welch on the relationship between education, farm employment, and agricultural production and the vast emerging literature on the importance of education in a dynamic context, summarized by Schultz, are notable examples. Economists have also been studying the determination of the level of human capital acquired by individuals as well as the returns to various dimensions of schooling that go beyond the most commonly utilized measure—years of school completed. These latter studies, however, have primarily focused on the nonagricultural population. In this paper an attempt is made to formulate and test on U.S. data pertaining to the early 1960s a model of the farm family that integrates the schooling of farm children among the set of household production and consumption decisions and explicitly accommodates the roles of education in agricultural production while distinguishing between the quantity and quality of schooling. This latter distinction is particularly important in the farm population.

Theoretical Framework

Two principal characteristics of farm families differentiating them from their nonfarm counterparts are that school-age farm children can readily participate in farm production and contribute to family income and that the level of schooling a child acquires directly influences the farm family's income to the extent that schooling enhances farm productivity. Moreover, schooling plays an important role in the migration of children from the family farm. In describing the demand for the schooling of children by farm parents in an optimizing framework, three functions are central to the analysis. (A formal two-period version of this model is found in Rosenzweig 1977b.) The farm family is assumed to maximize an intertemporal utility function whose arguments are the per period flow of services from purchased commodities and the accumulated human capital of the farm children (child quality).

Parents can augment child quality in each period according to a schooling production function, which describes the relationships between gross investment in child human capital per period and the schooling inputs—the time children spend in school (measured in years, days, hours, etc.)—school quantity—and the total amount of school-related goods and services purchased in the market (teachers, books, and other classroom materials)—school quality. For simplicity it is assumed that the farm family is in the stage of its life cycle such that the total number of children, hence the maximum amount of child time available for schooling each period, is predetermined and all child investment occurs in school. Thus, the possible interactions between decisions concerning the quantity of children and child schooling (quality) is excluded from the analysis as well as the important roles parents play in the preschool years, as documented by Leibowitz and others. (For an analysis of child-quantity decisions by farm families, see Rosenzweig 1977a.) To capture the latter in part, assume that the educational level of the farm parents enhances the productivity of child time in school as well as the productivity of school-oriented expenditures.

The third function describes the intertem-

poral production possibilities of the farm family, assumed to live on a farm of predetermined economic capacity as measured by the value of the farm assets owned by the farmer. Within the vector of farm production, inputs are assumed to be the time ("raw") farm children devote to farm production in the schooling periods and the services of the human capital of "skilled" farm children in the postschool periods. Child human capital is thus a production as well as a consumption commodity. Schooling investment, however, increases earnings capacities in both farming and other activities, thus enhancing the prospect of farm children obtaining nonfarm jobs. The willingness of farm parents to finance investment in general skills may in part be explained by the declining nature of farming as an occupation; farm parents anticipate that many of their children have to leave agriculture and see schooling as a means of increasing their welfare in the nonfarm sector.

The optimal levels of school quantity and quality are determined where marginal costs equal marginal returns. The returns to, in contrast to the marginal costs of, both schooling inputs are similar: the marginal product of the input in the schooling function multiplied by the sum of the marginal pecuniary and nonpecuniary benefits from schooling, the values of marginal product and marginal utility of child human capital. The marginal cost of school quality is the market-determined price of the school quality inputs.

The cost of an additional unit of the quantity of schooling, the transfer of a unit of child time from farm to human capital production in school, is equal to the marginal value product of "raw" child labor in agricultural production. Thus, the shadow price of the quantity of schooling in agriculture is dependent upon the allocation of production and consumption inputs by the farm family, while the cost of a unit of school quality is not.

To illustrate the importance of the differential shadow prices of school quantity and quality in agriculture as well as the consumption and production aspects of education, consider the influence of an increment in the economic capacity of the farm (value) on the demand for school quantity and quality. Increases in farm value unambiguously raise the demand for school quality as long as child quality is a noninferior consumption commodity. An increase in farm capacity leads to a higher demand for schooling and for the quality input because it raises both farm income and the marginal value product of "skilled" farm children.

The relationship between farm value and school quantity is not unambiguous. While the effects of an increase in farm productive capacity on the returns from the school quantity and quality inputs are similar, unlike in the former case the shadow price of school quantity also rises as increases in farm value raise the marginal value product of "raw" labor and the opportunity cost of time in school. Farms with greater potential productivity demand higher levels of schooling but also tend to substitute school quality for quantity. The (positive) effect of farm value on school quality is stronger than its effect on school quantity. If the substitutability between productive assets and unskilled child labor is high, a negative relationship between the quantity of schooling and farm value may be observed.

A general implication of the analytical framework is that parameters related to agricultural production, such as the cost of production inputs, the quality of land, and the available technology, differentially influence the demand for the quantity and quality of schooling in agricultural populations. In addition if mature children participate in the allocative decisions on the farm, the rate of technological change would increase the demand for child schooling if the farm parents perceive the usefulness of education in the adoption and use of new technologies. Farmers may also be sensitive to variables affecting the off-farm employment prospects of their offspring, since these variables influence the expected pecuniary returns from school investment as well as the welfare of their migrant children.

Empirical Analysis

The Data

Demand equations for school quantity and quality relating the level of the two school inputs to the exogenous production and consumption variables discussed can be derived from the theoretical framework. To estimate these equations, U.S. state cross-sectional data are utilized, extracted mainly from 1960 census sources. (A detailed description of the variables and their sources are contained in Rosenzweig 1973, 1977b.) The two dependent

variables representing, respectively, the quantity and quality of schooling are the natural logarithm of the nonenrollment rate of rural farm teenagers aged 15 to 18 (see Edwards for a rationale for this form of the enrollment variable) and instructional expenditures per enrolled child in rural school districts and counties.

While micro data may be more appropriate for testing models of household behavior, data availability preclude the use of less aggregative variables. However, because expenditures on education are implemented for the most part by governmental units in the United States, the assumption of the theoretical analysis that the levels of school quantity and quality are jointly determined at the household level may be unrealistic, as all households, including those in other geographical areas and those without school-age children, participate collectively in the budgetary process. In considering the aggregate demand for school quantity and quality, the population demographic composition and fiscal structure must therefore be taken into account as well as the possibility that the two aggregate schooling variables may interact. Accordingly, both ordinary least squares and two-stage least squares estimating procedures are utilized.[1]

Of the independent variables, listed in table 1, those central to the analysis are farm value, representing potential agricultural income, total nonfarm income, and a measure of total factor productivity change constructed from the indices developed by Evenson and Landau and used as a proxy for the degree of disequilibrium. The wage rate of agricultural labor is used to represent the price of one farm input that varies significantly in the cross section. The educational levels of adult farm males and females are included to capture schooling preferences and child schooling adult schooling interactions. The unemployment rate of 20- to 25-year-old urban whites represents the set of possible variables measuring nonfarm employment prospects for farm children.

The state minimum lawful school-leaving age, the percentage of nonwhite farm operators, the ratio of the school-age (5 to 18) to total population, the proportion of the school population of high school age, and the proportion of the local governmental budgets financed by superior governmental agencies are also added to the data set as control variables. The latter three take into account the public expenditure aspect of the school quality proxy.

Table 1. Variable Means and Standard Deviations: U.S. Rural Farm Population, 1960

Variable	Mean	Standard Deviation
School enrollment rate of farm population aged 15–18	0.802	0.076
Per pupil instructional expenditures in rural schools	168.2	44.07
Farm value	23,955	16,650
Nonfarm income (1964)	907.0	330.4
Percentage (+100) total factor productivity change (1950–59)	113.2	9.45
Hourly agricultural wage (annual average 1954–59)	0.73	0.17
Median years of schooling of farm males aged 35–44	10.0	1.82
Median years of schooling of farm females aged 35–44	11.0	1.49
Urban unemployment rate of white males aged 20–25	5.95	1.36
Percentage of farm operators nonwhite aged 35–44	5.33	11.3
Minimum lawful school-leaving age	15.6	3.45
Percentage of 5–18 farm population aged 15–18	31.1	2.80
Proportion of total farm population aged 5–18	0.263	0.022
Percentage of local school budget locally financed	55.4	19.2

Note: n = 44 states; Alaska, Hawaii, Connecticut, Rhode Island, Delaware, New Jersey excluded.

Results

The results obtained using ordinary least squares (OLS) to estimate the enrollment equation, excluding the demographic variables, are presented in column 1 of table 2. The independent variables together account for 84% (adjusted) of the interstate variation in the school enrollment rates of farm teenagers. All of the variables derived directly from the theory are statistically significant, indicating that parameters relating to agricultural production are significant determinants of farm school enrollment.

The negative sign of the coefficient of the farm value variable supports the hypothesis that the opportunity cost of school quantity,

[1] Various tests for the existence of heteroscedasticity were all rejected; the regression equations are unweighted.

Table 2. School Enrollment and Expenditure Regression Coefficients: U.S. Rural Farm Population, 1960

[b] Endogenous variable.

the marginal value product of teenage children in farm production, is a significant deterrent to school attainment in the farm population. The farm value coefficient cannot be interpreted as evidence of the inferiority of child quality, as the coefficient of nonfarm income, which should provide a lower-bound estimate of the pure income effect, is significantly greater than zero.[2]

The positive coefficient of the productivity change variable suggests that farmers perceive that the returns to schooling are higher in settings where the pace of technological change is more rapid; a 10% increase in the rate of productivity change would be associated with a rise in the enrollment rate of farm teenagers of 5%. However, a plausible alternative hypothesis also consistent with this finding is that a high rate of technological change in agriculture may be associated with a lower demand for relatively unskilled labor, such as that of school-age children, since such technical change is likely to make the production process in the U.S. context more capital intensive.

The positive and significant coefficient of the wage rate of agricultural laborers suggests that educated farm children and hired laborers are substitutes in farm production and/or that higher agricultural wage rates enable farm children to finance their schooling by working as unskilled paid laborers both inside and outside the agricultural sector during school vacations.

The coefficients of both schooling attainment variables are positive. Only the coeffi-

[2] One component of off-farm income may be the earnings of children, which would impart a negative bias to the off-farm income coefficient in the enrollment equation.

cient of the schooling level of adult farm males is statistically significant, reflecting perhaps the predominance of males in agricultural production. The insignificance of the coefficients on the race or compulsory schooling variables suggests, respectively, that the school enrollment behavior of farm nonwhites and whites do not differ and state compulsory schooling laws do not significantly increase the school enrollment rates of farm teenagers.

If at the aggregate level interactions between school quantity and quality are important, the specification in column 1 is not the complete reduced form, as it omits some of the exogenous variables influencing the supply of school quality. To test for the dependence of school enrollment on aggregate school expenditures in the farm population, the school quality variable is added to the enrollment equation. However, because teenage school enrollment may possibly influence total per pupil public school expenditures, as found by Gustman and Pidot, two-stage least squares (2SLS) is used to obtain consistent parameter estimates. These estimates, displayed in column 2 of table 1, do not differ appreciably in either sign or significance from those obtained using OLS techniques in column 1. The one exception is the coefficient of the urban unemployment rate. It becomes statistically significant (10% level, two-tailed test), suggesting that decreases in employment opportunities in the nonagricultural sector significantly reduce the school enrollment rates of farm teenagers. The school expenditure coefficient does not attain statistical significance. The OLS school expenditure coefficient estimates are displayed in column 3 of table 2.[3] The set of independent variables explains approximately 72% (adjusted) of the interstate variance of rural per pupil instructional expenditures although only the coefficients of farm value and the agricultural wage of the variables implicated in the theoretical analysis attain statistical significance.[4] The sign of the latter, consistent with that in the enrollment equation, suggests that the demand for both rural-farm schooling inputs, school quantity and quality, is greater in areas where agricultural wage rates are high.

The most important result is the positive coefficient on farm value, which indicates that a rise in farm value of 10% results in an increase in rural-farm school expenditure of slightly over 1%. In conjunction with the results displayed in columns 1 and 2, this finding supports the hypothesis that increases in child farm productivity lead to the substitution of school quality for quantity in the farm population. The relative magnitudes of the mean elasticity estimates of farm value on the enrollment and school expenditure variables (−0.02 and 0.10, respectively), and the evidence obtained by Johnson and Stafford and others that the rates of return to school attainment (quantity) and quality are approximately equal, suggest that increases in farm value on net raise the overall quality level of farm children despite their attenuating effects on school enrollment. Given that child human capital is noninferior in an economic sense, this latter finding is also consistent with the theoretical analysis, in which the demands for school quantity and quality are derived from the demand for child quality.

Conclusion

The empirical results obtained based on U.S. state data generally support the theoretical framework (Rosenzweig 1973, 1977b). As a consequence of farm children's participation in farm production their marginal value product represents an important component of the cost of school quantity in the farm population such that increases in farm potential productivity reduce the enrollment rates of farm teenagers. At the same time, rural-farm school expenditures, which are unaffected by this opportunity cost, tend to rise with increases in potential farm productivity such that farm child quality on net is enhanced.

Evidence also suggests that the quantity of schooling in agriculture responds to both agricultural production and nonfarm parameters associated with the returns to schooling. A strong positive correlation is found between the school enrollment rates of farm teenagers and the rate of agricultural productivity change, a result consistent with the view that the returns to education in agriculture may be higher in situations characterized by disequilibrium because schooling increases the efficiency of technological adaptation. More research is needed, particularly on the direct

---

[3] Because no identifying restrictions based on the available data were considered plausible, it was not possible to estimate the impact of farm school enrollment rates on rural school expenditures using 2SLS.

[4] The roles of the demographic and fiscal variables are discussed in detail in Rosenzweig 1977b.

contribution of the farm parents to the education of their children prior to, during, and after the schooling years, on the interplay of family size and education decisions, and on the transfer of pecuniary assets from parents to children.

Household Capital Labor Ratios in Poor Farm Families

W. Keith Bryant

The major insights provided by the so-called "new home economics" are that household activities are productive in nature and that they involve the use of the traditional factors of production. The implications are far ranging and continue to be unpacked ten years after the formal treatments by Becker, Lancaster, and Muth. The particular implications pursued in this paper deal with the behavior of capital-labor ratios within the households, not the farms, of farm families. In particular, how do household capital-labor ratios of farm families respond to changes in the prices of family members' time, in family income, in family size, and in certain characteristics of the farm enterprise?

There are several reasons for interest in these responses. Principal among the implications are those analyzed by Linder to wit: as labor productivity rises with growth, labor becomes increasingly expensive to the family relative to capital, and family capital-labor ratios rise. Other implications have to do with the value of time spent in household activities (Gronau), the economic contribution of households to the national product (Siragelding), and the extent to which consumption over the household's life cycle is a function of the changing value of the household's time (Ghez and Becker). The reasons for analyzing farm families are that they are the most numerous of self-employed families making empirical work easier and that the implications of self-employment for household activities have been neglected.

In this paper two simple models of the farm family are outlined. One allows family members to work both on and off the farm, while the other provides for farm work only. Both the theoretical and empirical analyses neglect children's time and concentrate on the ratio of household capital to the wife's home time. (The models are developed in the paper by Bryant; copies are available from the author on request.) The ratios for poor farm families in three counties in Iowa and North Carolina are analyzed and discussed in the light of the models. The data for the empirical analysis come from the Rural Income Maintenance Experiment (RIME), which operated 1969–72 (Bryant and Hager).

Two Models of Farm Families

The Traditional Farm Family

For many farm families off-farm wage rates of the spouses, w_i ($i = h, s$; h denoting husband and s the wife), are lower than their marginal products on the farm. Thus, they allocate their available time (T_i) between household (A) and farm (F) activities. Both A and F are regarded as aggregate household and farm output, respectively. Their home times (T_{ia}) are combined with consumption goods (X) to produce commodities (A) from which the family derives satisfaction. They combine their farm times (T_{if}) with nontime farm inputs (K) in the production of farm products (F), which they sell at a price (p_f).

If X is considered to be household capital from which the service flow per period (t) is proportional to the stock, then X/T_{sa} is the household capital-labor ratio of interest. Family composition, type, and size denoted by the vector S, the tenure of the farm dwelling (D), and a vector of personal characteristics of the wife (Cs) all may have important effects on the productivities of X and T_{sa} as well as upon family preferences. Likewise, farm tenure (Tn) and farm size in terms of tillable acres (TA) affect the productivities of K and T_{if}. Thus, the demand functions for X and T_{sa} have as their arguments S, D, Cs, Tn, and TA as well as the prices of X, K and F, p_x, p_k, and p_f,

W. Keith Bryant is a professor of consumer economics and public policy, Cornell University.

R. Boisvert, J. Gerner, W. Huffman, R. Hutchens, and K. Stafford-Panourgia all helped in the development of this paper.

respectively, and unearned income (V). The ratio X/T_{sa} is a function of these same variables, i.e.,

$$(1) \quad X/T_{sa} = r_s^1(p_x, p_k, p_f, V; S, D, Cs, Tn, TA),$$

where $r_s^1(\cdot)$ is the ratio of the two demand functions. The variables in equation (1) after the semicolon represent characteristics on which the demands are conditioned. Net farm income does not appear in equation (1), being caught by variations in p_k and p_f.

The Part-Time Farm Family

For an increasing number of farm families, off-farm wage rates are higher than family members' marginal products on the farm, given some amount of farm work. Consequently, off-farm work competes with farm work. Family members divide their labor among home activities (T_{ia}), farm work (T_{if}), and market work (T_{iw}). This fact alters the demand functions for X and T_{sa} in two ways. First, off-farm market wage rates (w_i) enter the demand functions for both X and T_{sa}. Second, the prices of farm inputs and of farm outputs, as well as the variables on which farm production is conditioned, disappear as arguments in the demand functions and farm income (FY) appears, since off-farm work of both spouses makes the household and the farm separable. Thus, for part-time farm families in which both spouses work off the farm,

$$(2) \quad X/T_{sa} = r_s^2(w_s, w_h, FY, V; S, D, Cs).$$

Off-farm earnings, of course, affect the ratio via w_s and w_h.

Two intermediate cases exist in which one spouse works full-time on the farm while the other divides his/her labor among home, farm, and market work. In these cases the function for the wife's household capital-labor ratio is as follows:

$$(3) \quad X/T_{sa} = r_s^3(w_s, p_x, p_k, p_f, V; S, D, Cs, Tn, TA)$$

and

$$(4) \quad X/T_{sa} = r_s^4(w_h, p_x, p_k, p_f, V; S, D, Cs, Tn, TA),$$

where the wife and the husband, respectively, are employed in market work. Here, both off-farm earnings and farm income enter the functions via wage rates, prices, and the circumstances on which farm production is conditioned also appear as arguments.

The Data and The Variables

The data used to estimate the equations are on continuously married, husband-wife families in Calhoun and Pocahontas Counties, Iowa, and Duplin County, North Carolina, who participated in the RIME in 1970–72 (Bryant and Hager). Farm families are defined as those who completed the farm section of each quarterly interview throughout the experiment and who had no nonfarm business assets. Because data on farm work of wives were not collected in 1970, only data for 1971 and 1972 were used in this analysis. The subsample was divided into four subgroups corresponding to the cases analyzed in the previous section.

The means and standard deviations of variables used in the analysis for each family type are given in table 1. The definitions of some of the variables and their use in the analysis need elaboration. The dependent variable is the dollar value of the stock of consumer durables per hour of the wife's home time per year. Consumer durables exclude cars and include all appliances, furniture and furnishings, sporting equipment, lawn and garden tools, jewelry, dishes, etc. (see Bryant and Hager for further details). Home time is defined as the total time available to the wife per year (8,760 hours) minus her farm and market work time.

Families are either in the payments or the control group. Families in the payments group are eligible to receive experimental negative income tax welfare payments (NIT) of the form

$$(5) \quad NIT = G - \alpha Y,$$

if $Y < B$ and zero otherwise, where NIT is annual welfare payment, G is dollar amount of NIT if income (Y) is zero, α is the negative income tax rate, and B is breakeven income. Within the payments group different families are exposed to G's of 50%, 75%, and 100% of the family's poverty-line income and α's of 0.3, 0.5, and 0.7. A treatment variable taking on values of one if the family is in the payments group and zero if it is in the control group is included to take account of systematic differences between the two groups. G was included in the analysis in early fittings of the equations but was omitted when found to have no effect.

Note: Numbers in parentheses are standard deviations.

Wage rates are adjusted for α but not for positive income tax rates. The wage rates are averages of wage rates reported during the year weighted by the times worked at each. As a result w_s is not independent of the random error terms in the equations in which it appears. Equations (2) and (3) are fitted by the method of instrumental variables (IV) with w_{st-1} as the instrument for w_{st}. Equations (1) and (4) are fitted by ordinary least squares (OLS).

No data on prices other than wage rates were collected. Race (1 if black), region (1 if N.C.), and year (1 if 1972) are included as variables to adjust for any such differences, some of which could be due to price differences. Dummy variables indexing head's age and the presence of children take account of family life cycle effects. The subsample does not include any childless families with the head under 45. The wife's age is not included as a variable because it is highly collinear with the life cycle dummies. Farm land is included either as total tillable acres or as acres by tenure arrangement.

The Empirical Analysis

The results of estimating the X/T_{sa} functions, equations (1) through (4), for each of the four subgroups are shown in table 2. All equations

fit the data surprisingly well given that the data are essentially cross section. The traditional farm family equation fits least well. Both the equations fitted by IV account for over 45% of the variance in X/T_{sa}.

A major hypothesis flowing out of the discussion of the models is that farm production inputs help determine household capital-labor ratios for all but the family in which both spouses have off-farm work.[1] The evidence is mixed. In only one of the three cases (columns 1, 3, and 4 of table 2) in which tillable acres or acres by tenure arrangement are expected to affect the durables/wife's home time ratio are the expectations fulfilled. One reason might be that acres farmed is a proxy for per-

[1] There are four exceptions to this result. They are if (*a*) the family physically consumes some farm production, i.e., if *F* is treated as *X*; (*b*) nonlabor farm inputs are the same as consumption goods; e.g., if credit for farm and home use are indistinguishable; (*c*) the marginal product of farm labor is everywhere lower than the wage rate but spouses cannot obtain all the income they desire from wage work because, for instance, hours of work are limited; and (*d*) the family derives satisfaction from farming independent of any farm output it physically consumes (Bryant).

manent income, and its effect is thus confounded with that of income. Another, less probable reason might be that the farm production function is additive in K and T_{tf}.

Folklore about farm families, and poor ones in particular, asserts that they consume much of their own product and derive much utility from farming. If such was the case farm production inputs would importantly influence the household capital-labor ratios of all four family types (Bryant). The findings provide little empirical support for such ideas.

In most of the work on the economics of home production homotheticity has been assumed (Ghez and Becker, Linder, Michael). In the present context homotheticity implies zero income elasticities of demand for X/T_{sa}. The income elasticity of demand for the ratio is

$$(6) \qquad \eta_{(x/s)} = \eta_x - \eta_s,$$

where η denotes the income elasticity, x, the stock of consumer durables, and s, the wife's home time. Evaluated at the means where relevant the estimated $\eta_{x/sa}$ are 0.21, 0.18, 0.12, and 0.28 for the subgroups represented by equations (1) through (4), respectively. All are computed from coefficients significantly different from zero at the 0.10 level or lower. Homotheticity is a strong assumption, and there is no question that it can be rejected on the basis of this evidence. Clearly, for poor rural families the income elasticity of demand for consumer durables is higher than the demand for the wife's home time. As income increases the household capital-labor ratio increases.

The effects of wage rates on the household capital-labor ratio are of interest. The wife's wage rate elasticity of demand for the ratio of household capital to the wife's home time is

$$(7) \quad E_{(x/s)s} = \beta_s(\sigma_{xs} - \sigma_{ss}) + \beta_s(\eta_x - \eta_s),$$

where β is the market work budget share and σ is the Allen partial elasticity of substitution between subscripted goods. $\sigma_{ss} < 0$ and $\sigma_{xs} \gtreqless 0$ as durables and wife's home time are substitutes, independent, or complements, respectively. Similarly, the husband's wage rate elasticity of demand for the ratio is

$$(8) \quad E_{(x/s)h} = \beta_h(\sigma_{xh} - \sigma_{sh}) + \beta_h(\eta_x - \eta_s).$$

The present study provides two estimates of each of these wage rate elasticities. Estimates for the elasticity in equation (7) are 0.26 and 0.29 for the subsamples with both husband and wife and just the wife engaged in market work, respectively. Estimates for the elasticity in equation (8) are 0.14 and −0.14 for the subsample with both husband and wife and just the husband engaged in market work, respectively. Both wife's wage rate elasticities are computed from coefficients at least one-and-one-half times their respective standard errors, while the husband's wage rate elasticities are computed from coefficients about the same size as their standard errors. The elasticity of the ratio with respect to w_h can be taken as zero, a finding consistent with current knowledge about labor supply and home production. Estimates of $(\sigma_{xs} - \sigma_{ss})$ and of the compensated wife's wage rate elasticity, $E^c_{(x/s)s} = \beta_s(\sigma_{xs} - \sigma_{ss})$, are 2.2 and 0.24, respectively, for families in which both spouses have wage work. For those families in which only the wife has wage work, estimates of $(\sigma_{xs} - \sigma_{ss})$ and $E^c_{(x/s)s}$ are 1.81 and 0.27, respectively. In both cases, home activities become more capital intensive with respect to the wife's home time as her wage rate rises. Both substitution and income effects, therefore, lead to a capital intensification of household activities.

Wife's education has a significant positive effect on the ratio of consumer durables to the wife's home time, for the case in which both spouses have off-farm work. Education could be picking up part of the own-wage rate effect as w_s and wife's education are highly correlated. Also, it is likely that education has life style effects as well as effects on the productivity of the wife's home time (Michael, Morris).

As family size rises the ratio of durables to the wife's home time can be expected to rise. There are economies of size with respect to major appliances (washers, driers, etc.) stemming from technical indivisibilities. As family size rises, especially above two, families can take advantage of these economies. Also, in large families, older children's time can substitute for the wife's home time leading to a capital intensification with respect to the wife's home time but not necessarily with respect to total family home time. The evidence for such effects is clear with respect to farm families in which only the wife has market work and is less clear for the traditional farm family and for families in which both spouses have market work. Evidence does not exist for the farm family in which only the husband has off-farm work.

Family life cycle effects are caught by the dummy variables indexing the head's age and the presence of children. The coefficients provide weak evidence for a labor intensification of household activities in older families with children as the stock of durables purchased after family formation depreciates out and, perhaps, as some of the wife's home time is replaced by the children's.

In two of the family types home ownership serves to increase the ratio of consumer durables to the wife's home time. This is in conflict with the evidence that the gross value of the home, if owned, appears to depress the durables/wife's home time ratio in farm families in which only the wife has off-farm employment.

Summary

In summary, one can conclude, first, the household activities of poor farm families experience capital intensification relative to the wife's time as family income rises. This seems reasonable since one expects poor families to value goods over time relatively. This finding also provides evidence against the assumption of homotheticity. A test of the proposition that the total goods-time ratio is unaffected by income remains to be conducted. Second, household activities also undergo capital intensification as the value of the wife's time increases. Here, both substitution and income effects appear to augment each other raising the stock of durables relative to the wife's home time. Third, while the theoretical roles farm production inputs play in determining household capital-labor ratios were specified, the empirical evidence was, at best, blurred. Alternative hypotheses having to do with the subsistence nature of poor farms and that they derive utility from farming fared no better. Considerable more research of such questions over the whole range of the income distribution and for other types of families needs to be done.

Antitrust Policy in Agriculture
(Ronald D. Knutson, Texas A&M University Chairman)

Antitrust Issues in the Food Industries

Russell C. Parker

The United States is unique among countries of the world for its strong reliance on antitrust as its main public policy vehicle for regulating business. In the U.S. economy, the market is extant over almost 90% of the production of goods and services, while direct government regulation encompasses a little more than a tenth (Sherer, p. 519). Aside from government regulations to protect the environment, worker safety, and a number of other aspects of company conduct, the free market sector is essentially self-regulating with the government acting only infrequently and very selectively as a policeman to ensure that fair and open competition prevails.

The history of antitrust has been mostly one of public indifference. However, the last five years, and especially this election year, have seen at least a minor ground swell of interest develop. This interest reflects frustration over the prolonged period during which the economy has experienced simultaneously high inflation and high unemployment rates.

In 1971, the perceived failure of markets to operate without uncontrollable inflation and high employment saw the Congress and the most laissez faire national administration in two generations of American politics opt for a rigid system of price controls. The vestiges of that system lasted until April 1974. Abhorrence of regulation by the administration together with the unsure success of its price control program saw a major increase in the rhetoric supporting strong antitrust enforcement to make markets more competitive and self-regulating.

The wave of food price increases that began in 1972 caused food to be a focal point of the public concern. Both the Federal Trade Commission (FTC) and the Department of Justice responded to the concern by increasing dramatically the amount of their resources spent on investigations involving food processing and retailing companies. In 1975, the FTC spent about a fifth of its total antitrust resources in the area. Because of this high level of activity, it is particularly appropriate that the American Agricultural Economics Association should consider the antitrust policy in agriculture.

I discuss antitrust issues relating to the food marketing industries. In so doing, I limit myself to economic issues even though many people would argue, and correctly so, that the antitrust laws are deeply rooted in social philosophy. In limiting the discussion to antitrust issues relating to competitive efficiency, I focus on the potential competitive problems identified in the economic literature describing the structure and performance trends in the food manufacturing industries and food retailing industry and on the group of issues that are perceived by antitrust agencies in their enforcement activities. The latter differ from the former because of operational limitations imposed on the agencies by the antitrust statutes and court interpretations and by the attitudes and philosophies of agency administrators and staff.

Structure Performance Issues in Food Manufacturing

I see the following as anticompetitive trends in food manufacturing and the major economic issues to be addressed by antitrust policy. The number of food manufacturers is declining rapidly, and the rate of exit is rising (Dixon, table 2), in sharp contrast to all manufacturing

---

The discussants for this session were Timothy Hammonds of National Association of Food Chains and Oregon State University and James F. Falco of the Committee on the Judiciary, House of Representatives.

Russell C. Parker is a visiting professor at the University of Wisconsin on leave from the Federal Trade Commission.

where the number of companies has been increasing. The first post-World War II quinquennial *Census of Manufacturers* in 1947 enumerated over 40,000 companies in food manufacturing. In the most recent census year, 1972, this number was 22,172. The decline in company numbers is widely dispersed among the food industries (U.S. Dep. Commerce 1975b, table 2). Whereas at the beginning of the post-World War II era, it was mainly small companies that were disappearing, the most recent decade has seen the trend increasingly encompass medium-size and larger companies. A projection of current company disappearance rates indicates that half of the current number of food manufacturers will disappear within the next decade.

The decline in company numbers is effecting the size distribution of companies. Average industry concentration in the food and kindred products manufacturing industries is high relative to most other industries. Census concentration data indicates that about three-quarters of all value added by the food industry comes from oligopolies as defined by Bain's classification system and about 30% comes from highly concentrated oligopolies (U.S. Dep. Commerce 1975a). An accumulating body of statistical analyses shows these oligopolistic industry categories having higher profits and cost-price margins than competitively structured industries (Weiss).

Available evidence indicates a trend toward even higher concentration levels. There was a particularly sharp increase between the two most recent census years, 1967 and 1972. This followed slower increases between the previous postwar census years (Parker, table 3).

Although the average level of concentration in the food industries is high enough to suggest the presence of competitive problems, there is a great diversity of concentration levels among the 47 four-digit food industries and the 130 food product classes. In general, concentration has been declining in those food manufacturing industries that produce products for other industries (producer goods industries) and also in low differentiation consumer product industries like meat packing (Mueller). Conversely, concentration is high and increasing in industries where product differentiation is important.

Besides the rising levels of concentration within individual industries, there is high and increasing overall concentration of total food and kindred products manufacturing activity. The control by a few very large enterprises extends especially to those positions in the individual food industries that have potential for market power. Since large market share positions are increasingly important to the structures of individual industries, the concentration of these positions in the hands of about fifty very large companies of the total of 22,000 food manufacturers is significant.

The share of assets of all corporations primarily classified as food manufacturers accounted for by the fifty largest was 56% in 1974, an increase from 41% in 1950 (Dixon, p. 3). This is an understatement of the upward trend because in the early 1970s the data were adjusted to exclude the holdings of foreign assets, which were more extensively concentrated in the hands of larger corporations (Penn).

In 1963, when the fifty largest food companies controlled about 48% of total food manufacturing assets, a special census tabulation showed that they controlled about 70% of the four leading producing positions in all of the food industries and product classes defined by the Bureau of the Census (NCFM 1966b, pp. 25, 66, and 221). The same tabulation showed that large food manufacturers tend to occupy positions in concentrated industries more often than in less concentrated industries (p. 49).

The tabulation showed, further, that the fifty largest food manufacturing companies of 1963 each held an average of over eleven top four positions in four-digit industries, including nonfood industries (p. 50). This was an increase from nine in 1954. Data more recent than 1963 are not available; however, the high rate of large food company acquisitions by other large food products companies since 1963 suggests that the concentration of potential market power positions with the largest food manufacturing companies has increased.

In addition to holding entrenched positions, the fifty largest food manufacturing companies account for nearly all of the most important media advertising in the food area. In 1964, they had 90% of all network TV advertising of food products. In addition, they accounted for most of the field sales force personnel employed by food manufacturers. Their strong positions in markets plus their diversity both within the food area and in other grocery store products give the largest food manufacturers access to strategies such as reciprocity and full-time forcing that smaller less diversified

firms cannot employ. The largest companies, because of access to shelf space and a capacity to reach consumers with effective promotional efforts, are clearly a class by themselves. They are the leading potential entrants in all food and kindred industries and particularly in those industries that are oligopolistically structured.

Impact of Food Industry Mergers

The increase in aggregate concentration with the largest food manufacturers is strongly related to mergers. When food company mergers were examined in 1966, it was found that were it not for mergers the combined share of assets of the fifty largest food manufacturers would have declined between 1950 and 1965 (NCFM 1966b, p. 120). Although the data subsequent to 1965 have not been analyzed, the brisk continuation of food company mergers, especially of larger companies, suggests that mergers are continuing to contribute to the increasing overall concentration. Since 1965, the proportion of large food companies acquired relative to all large manufacturing companies acquired increased. Each year mergers have eliminated a significant percentage of the remaining number of independent medium-sized and larger food manufacturers.

Although most acquisitions by the largest food manufacturers during the last two decades were product extension rather than horizontal, they still had the likely effect of increasing concentration levels in the industries involved. Firms acquired by the fifty largest food manufacturers were typically larger firms and often were among the four leading producers in one or more food product areas (NCFM 1966b, pp. 126–27). Many were also substantial advertisers of well-known food product brands. However, within a year after acquisition the acquiring companies, on the average, doubled the amount of advertising expenditures for the acquired brands, with television advertising showing the greatest percentage increase (NCFM 1966b, pp. 125–27). Though market share change data are not available, it is hard to conceive that the additional advertising did not increase market shares and the level of industry concentration.

Another interesting fact reported in the 1966 study was that acquisition was almost the sole route by which the largest companies entered new industries. FTC analysis of detailed product data for the twenty-five largest food manufacturers indicated that nearly 90% of the product areas entered by the companies were directly traceable to merger (p. 124). The very low research and development expenditures of the largest food manufacturers are consistent with this finding (p. 80). In addition, food manufacturing was found to be the only one of the twenty major industrial groups in manufacturing where there was an inverse relationship between size of firm and the number of research and development personnel per 1,000 employees. The picture that emerges from these data and others, such as use of field sales force personnel and advertising, is that usually large food manufacturers move into new products only after those products are first developed by smaller firms. The acquiring corporations then enhance the market positions they acquired through intensive advertising and other product differentiation strategies.

For the last several years average profit rates of food manufacturers have been higher than those of other manufacturers (Parker). More important is the upward trend relative to other manufacturers that has been sustained for a quarter century. Profits of food manufacturers are strongly related to industry concentration levels, individual company market shares in their industries, and industry advertising expenditures. Profit rates are found to average three times higher when these variables took on high values rather than low values (FTC 1969b, p. 7).

Structure Performance Issues in Food Retailing

Grocery retailing has experienced a major shift toward larger companies since World War II. This shift, which generally followed the "supermarket revolution" of the 1930s and 1940s, saw concentration increase both in metropolitan area markets and for the nation as a whole.

Local area concentration is of prime importance because local areas are the main arenas of competition for consumer purchases. Few consumers consider traveling to a different city to buy groceries. Large metropolitan areas, however, are often too broadly defined for purposes of consumer grocery purchases. Many contain significant submarkets that are geographically distinct and are served by separate advertising media. Supermarkets and small convenience stores are also separate submarkets. For these reasons, grocery store

concentration ratios for whole metropolitan areas should be considered minimum estimates of concentration.

The unweighted average four-firm concentration ratio for over 200 U.S. standard metropolitan statistical areas (SMSA's) increased from 45% in 1954 to 52% in 1972 (Parker). Eight-firm and twenty-firm concentration experienced much greater rates of increase. Concentration in large SMSA's made an especially large jump between 1967 and 1972 (Parker).

Concentration levels vary considerably between SMSA's. Some SMSA's have had consistently low concentration ratios. Others, however, including some of the nation's largest cities, have concentration levels as high or higher than the most concentrated manufacturing industries.

National concentration becomes important in the procurement of grocery products and has shown a strong upward trend over the post-World War II period. Just twenty large grocery chains accounted for 37% of total grocery store sales in the United States in 1975 (Parker). This was an increase of more than a third over the 27% controlled by the twenty largest chains in 1948.

Major studies of grocery retailing, including those of the National Commission on Food Marketing (NCFM 1966a, p. 75) and the Federal Trade Commission (FTC 1966, chap. 11), have found significant barriers to entry and significant pecuniary advantages of size to the largest established food chains in local markets. Pecuniary advantages of large size are especially important in newspaper advertising and in procurement. The largest established chains in cities and regions also have advantages in the selection of store sites and, when their market shares are high, they have neighborhood pricing strategies available to them that can discourage new entrants (FTC 1969a). Given these advantages, little hope exists for a quick erosion of the very high levels of grocery store sales concentration in some metropolitan areas or a dampening of the upward trend that has brought the average concentration level for the over 200 U.S. metropolitan areas to a point that is statistically associated with competition problems.

Food Chain Profits and Margins

Long-run profit rates of food retailers averaged about 50% higher than the rate earned by other retailers for the twenty years prior to the A&P-WEO discount program that began in 1972 (FTC 1975). Since then the level and the trend of food chain profits has been subject to a number of unusual temporary occurrences including changes in accounting practices. However, recent profit rates appear to be more consistent with the previous long-run trend.

Food chain average gross margins and profit rates are strongly related to market share levels (Parker). On the average the price consumers pay for food retailing services goes up as retailer's market share in a city increases. On the average, large food chains report losses in their low market share areas. This indicates significant subsidization by large chains to their low market share cities from profits earned in high market share cities. My estimate of the total amount of the subsidy for the fifty largest chains based on current sales and profit figures is between $250 million and $1 billion (Parker).

Food chain gross margins increased significantly in the decade and a half between the early 1950s and the late 1960s ending at a level equal to what they had been prior to the supermarket revolution. A principal reason for the increase was the redirection of grocery retailing competition to expensive forms of nonprice competition. For the decade between 1955 and 1964, the period when percentage gross margins grew the most, 41% of the increase in supermarket operating costs was due to the increased costs of trading stamps and other promotional expenses according to the final report of the National Commission on Food Marketing (1966a, p. 78). In recent years, overstoring (excess capacity), a characteristic often found in oligopolistic industries, has resulted in higher operating costs for food chains. Between 1969 and 1974, sales per square foot (in real dollars) for supermarkets reporting to the Supermarket Institute declined about 20% (p. 11). A Canadian government report estimates that "overstoring" by food retailers in Canada caused consumers "to pay an average of 4 cents more than necessary per dollar of sales" (Canada, p. 200).

An extensive merger movement in food retailing that began in the 1950s was part of the underlying cause of the shift from price competition to nonprice forms of competition. The merger movement and the increasing trend in percentage gross margins began almost simul-

taneously. The effect of the merger movement was to eliminate the procompetitive force of actual and potential entry of chains from other cities. This kind of entry is a a very significant force directing food retailers to compete on a price basis. When large chains chose the merger route for expanding into new markets, the price rivalry associated with entry was avoided. In the mid-1960s, court victories in federal antitrust cases curtailed large market extension mergers.

Several of the most active acquiring companies of the 1950s and 1960s continued their growth objectives after the new merger enforcement policy was achieved (FTC 1971, pp. 14–15). In place of buying market shares of going concerns, these chains were forced to enter new markets de novo through price competition. Often they accomplished this by promoting themselves as "discounters" and thus popularized that term in grocery retailing. Since 1965, gross margins have not only stopped going up but dropped by slightly more than a percentage point (Parker). Considering that annual grocery store sales are currently over $150 billion a year, savings to consumers due to the decline in margins are in the area of $1.5 billion a year. Calculated savings would be substantially higher if the previous increasing trend in margins were projected forward.

The issues that emerge from the structure and performance trends in the food industries are (*a*) high and increasing market concentration, (*b*) significant degrees of product differentiation, and (*c*) moderately difficult entry. In many food manufacturing industries, entry can be achieved only through high product differentiation costs that are passed on to consumers in the form of higher prices. A fourth issue, in both food manufacturing and retailing, is the positions of market power concentrated with just a few large companies. This concentration provides strategies to those companies that are used to insulate them from the competition of medium-sized and smaller firms in their industries. Prospects of an erosion of these advantages without public policy intervention are dim. The structures of most food manufacturing and retailing markets are likely to continue their trend toward more tightly oligopolistic markets.

Antitrust Enforcement Issues

Antitrust enforcement is accomplished within a highly legal framework. The main vehicle is case-by-case litigation. While economists may perceive concentration as an economic issue and proceed to construct a structural model for improved efficiency, antitrust enforcement is constrained from such a direct approach both by the conduct-oriented language of the antitrust laws (Kaysen and Turner, chap. 3) and by court interpretations. Enforcement agencies deal with the problem of concentration primarily by reacting to acts and practices described in statutes such as mergers, predatory practices, and other concentration enhancing activities. Only recently has the FTC taken a first, cautiously chosen step to deal with the problem of concentration more directly through a deconcentration remedy connected with a shared monopoly case (*Trade Reg. Rep.*). The investigation leading to that case, which is against the largest breakfast cereal producers, was begun in 1968, and the final court ruling affirming the deconcentration remedy, if it should occur, may be as far away as five to ten years. Until then, unless there is a change in the law, the legal ground for a direct attack on concentration is tenuous.

Mergers

Merger enforcement policy probably has more impact on industry structure and performance than any other single area of enforcement. FTC merger enforcement guidelines are in effect in both the food manufacturing and food retailing areas. These guidelines, issued in the late 1960s, spell out the specific characteristics of mergers that the commission considers most likely to cause competitive problems.

The issues in horizontal merger cases are (*a*) the definition of the market, (*b*) market share and concentration levels, and (*c*) the health of the acquired and acquiring companies. In recent years, however, performance variables have taken an added importance in determining the probable effects of a proposed merger. In net the consideration of these additional factors has been to weed out merger investigations that would have been conducted on the basis of structural data alone.

In product extension mergers, which is the principal category of large mergers in food manufacturing, the degree of relatedness of acquired and acquiring companies is the major issue in determining potential competition. The required degree of relatedness has probably increased in recent years. The concept of potential competition is generally under attack

on the grounds that the standards for identifying potential competitors are too vague.

Market extension mergers are the main category of mergers in food retailing. A market extension merger is where a company in one geographic area expands by acquiring a firm in another geographic area. A basic question in a market extension merger is the threshold distance for defining a potential entrant. A related issue is that of distinguishing between a toe-hold acquisition and an acquisition of a significant participant in a market.

Vertical merger cases are not currently popular with antitrust agencies in my opinion. This is because of increasing criticism urging that a vertical merger must involve a very large share of a market before it represents substantial foreclosure or poses a substantial threat of possible dual distribution predation.

No conglomerate merger case has been brought since 1969 nor, in my opinion, is one likely to be brought by either the FTC or the Antitrust Division of the Justice Department. The principal conglomerate merger theories of deep pocket and cross-subsidization, reciprocity, and entrenchment of leading firms have fallen on hard times with respect to enforcement activity.

Conduct

Conduct includes such antitrust areas as price fixing, territorial restrictions, and price discrimination. In the conduct area per se doctrines previously focused almost exclusively on narrow legal issues rather than on more encompassing economic models. This is changing, and for the last four years screening of actions in these areas and requests for use of compulsory process have been made by an evaluation committee that is jointly staffed by economists and lawyers. Within the overall conduct area is an increasing zeal for price-fixing cases and a declining zeal for most other per se cases.

The main support of price-fixing cases, now, as always, is the hot piece of evidence that proves intent. This is usually obtained from informers or through file searches. Identical bid information also has been used in a number of cases. The problem of detecting price fixes, however, remains serious, and new antennae systems for discovering price fixes are needed.

Price discrimination (Robinson-Patmen Act) cases have declined dramatically in the last five years. In my judgment, the reason for the decline at the FTC, which in the past brought most Robinson-Patmen Act cases, is an increasing belief on the part of the economics staff that discriminatory prices are usually no more than a payment for shelf space, which is a scarce commodity that manufacturers should pay for. Secondly, price differentials to large buyers are believed to occur mainly because a market is soft, and price cuts to the large buyers are thought to simply reflect a prediction of a general price decline. In this context price cuts to large buyers are believed to speed up the general decline and therefore are a beneficial contribution to efficient market operation and should not be prosecuted even though they may be discriminatory and have potentially anticompetitive effects. Some critics of the Robinson-Patman Act have gone further by saying that the history of FTC enforcement has often buttressed existing price fixes. In my judgment very little is known about the effect of Robinson-Patman Act enforcement, and an objective study of it is badly needed.

Predation, including primarily line price discrimination, is being increasingly discounted as an anticompetitive practice because most benefits are assumed to be external to the company engaging in the predation. Also, there is a presumption of a general ease of reentry because productive assets of the target companies of the predation usually can be easily restored to use. The critical challenge to an attorney proposing a predation case is a showing that the predatory firm had a cost-benefit ratio for the use of predation that justified its employment.

Territorial restriction cases are usually persued on a straightforward per se basis. The future of territorial restriction cases in the food area is uncertain because of an effort in Congress to pass a law exempting food retailing and soft drink bottlers from prosecution on a per se basis.

A recent area of interest to the commission, which may have a profound effect on agriculture, is the analysis of agricultural cooperatives and federal marketing orders. Although some current investigations are being conducted for possible legal actions, there is a feeling on the part of the staff that the cooperative exemption may constitute a significant hinderance to competition and that federal market orders distort markets causing a serious waste of agricultural resources.

Conclusions

I think the most serious weakness of antitrust enforcement in the food area is the lack of up-to-date data and analyses. It has been a decade since the National Commission on Food Marketing and the FTC studies of the 1960s began to scratch the surface. Available current data suggest worsening structure and performance trends. We need a thorough review of antitrust policy in the food area.

Unfortunately, identifying the need will not automatically result in its being filled. I believe it is time to establish a national center for evaluation and support of antitrust policy in the food area. The center should be staffed by a critical mass of people with expertise in industrial organization problems in the food industries. They should be in a research environment that has continuity over time and one that is isolated by distance from day-to-day enforcement activities. It would be appropriate if the AAEA would propose establishing such a center at a university. The center should be funded by Congress and should have access to federally collected data. Committees of Congress should use the center as an arm to help them more efficiently perform their legislative functions and oversight over the federal antitrust agencies.

Antitrust—A Route to Centralized Governmental Planning?

Luther C. McKinney and Donald A. Washburn

It is popular to contend that bold new antitrust theories will eliminate numerous social problems. We are witnessing a flood of proposals to cure inflation, unemployment, productivity shortfalls, advertising abuses, nutritional deficiencies, industrial concentration, and almost every conceivable economic difficulty (U.S. Congress, Senate 1976a, b; House 1976; *Trade Reg. Rep.* 1973a, para. 20388, pp. 20269–71). Unquestioning application and testing of these patent-medicine claims in the food industry are leading to counterproductive, centralized governmental planning in the guise of antitrust policy. Hence, we would urge every American to critically consider the merits of emerging antitrust policy rather than accept it at face value.

Antitrust policy has historically developed as a unique mixture of politics, economics, and law. Over an eighty-six-year period, Congress has generally legislated a national economic policy of free competition. Economists have joined in an attempt to define a concept of free competition worthy of achievement. Lawyers, as advocates and judges, have engaged in a case-by-case interpretation of these laws and theories.

The policy originated in 1890 with the Sherman Antitrust Act, which requires each firm to make its business decisions independently and to avoid monopolization or attempts to monopolize. Next, Congress, in response to claims that the Sherman Act was too vague (Henderson; U.S. Congress, Senate 1914a, 1913; House 1914), enacted the Federal Trade Commission Act outlawing "unfair methods of competition" and also passed the Clayton Antitrust Act prohibiting, among other things, acquisitions and price discrimination that may substantially lessen competition or tend to create a monopoly.

In 1936, the Clayton Act was amended by an anti-chain store bill known as the Robinson-Patman Act to more specifically prohibit discriminations in price, service, or facilities in an effort to stop concessions demanded of food suppliers by large chain stores. In 1938, the Federal Trade Commission Act was amended to prohibit deceptive acts and practices.

Any objective ranking of these acts in terms of ability to preserve the fundamental aspects of competition affecting both the competitor and the consumer would rank the Sherman Act prohibitions against price fixing and other per se illegal restraints of trade in first place by a wide margin. The Sherman Act prohibitions against illegally obtaining or maintaining the market power to control prices or exclude competitors have been effective as well, but time consuming to enforce due to the complex economic issues involved.

The remainder of what is popularly regarded as U.S. antitrust legislation reads well on paper but is the subject of mixed reviews from a practical standpoint. Theoretically, an antimerger statute intended to nip incipient monopolies in the bud is difficult to criticize. Likewise, the concept of preventing discrimination or the inducement thereof when it is destructive of competition is appealing. The problem has been one of application. All too often such legislation has been viewed as a tool to maintain the status quo in the face of inevitable and desirable change.

The Clayton, Federal Trade Commission (FTC), and Robinson-Patman Acts are all based on the idea that public interest is best served by preserving many small firms operating in a purely competitive market (U.S. Congress, Senate 1913, 1914b). Obviously, that policy has not been literally enforced, or we would all be associated with World War I horse and buggy industries instead of a modern, international marketplace requiring economies of scale to survive.

A realistic compromise between theory and

Luther C. McKinney is group vice-president, Law and Public Affairs, and Donald A. Washburn is in the Law Department of the Quaker Oats Company.

practical reality has resulted from a strenuous adversary process. For example, countless antitrust enforcement resources were expended over many years out of fear that the rapid development of a more efficient food distribution system would destroy small food retailers (*Federal Reporter* 1939, pp. 667–79; *U.S. Supreme Court Reports* 1960, pp. 166–89; 1968, pp. 341–64). Nevertheless, the trend to modern methods prevailed. Efficient small stores offering convenience survived, and the facts clearly establish that the consumer is significantly benefited where scale economies accrue (Kunreuther). Indeed, members of the federal agencies who fought this delaying action now admit that in the food industry "divestiture or deconcentration . . . could well raise prices and injure consumer welfare" (*Antitrust and Trade Reg. Rep.* 1974, p. A-10).[1]

In spite of the inconsistencies between theory and reality, a gradual give-and-take, case-by-case interpretation of the four underlying statutes resulted in evolutionary changes that had no crippling or shock effect on business generally, since there was sufficient time and opportunity to present opposing views and to adjust to policy shifts.

The regulators, however, were not totally satisfied with that approach. They desired a more immediate involvement in business decisions. Businessmen provided an escape for the administrators by demanding more certainty regarding the applicability of antitrust policy. Consequently, the issuance of government guidelines became popular.[2] FTC Trade Regulation Rules, with binding legal effect, cover numerous areas (*Federal Reporter* 1973, pp. 672–709). Recently, in a further effort to avoid case-by-case interpretations, the FTC sought and secured legislation providing that a cease and desist order against one industry member subjects other industry members to a $10,000 per day penalty, providing they had notice of the order and engaged in acts that would be a violation of such order (see, for instance, P.L. 93-637).

The result has been to arm the regulators with strong procedural devices to minimize the role of the historical adversary system of policy evolution. Since the penalties for violation are so immense, many business people fear incurring the wrath of these regulatory czars. As a result, desirable changes in market structure, dictated by changing circumstances, may be slowed substantially to the possible detriment of consumer welfare. Still, our business system has been sufficiently strong to endure. We suspect that change can still occur as needed, even under the guidelines approach to antitrust policy, to permit continuation of the efficient system we have come to expect.

The same cannot be said for the move now afoot to establish the next generation of antitrust policy. Reduced to its lowest common denominator, that policy would allow the government to restructure through divestiture orders any industry deemed to be too concentrated. Current examples of the FTC's attempts to create such a policy include suits against the four largest ready-to-eat cereal manufacturers (see below) and the eight largest oil marketers in the United States (*Trade Reg. Rep.* 1973a, para. 20388, pp. 20269–71) for so-called "shared monopolies." If these proposals succeed, they will outlaw the market structures of about one-third of U.S. industry ("Antitrust: Snap. Crackle and Pop").[3] The shock of such a change would be too great for our business community to absorb without some unpleasant effects.

The FTC's assault in the cereal case goes to the very heart of numerous segments of the food industry where many companies find themselves among the top four to eight firms accounting for more than half of a segment's sales (U.S. Congress, House 1976; U.S. Dep. Commerce). In 1972, the FTC charged that Kellogg, General Mills, General Foods, and Quaker Oats were participating in a "shared monopoly" of the ready-to-eat (RTE) cereal industry. The charges were said to be justified, based on the limited number of firms in the business and their aggregate market share—an approach that had no prior basis in either legislation or case law. A few of the

[1] Enforcement of the Robinson-Patman Act provides countless illustrations. For instance, food retailers, over the years, who operated truck fleets were forced to run empty on return trips because the FTC viewed back-haul allowances by suppliers as discriminatory. While this area of policy is still murky, pressure to improve productivity has forced the agency to begin clarifying its position on the subject (*Trade Reg. Rep.* 1973b, para. 18089, pp. 20537–38, paras. 20498, 20850, 21031; FTC).

[2] For example, the FTC issues restrictive trade rules governing prospective mergers in the dairy and grocery manufacturing industries (*Trade Reg. Rep.* 1973b, para. 4532, pp. 6914–16; 1968b, para. 4530, pp. 6908–13). Similarly, the Justice Department issued its own merger guidelines (*Trade Reg. Rep.* 1968a, para. 4510, pp. 6881–89).

[3] Publicity indicates that the recently announced investigation of the automobile industry is based on this same emerging policy (*Wall Street Journal; New York Times*, p. 1; *Chicago Tribune*, sec. 4, p. 9).

facts of this case may serve to illustrate the "wonderland" philosophy associated with this type of antitrust policy.

In June 1969 Rufus E. Wilson, then chief of the Division of General Trade Restraints at the FTC, suggested in an internal memorandum that an RTE case be instituted on the basis that the industry was a "non-competitive" business "with a three-firm market share of 83%, with entry virtually barricaded by these three firms . . ." (p. 64). He referred to the "controlling oligopoly" as including Kellogg, General Mills, General Foods, but not Quaker Oats.

In view of that background, the naming of Quaker Oats as a respondent, along with the top three firms in the business, came as a surprise. Facts adduced in the trial have not cleared up the confusion. These facts show that Quaker Oats's share of sales has never exceeded 10% of the business and that for twenty-six years preceding 1970 Quaker Oats's average share of the RTE business was 4%, compared to the aggregate share of 82% enjoyed by the three largest firms. For thirty-one of the thirty-five years preceding the 1972 complaint, Quaker Oats was not even among the top four firms. In fact, Quaker Oats only achieved fourth position in 1968, moving from sixth position where its share of the business for years had been in the magnitude of 2% to 4%. Interestingly, Nabisco, which was not named a respondent, averaged 9% of the business from 1937 to 1970 compared to Quaker Oats's 3.8%.

While we may never learn precisely what the FTC hoped to gain by involving Quaker Oats, it seems apparent that Quaker Oats was included because of successful competition against the rest of the industry in the mid-1960s, since before then its share had been only in the 2% to 3% range. Maybe Quaker Oats is being penalized for competing vigorously with the three industry leaders, moving from a modest RTE business to the fourth-ranking position in the industry. Is the FTC now saying that internal growth by a small competitor to a fourth-place position warrants suit? Is that an unbending, bureaucratic dedication to a four-firm concentration ratio? If so, there is clearly a point where a company should stop competing because of the new risk that a government bureaucracy may decide that success has made it part of a "shared monopoly."

The remedies the FTC seeks from Quaker Oats are limited and contradictory to the basic charges of the complaint. It wants to prohibit Quaker Oats from making any acquisitions in the RTE cereal area for the next twenty years. Quaker Oats has not acquired a cereal business in the last fifty years and has no present plans of doing so.

The only other relief requested from Quaker Oats is the prohibition of its shelf-space programs designed to assist retail grocers in managing displays of RTE cereal in their stores. But the thrust of the complaint on this subject is that Quaker Oats did not push its shelf-space program hard enough in competition with the program offered by Kellogg. The FTC staff would, therefore, ban that which the complaint claims Quaker should have promoted aggressively. This is contradictory.

Much more is sought from the three industry leaders (Kellogg, General Mills, and General Foods), including a sweeping restructuring of their businesses, extensive trademark licensing, and a redistribution of some top-selling brands. The FTC staff wants three new companies spun out of Kellogg, asking that Kellogg give up its Rice Krispies and Special K brands along with manufacturing facilities and other unnamed labels to get the new companies started. General Mills would have to spin off one new company, giving it a plant and the Wheaties brand, while General Foods would also have to spin off one new company and give it a brand as yet unspecified.

The foremost pressure on federal officials to take an anti-big business stand and bring this type of case is to be found in an overly simplistic ideal called "atomistic competition." Since the late nineteenth century, orators in the political arena have proclaimed over and over that the strongest economy is one involving many small business units operating in a purely competitive marketplace (U.S. Congress, Senate 1913). This belief has permeated our thinking as a principle of the first order, becoming a political and social ideal. But the principle is, as many leading economists have noted, self-deceptive, because "this standard has little or no relation to competition as it exists in the real world" (Backman, p. 18). Competition so conceived has probably never existed in any economy and in fact could not exist. A well-intentioned minority in the academic community had embraced that self-deceptive illusion as the cornerstone of a move to fragment American industry. This illusion built up steam with the claims of de-

pression economists that concentrated industries were extracting supracompetitive profits (Bain). It was encased in a shiny veneer in the 1960s by industrial organization economists who claimed that industry performance is dictated by industry structure (Scherer). Thus, the apparent solution looked simple—atomize an industry and better performance will flow.

In that connection, it is appropriate to repeat Harry Truman's belief that "If you laid all the economists in the U.S. in a straight line, they'd point in all directions" (*Give 'Em Hell, Harry!*). The truth is that the structural view is not fully established, even in industrial organization economics (Goldschmid, Mann, and Weston). Unfortunately, "trust-busting" claims receive prominence, and informed explanations to the contrary are often ignored. Consequently, a theory, unsupported by empirical evidence and still being hotly debated among economists, has been adopted by the FTC as the basis of a radical change in antitrust policy.

None of the four major U.S. antitrust statutes decrees that an industry may be dismantled solely because some arbitrary, aggregate level of concentration is reached. This past June, Thomas Kauper, recently assistant U.S. Attorney General in charge of the Antitrust Division, stated that he did not believe that Congress had yet delegated this role ("Antitrust Division Experience etc."). The Justice Department has dropped a "shared monopoly" case against tire manufacturers (*Antitrust and Trade Reg. Rep.* 1976b, p. A-2). Nevertheless, the FTC is assuming a regulatory role similar to that of the Interstate Commerce Commission (ICC), in which it would judge the structure and performance of an industry as if it were a public utility[4] and then reorganize and regulate the industry in order to improve its performance. It is doing so despite congressional deliberations during which there was expressed a total opposition to the establishment of any trade commission that would be authorized to regulate industry generally as if it were a public utility (*Congressional Record,* p. 11089; U.S. Congress, Senate 1914a).

Current congressional activity demonstrates that Congress does not feel it has delegated such authority to the FTC. If the FTC has the power to restructure industries under existing laws, why are members of Congress presently debating the merits of anticoncentration bills to accomplish this very objective? Very recent examples are the Antitrust Improvement Act and Indiana Senator Birch Bayh's bill to break up vertical integration in the country's eighteen largest oil companies by dividing them into separate firms engaging only in production, refining, pipelines, or marketing (U.S. Congress, Senate 1976b; *Antitrust and Trade Reg. Rep.* 1976a, p. A-1). If Congress believed that federal officials already possessed this power, why bother?

In our view, the FTC is being goaded into continuing the pursuit of these doubtful horizons by a proliferation of the works of popular writers who characterize the profit-maximizing goal of business as cold hearted. Robbins, in his book *The American Food Scandal,* charged the four largest cereal producers with "profiteering" and the food industry, in general, with lying to the American people about the true price and quality relationship of their food. Speaking for Quaker Oats, these charges are false. The point is, however, that these books have a strong, immediate, political impact, even when inaccurate. Through emotional appeals, they cause fear and confusion. This leads to demands for someone to act. Federal officials react under such pressure and are so doing despite the consequences.

Before this process carves the new policy in stone, we sincerely hope that someone in a position to be heard will cry out with the truth that federal reorganization of industry is necessarily based on a false assumption. That assumption is that nonelected, transitory government officials have the wisdom, despite a general lack of business experience, to more properly structure an industry than the vast combination of economic forces bearing on the market.

The public should be informed that the United States is, by this policy, moving into a new era of central economic planning. Frightening questions arise. Who in the federal government will fill this god-like role of reorganization? Who will determine which firms deserve what share of each industry after deconcentration? If after reorganization some firms, through competition, enlarge their market shares, will another round of reorganization be required, and, if so, how often?

Have federal bureaucracies previously demonstrated such high competence and skill in

[4] For example, individual firm rates of return on capital employed will be acceptable to the regulators only if they compare favorably with the average rate of return of all manufacturing firms in the United States.

coordinating lesser tasks that they deserve faith with such a monumental responsibility and undertaking? Were people satisfied with their performance during price controls? Did the effects of the Russian wheat deal meet with their approval? Have they been impressed with regulated industries such as railroads controlled by the ICC? Has the postal service been up to their expectations? Have they been impressed with the government's management of our social security fund? Since bureaucratic rules may often be perpetuated to insure job security for the regulators themselves, can we be sure that they are a tolerable substitute for the impartial laws of supply and demand?

For business people, the best indicator of growth of the federal government is the number of new regulations that continually pour out of Washington. Before they can become official, all regulations must be published in the *Federal Register*. When it was first published in 1936, the *Register* had 2,411 pages. By 1974, it had grown to 45,422 pages and last year grew to an astronomical 64,000 pages—a growth of 42% from the previous year. One source likened the massive document to the most monumental book since Gutenberg's *Bible*! It is estimated that each American family pays $2,000 per year (at least one year's supply of groceries) to support this and other aspects of the federal bureaucracy (Sites).

This movement to fragmentize and sterilize domestic firms comes at an odd moment in our economic history. With the passing of the stable international economic system established at the end of World War II, so passed America's ability to remain isolated. Americans cannot afford to be overly protective of economic ideals other than those capable of satisfactory performance in both domestic and international marketplaces.

Given the worldwide, intensive competition for scarce resources, "bigness" in American business may finally be coming into an age when it may, by necessity, be "goodness" in critical economic areas. The federal government, however, has limited its economic focus to domestic market protection via its emerging antitrust policy, with seemingly little concern for the international implications.

The four laws that make up our national economic antitrust policy were framed and passed when development of the national marketplace greatly overshadowed international trade in economic importance. The periods surrounding 1890, 1914, and 1936 were times of political isolationism as well as strong grass-roots discontent with domestic economic conditions. Rather than now using these laws to dismantle our business system, it seems more appropriate to consider whether these acts remain valid in the present era when international economic considerations must rank equally with domestic priorities in order to assure that the United States retain its competitive position in world markets? Shouldn't we be looking to secure entrepreneurial opportunity within the context of a strong, private enterprise system rather than embark on a project of destroying our business structure in favor of a giant bureaucracy?

Concentration of business in the United States is lower than in other major countries in the world (Whitney). In the Soviet Union, concentration is a fundamental principle of that nation's centrally planned economy. Thus, in terms of international trade, the strokes of our antitrust law brush may be painting us into a very tight corner.

Additionally, we are curious as to how the regulators will stimulate the innovation required to discover substitutes for dwindling supplies of necessary resources, improve productivity, and increase consumer satisfaction. Structural remedies, as sought by the FTC in the RTE cereal case, could effectively stagnate a target industry. Innovation normally flows from experimentation and risk taking, spurred on by the profit motive. Whether firms will invest in research and development and take risks to produce major innovations is an open question if, upon success in the marketplace, they will be told to divest the successful assets or license trademarks, royalty free, so that others may capitalize on their hard-won goodwill and success.

It was alarming to learn that the cereal business was selected as a test case because it was viewed as having less political clout than others ("Antitrust: Snap, Crackle and Pop"). This implies a desire by some regulators to quietly establish this controversial policy without risking political and public debate. The real problem with such a low profile is that it masks an attempt to withhold freedom of choice from American consumers. It seems some federal regulators have concluded that consumers buy too many varieties of RTE cereals. The trademark-licensing remedy in the cereal case is designed to discourage development of further varieties. Yet, Americans have jealously guarded their constitutionally protected freedom of choice in other

areas. Why would we surrender this freedom to government officials in deciding what food products we will consume (so long as there is no health or safety hazard)? How long will our freedom of choice last elsewhere if we let federal officials assume they have the right to absorb it in this instance? An individual's economic, social, and political choices are interwoven and not easily separable. Restriction of one must have substantial effects on the others. How safe are our freedoms of speech and press when the economic forum, of which they are parts, is to become the realm of the government regulator?

In Orwell's prophetic work *1984*, he portrayed a society where reality was the opposite of the image painted by the government. His Ministry of Love controlled the minds of citizens through terrifying uses of fear. Similar contradictions are present in the federal government's move against our private market structures. It declares that concentration in business must be reduced through concentrated, centralized government planning. If we accept this panacea, we may learn to our detriment the truth of Orwell's view that the inherent nature of all highly centralized governmental organizations is to suppress that which they profess to protect.

Many agree with the editors of *Fortune* magazine who recently warned that the "real danger to American liberty is not that it will be trampled by iron heels but that it will be slowly buried in a dust of bureaucratic oppression. . . . We will have to insist, as a start, that legislators be much more cautious about authorizing government agencies to do things—and much more diligent about specifying what they may *not* do" (p. 118).

An Evaluation of the Economic Basis for Antitrust Policy in the Food Industry

Bruce W. Marion and Thomas L. Sporleder

Distrust for concentration of economic power pervades U.S. antitrust history, stemming as much from concern for protection of democratic institutions, equality of opportunity, and preservation of citizen control as from concern about economic performance.

The goals and rationale of antitrust are only partially revealed by the language of antitrust laws. Although these laws emphasize economic criteria (e.g., to substantially lessen competition), the history of their enactment and enforcement reveals the strong influence of political and social goals as well as evolving legal and economic theories. Dewey may be right in contending that antitrust policy in this country has been aimed most consistently at limiting the power and growth of big business in order to encourage a more equitable distribution of power in society.[1]

This paper concentrates on the economic underpinning of U.S. antitrust laws. We recognize, however, that economic concepts and evidence are not alone in providing the basis for antitrust policy and that a restricted treatment ignores important noneconomic goals and concepts.

Economic Basis for Antitrust

Industrial organization theory, as set forth by Bain, posits that industry structure determines (or strongly influences) the conduct or behavior of firms within an industry and that firm conduct determines (or strongly influences) their collective performance. In recent years, Bain's model has become the main economic paradigm for interpreting and enforcing U.S. antitrust laws. The many attempts to verify or refute Bain's model since 1960 have added much to the theoretical richness and practical understanding of imperfectly competitive markets. Although varying greatly in focus and rigor, much of this research has examined relationships between the structure of markets (especially market concentration) and their performance (especially profits). Given the critical role accorded Bainsian theories, a brief critique of methodology and empirical findings is warranted.

Methodological Concerns

A survey of methodology in existing industrial organization studies is beyond the scope of this paper. Several such surveys are available (Weiss 1971, Vernon). However, a few topics of importance to the food industry receive comment.

Definitions, data, and methodology are each essential to theory verification. Each represents unique potential for invalid theory verification. Reverence for precise definition is innate to theory. Concepts such as market, firm, and industry reside as part of rather precisely defined theoretical constructs of the structure-conduct-performance (S-C-P) model. Although theory may be eugenic, secondary data coincident with relevant market areas for a neatly defined single product firm or industry may be impossible to obtain. Increased propensity toward diversification and conglomeration aggravates the problem of obtaining theoretically relevant data.

Access and cost constrain many verification efforts from utilizing primary data that are more consistent with theoretical definitions than existing secondary data. Of special rele-

---

Bruce W. Marion is a visiting professor in the Department of Agricultural Economics, University of Wisconsin, on leave from Ohio State University, and Thomas L. Sporleder is an associate professor in the Department of Agricultural Economics, Texas A&M University.

The order of the authors is not intended to reflect relative contributions.

[1] Kaysen and Turner suggest four possible aims of antitrust policy: (*a*) the attainment of desirable economic performance with respect to efficient use of resources, progress, stability of output and employment, and equitable distribution of income; (*b*) protection of competitive processes by limiting market power; (*c*) enforcing a standard of fair conduct in business; and (*d*) limiting the power and growth of big business and promoting small business to encourage a more equitable distribution of power in society.

vance to the food industry are market area data. Most large grocery chains and food manufacturers operate in multiple markets, whether product or geographic. Secondary data available on major variables, such as concentration, profits, and prices, often lack appropriate levels of disaggregation and/or appropriate time periods.

Adequate quantification of theoretically important variables has continually plagued industrial organization studies. Barriers to entry and product differentiation, as dimensions of market structure, must be estimated largely via surrogate variables, as must the performance dimensions of progressiveness and technical efficiency. In addition, measures of market concentration have largely relied on Bureau of the Census's four- and eight-firm concentration data that have widely recognized definitional problems. Concentration measures also do not distinguish between various institutional arrangements such as retail chains versus affiliated independents or national brand versus private label processors. Plausibly, concentration both within and among such institutional groups is important for determining market-specific industry performance.

Since most industrial organization studies of the food industries rely on cross-section multiple regression models, the ubiquitous question of association versus causality is of continuous concern, particularly in examining certain aspects of the S-C-P model (Asch and Seneca). Regression analysis of food manufacturing companies also have revealed serious problems of heteroskedasticity (Imel and Helmberger, Arnould and Fletcher). Increased diversification of food manufacturers is likely to force more studies to use firms rather than industries as the unit of analysis, thereby making heteroskedasticity a more common problem in the future. Fortunately, methodology is available for dealing with this problem (Imel and Helmberger).

Relatively scant attention has been paid to conduct in the S-C-P approach. This undoubtedly relates the methodological difficulties inherent in quantifying conduct. Some recent advances, however, have involved utilization of the theory of investment under uncertainty and more generally probabilistic approaches (Weston). Pricing behavior analyzed in a probabilistic framework could add fresh insights to market conduct-performance relationships.

In an enumeration of methodological issues relevant to antitrust, measurement of welfare loss must be included. One interindustry comparison of welfare loss indicated severe concentration of the industry source of the welfare cost of monopoly. However, the percentage of the total welfare loss attributed to food and food-related manufacturing industries was relatively small (Siegfried and Tiemann, p. 197). Interindustry estimates of welfare loss are of obvious importance for prioritizing antitrust activities in the economy but are subject to attack on methodological grounds, such as the assumption of constant own-price elasticity of demand across industries or the failure to consider monopoly effects on costs as well as prices. Research is needed on the welfare loss question in agriculture and the food industry in general.

The data and methodology problems in industrial organization research are substantial and should not be understated. Still, these problems have not prevented a large number of valid research efforts from being conducted. The problems do increase the difficulty of empirical efforts and account for some of the variability in results.

Empirical Evidence

The strongest and most consistent empirical relationships have been found between market concentration and profits (allocative efficiency). This relationship has been extensively tested. Weiss, after carefully reviewing nearly fifty studies, concluded: "In general, the data have confirmed the relationship predicted by theory, even though the data are very imperfect and almost certainly biased toward a zero relationship. . . . Altogether, there is still plenty of reason to believe on both theoretical and empirical grounds that high concentration facilitates tacit or explicit collusion" (1974, pp. 231–32).

Relationships between allocative efficiency and structural elements of entry barriers and product differentiation also have received considerable analysis. In general, industries with high barriers to entry and/or high advertising expenditures (proxy for product differentiation) tend to have significantly higher profit levels than industries characterized by low or moderate entry barriers and/or advertising (Scherer, Mann). The direction of causality and theoretical rationale for the profit-

advertising relationship are subject to some debate, however.

Relationships between market structure and other dimensions of market performance are less clear. Although it is often assumed that concentrated markets are technically more efficient, the large size of most U.S. markets allows for firms that are large in absolute terms without high concentration. Bain concludes from his analysis that the main impact of market structure is probably on performance dimensions other than technical efficiency.

However, empirical studies of scale economies have concentrated on production economies, virtually ignoring economies that may exist in procurement, finance, marketing, and planning. Scale advantages in marketing (advertising, physical distribution, and new product development) likely account for the substantial increase in concentration in consumer goods manufacturing industries, while concentration in producer goods manufacturing industries has remained relatively stable in recent years (Mueller and Hamm).

Progressiveness in relation to market structure has been extensively examined, albeit with relatively weak data. Scherer concludes that neither very low nor very high concentration is conducive to progressiveness, that a "subtle blend of competition and monopoly" (p. 378) with modest entry barriers is needed for rapid technical progress.

The foregoing highlights the empirical efforts that have particular relevance to antitrust. Some important topics have been bypassed for lack of compelling evidence.[2] Where do we come out on balance? Is the S-C-P model verified? We believe the weight of evidence calls for a qualified yes. Certainly, a thoughtful person would find it difficult to review the myriad of studies and contend that market structure and performance are unrelated. Although the direction and strength of the relationship between certain structural and performance elements is still rather murky, we accept that market structure does in fact influence several aspects of market performance.

While this conclusion may be open to challenge, an equally interesting question is whether Bain's model is relevant for analysis of current antitrust issues in the food industries. To examine the relevance of the S-C-P model, identification of critical antitrust issues is necessary.

Antitrust Issues in the Food Industry

Many food industry antitrust issues are germane issues to the general economy as well. The most critical issues are briefly outlined.

(*a*) What structure of food retailing and food manufacturing markets will generate the optimum balance of operational efficiency, allocative efficiency, and progressiveness, and what are appropriate policies to move industries toward the ideal structure? The interrelationships of market structure, progressiveness, and economies of scale are critical to this issue and are not well defined. Policies for dealing with established positions of excessive monopoly power must also be determined.

(*b*) What is the extent and effect of various types of conglomeration in the food industry? For example, what is the effect of multimarket grocery chains or conglomerate food manufacturers on competitive behavior and small firm competitors?

(*c*) What is the extent and influence of various vertical linkages and arrangements in the food system, including vertical integration, contractual and tying arrangements, exclusive dealing and situations involving monopsonistic procurement power?

(*d*) How adequate are the information and communication systems in the food system? For consumers to be sovereign, they must be informed. Information, rightfully a dimension of market structure, has for too long been ignored via assumptions of perfect (or at least adequate) knowledge. Since much information flows vertically, vertical arrangements may have an important bearing on the status of information.

(*e*) What is the power and effect of producer cooperatives and labor unions (both presently exempt from antitrust laws)? What are the propensities of these organizations toward concentration, and what are the performance implications?

(*f*) What are the forces operating in the food industry that generate structural change or stability? What changes are likely to evolve under a laissez-faire public policy?

The Bain model and empirical evidence

---

[2] The relationship between market structure and prices, wages, and employment has received considerable but spasmodic attention over the years. Evidence on this important topic is still somewhat cloudy, although the experiences of the Nixon administration support the administered inflation theory. There is also a growing amount of empirical work on the sociopolitical effects of monopoly power and large firms.

provide a useful framework within which to examine the above issues, but they are not in and of themselves adequate to guide public policies on any of these issues. At present, the S-C-P model provides the most guidance on issue (*a*) and the least on issues (*b*) and (*c*). Empirical research has shed valuable light on the critical levels of concentration, product differentiation, and entry barriers. This research has provided the economic basis for merger guidelines and enforcement action, for proposed legislation calling for industry restructuring, for proposals to limit advertising, and for the selection of key cases such as the shared monopoly case against four cereal companies. With some modifications, the model lends itself to examining aspects of the other issues. However, the lack of empirical research on these subjects results in few policy guidelines.

In examining the strengths and limits of the S-C-P model for addressing current antitrust issues, some limits of the model can be attributed to the lack of data or empirical efforts needed to verify or refute, some to the failure of researchers to include important structure, conduct, or performance variables, and some to limitations in the construct of the model itself. For example, the model does not consider the influence of alternative vertical linkages on subsector performance. In addition, by excluding business conglomeration and multinational characteristics as structural variables, the model has limited the research focus of many industrial organization economists (Mueller). The paucity of empirical analysis of the causes and consequences of various types of market conduct limits model usefulness for addressing antitrust issues such as price discrimination, tying arrangements, and predation.

The model clearly "fits" best in addressing the structure and performance of industries composed of relatively specialized firms and in which product or process technological change is relatively unimportant. With increasing diversification in the food industries, this is less and less the case. Modification and adaptation of the basic Bainsian model are called for in order to address some of the current issues. Also, analyses increasingly must be done using individual company data similar to the Federal Trade Commission (FTC) "Kelly Report" and are highly dependent upon data such as the FTC line of business reports.

Alternative Economic Bases for Antitrust Policy

The S-C-P triad is based on static deterministic microeconomic theory. Within this context "at least twenty-one concepts of the firm" have emerged that in some way change the objective of maximizing money profits (Malchup, p. 26). Although many alternatives have sought more realistic and/or more dynamic concepts of economic organization, few distinct and definable paradigms that are empirically verifiable have emerged.[3] Only two alternatives to the conventional profit preference function have emerged in terms of marginal analysis that have been recognized widely. This section briefly reviews each and the relatively new organization failures paradigm.

Alternative Preference Functions

When ownership and management are separate, Williamson (1964) proposes a management discretion theory where management maximizes a utility function $U = U(E, I, S)$, subject to $\pi \geq \pi_0$, where E is expenditure on staff (monetary compensation of management and the quantity and quality of their staff), I is investment expenditure that management controls in a discretionary manner, S is management slack (quantity and quality of nonmonetary compensation received by management, which is strictly in excess of amounts needed for the firm's operation), and π_0 is the minimum profits necessary to ensure survival of existing management. Neither I nor S is assumed to influence marginal cost, but they are assumed to contain sales promotion expense that may influence marginal revenue by shifting demand. Optimality is defined by $\partial R/\partial Q = \partial C/\partial Q$ and $\partial R/\partial E < 1$. Total revenue is denoted by R, total cost by C, and output rate by Q. Equilibrium output rate may exceed conventional profit preference function equilibrium and X-inefficiency will exist.

Baumol has suggested an alternative preference function that involves maximization of dollar sales subject to a minimum profit constraint. Profit maximization is rejected because this preference function cannot explain

[3] The many writings on workable competition and dynamic innovative competition represent alternative rationale for antitrust to Bain's model. This body of thought has supported the "rule of reason" approach to antitrust, which has spasmodically been in favor with the antitrust agencies. Clark, Sosnick, and Schumpeter have provided some of the fundamental concepts in this general area. It is such a diffuse body of thought we have chosen not to present it as an alternative framework.

some aspects of oligopoly behavior such as the tendency to raise price to cover increases in fixed costs. Rather than $MC = MR$, strict sales maximization would require $MR = 0$. Hence, some output would be sold where $MC > MR$; however, this is limited by a minimum profit constraint (Kafoglis, pp. 584–85).

Management will maximize a revenue function $R = R(Q, A)$, subject to $\pi \geq \pi_0$, where all symbols are as before and A represents expenditures on sales promotion and advertising. To maximize R requires $\partial Z/\partial Q \leq 0$, $\partial Z/\partial A \leq 0$, and $\partial Z/\partial\lambda \geq 0$ from the Lagrangian function $Z(Q, A, \lambda) = R - \lambda\ (\pi - \pi_0)$.

Revenue preference function equilibrium occurs at lower price and greater output than managerial preference function equilibrium. Also, revenue maximization is not necessarily consistent with preference for output or physical size of firm. Price and output comparisons among profit, revenue, and managerial preference function firms are difficult since various assumptions can be made regarding revenue-cost relationships. Also, comparisons of price-output are sensitive to cases of increasing, decreasing, and constant costs (Kafogolis, p. 585–86).

Organization Failures and Hierarchies

Another approach to economic organization, loosely referred to here as organization failures and hierarchies, stems mostly from Williamson's revival of the transaction as the principal unit of microeconomic analysis (1975).[4] The approach takes firms and markets as alternative methods for completing a related set of transactions and considers the relative efficiency of each method. Costs of contracting across markets may be explained by the interaction of environmental and human factors. For example, uncertainty from the environmental sphere and bounded rationality from the human sphere may interact so that "it is very costly or impossible to identify future contingencies and specify, *ex ante*, appropriate adaptations thereto," which results in internal organization replacing long-term contracts (1975, p. 9).

Organizational failure refers to both market and internal organizational failure.[5] Hierarchies refers to the subordinative association of work groups that represent nonmarket alternatives for completing transactions. Thus, the core of the Williamson analysis is transactional in nature and focuses on intrafirm organization as well as interfirm interaction for possible explanation of observed oligopoly behavior.

Conclusions and Implications

At this point in time, Bain's S-C-P model is the only well-developed, and at least partially operational, theory on which to base antitrust policy. However, this model provides limited guidance on several important antitrust issues and, because of data and methodology problems, may never be adequately verified.

Empirical results generated from the S-C-P framework provide rather persuasive evidence for limiting horizontal concentration of industries. Whereas moderate levels of concentration may often be beneficial, high levels appear to be seldom justified. This provides solid economic rationale for dealing with horizontal mergers. Economic rationale for dealing with price conspiracies is likewise strong. The economic underpinning is relatively undeveloped, however, for antitrust policies concerning predation, price discrimination, vertical mergers, and pure conglomerate mergers. Antitrust laws bearing on the latter topics also are heavily dependent upon the perceived purpose of antitrust, that is, the extent to which dispersion of economic power and preservation of small firms is a high priority of antitrust policy.

The alternative paradigms reviewed may in time prove useful in guiding antitrust policy. At present, however, they are largely undeveloped and untested. Their potential merit is, therefore, difficult to judge.

The greater realism of models with alternative preference functions is appealing, especially since the rigor of marginal analysis can be retained with these alternatives. Although neither of these models has been verified, we suspect they contain at least a "germ of truth." However, logic and empirical evidence suggests that alternative objectives do not replace or submerge the objectives to increase (if not maximize) profits. The consis-

[4] "Revival" because of the Commons antecedent and the antecedent of institutionalists in general. Also, an extension of transaction as the principal unit of analysis has evolved, divergent from Williamson (1975), that examines structure of property rights and is primarily associated with writings of Alchian and Demsetz.

[5] Market failure refers to transaction costs which can be reduced by substituting internal organization for market exchange (see Williamson 1975 for explanation).

tent positive relationship found between concentration and profits indicates that, whether or not profits are maximized, when the market environment allows an increase in profits, management is quick to oblige. Thus, the basic S-C-P relationship still appears valid although alternative preference functions may suggest a more complete set of causal factors affecting industry conduct and performance.

In both of the models reviewed, performance is largely determined by management discretion, not by the compelling force of the market. They would, therefore, seem to apply in those market situations where some degree of market power and management discretion exists. These models would provide a vague and transitory basis for antitrust policy and would support a "rule of reason" approach to antitrust. Experience suggests that this would result in little enforcement.

The organizational failures framework holds particular potential for dealing with vertical linkages and arrangements. Transactions play a major role in the organizational failures framework that attempts to merge concepts from organization theory and economic theory. This somewhat different view of the world, although still lacking a comprehensive taxonomy or analytical framework, should shed fresh light on vertical and possibly conglomerate organizational phenomena. This framework emphasizes the logic or rationale for creating or changing certain organizational designs. However, it is relatively mute on the performance consequences of alternative organization arrangements.

Perhaps the greatest contribution of the alternative paradigms at present is in offering a different set of glasses through which to see the world and hence suggesting alternative hypotheses to be tested. For example, the uneconomically large number of retail stores in a local market can be interpreted as entry barriers erected by established firms to maximize long-run profits or as an effort to maximize sales or consumer convenience to the detriment of both short-run and long-run profits. Similarly, conglomeration can be viewed from a S-C-P perspective in which reciprocity, cross-subsidization, and mutual forebearance are examined, or from the organizational failures viewpoint that contends that capital market failures may be a leading cause for conglomeration since through internal resource reallocation the firm can avoid "nontrivial" transaction costs. However, until the alternative paradigms are more fully developed and at least partially verified, they are of little value as a basis for antitrust.

The economic underpinning for parts of antitrust is rather solid, for other parts rather fragile. Additional empirical analysis is particularly needed in certain areas to test alternative theories and to lead to more complete theories. At this point, many industrial organization questions are still empirical questions. While this can be interpreted as a pessimistic assessment, it is probably no less so than an assessment of the economic underpinning for most areas of public policy. Although what we know about industrial performance may be an "island protruding from a sea of ignorance," at least we have that island.

Technical Change, Labor Use, and Small Farmer Development: Evidence from Sierra Leone

Dunstan S. C. Spencer and Derek Byerlee

In large areas of Africa where land-labor ratios are high and use of capital is minimal (usually less than $10 per farm annually), labor is the dominant factor of production. Effective use of labor is then a key element in any program to increase output and incomes among small farmers. Following Hayami and Ruttan, technical change appropriate to these factor endowments would involve adoption of labor-saving technology for peak season operations to raise labor productivity. When the labor bottleneck occurs at planting time as is common in tropical Africa, this translates into mechanization of planting operations, particularly land preparation to enable expanded acreage. However, because labor constraints are only seasonal, conventional land-saving technologies may also be appropriate. If planting labor is the bottleneck, biological-chemical technologies that increase yields per acre and hence increase weeding and harvesting labor but leave planting labor unchanged will in fact be labor saving with respect to labor at the peak season. It is not uncommon to observe both mechanical and biological-chemical technologies being adopted side by side in high land-labor ratio areas in Africa.

These interrelationships between technical change and demand for labor must also be examined within the context of available labor supply. Where there is no class of landless laborers because of the land surplus situation, labor supply to agriculture depends primarily on the time input and allocation of family members, particularly at the peak season. Competition with nonfarm activities has been shown to be one important component of labor supply to farming (Norman, Byerlee and Eicher). Recently, there has also been interest in the role of female labor supply in both traditional and improved farming systems.

Despite the obvious importance of these labor supply and demand relationships to small farmer development, there are relatively few detailed studies of labor utilization in traditional African agriculture and almost none that examine labor use under improved technologies. The objectives of this paper are then to briefly highlight some findings based on a detailed farm survey, with respect to labor use in two contrasting situations—one employing mechanical cultivation and the other improved biological-chemical technology—in rice production in Sierra Leone.

Specifically, we shall first examine labor use from the demand side, noting the impact of the different technological packages on resource combination and returns to labor. We then examine labor use from the supply side by analyzing the impact of technical change on household family labor inputs and the differentiation of labor use by sex.

Data Sources

Data reported in this paper were obtained as part of a nationwide farm management survey

---

Discussants for this session were William C. Merrill of the U.S. Agency for International Development and Richard O. Wheeler of Winrock Livestock Research and Training Center.

Dunstan S. C. Spencer is currently a visiting associate professor of agricultural economics, Michigan State University, on leave from Njala University College, Sierra Leone, and Derek Byerlee in an assistant professor of agricultural economics, Michigan State University.

This research was financed under a U.S. Agency for International Development Contract (AI D/csd 3625) with Michigan State University subcontracted to Njala University College.

conducted during 1974–75 of 500 rural households in twenty-four enumeration sites in Sierra Leone, chosen on a stratified random basis. Data were obtained by locating enumerators at each survey site and interviewing farmers twice weekly over a twelve-month period (Spencer and Byerlee). In this paper we discuss data from only two survey areas. The first area is situated in the center of the Boliland area where rice is grown in infertile swamp grasslands. Extensive mechanical cultivation is practiced in the area through a government hire tractor scheme that charges a subsidized price for tractor services.[1] The second study area is located in the Moa Basin region in an area served by an Integrated Agricultural Development Project (IADP) established in late 1973 with major emphasis on improved biological-chemical technology for production of inland swamp rice. Each farmer participating in the project receives credit, improved seed, fertilizer, and tools, as well as extension advice on constructing water control facilities. No mechanical cultivation is practiced in the area.

Technical Change and Labor Use in Rice Production

Labor inputs for rice production using varying technologies are shown in table 1. In the IADP area, farmers previously grew upland rice using traditional bush fallow cultivation where a new piece of land is cleared each year. Some farmers also grew swamp rice under traditional methods where land is continuously cultivated. These two production systems are used as benchmarks for the "without" project situation to be compared with the improved seed, fertilizer, and water control methods used by farmers in the project. In the Bolilands labor use under hand cultivation is compared with mechanical cultivation. It should be noted that we are comparing enterprises, not farms. In the IADP area farmers often produce traditional upland rice in combination with traditional swamp rice, while farmers in the IADP for the first year usually continue to produce upland rice in combination with improved swamp rice production. Farmers in this area also produce tree crops, particularly cocoa, coffee, and oil palm. In the Bolilands over half of the sample practiced both hand and mechanical cultivation of rice, but few other crops were produced.

Labor inputs are computed in person-hour equivalents assuming that the ratio of wage rates for hired men, women, and children accurately reflects the marginal rate of substitution between labor of different types. In the IADP area labor inputs per acre have increased substantially as a result of participation in the project (significant at the 1% level). The increased labor per acre is due to improved land preparation and a larger harvest.[2]

In the Bolilands labor inputs per acre declined by 40% as farmers substitute capital for labor in land preparation activities. To further understand these production relationships, a constant elasticity of substitution production function was fitted to farm data for the Bolilands with the form

$$\ln Y = V/P\,[\ln (S_1 L^P + S_2 K^P)],$$

[1] There is also some variation in biological technology in the Boliland area with respect to the planting procedures—broadcasting or transplanting—and use of fertilizer.

[2] Weeding is not an important activity in swamp rice production in either of the two study areas.

Table 1. Labor Inputs and Yields in Rice Production under Differing Technologies in Sierra Leone, 1974–75

	Labor Input per Acre[a] (Person Hours/Year)			Yield per Acre (Pounds/Acre)
	Family	Hired	Total	
IADP area				
Traditional upland	884	60	953	798
Traditional swamp	697	39	736	1,260
Improved swamp[b]	1,125	256	1,393	1,734
Bolilands				
Hand cultivation	270	47	317	858
Mechanical cultivation	153	40	193	1,008

[a] Person-hour equivalents computed by applying weights of 1.0, 0.75, and 0.5 to men, women, and child labor, respectively, in the IADP area and weights of 1.0, 1.0, and 0.5 to men, women, and child labor in the Boliland area. Weights reflect relative wage rates in those areas as discussed in Spencer and Byerlee.

[b] IADP package of fertilizer, seed, and water control.

where Y is total value added in rice production, L is input of labor (in person-hours), K is payment for the tractor hire services, V is the returns to scale parameter, P is the substitution parameter such that the elasticity of substitution is $1/(1 - P)$, and S_1 and S_2 are distribution parameters. The value of P estimated was 1.0 with standard error 0.82, indicating a high elasticity of substitution.[3]

Although land is not included in this equation, the returns to scale denoted by V is 0.99, indicating constant returns to scale on labor and capital services. This provides evidence that land is not a limiting factor. Because land is relatively abundant in this area, farmers expand acreage with mechanical cultivation. The average size farm for those farmers with only hand cultivation was 8.4 acres, compared with 12.7 acres for farmers using mostly mechanical cultivation. These results indicate that substantial flexibility exists to substitute capital for labor in the Bolilands. However, it is important that this substitution enables an expanded acreage to be cultivated, and, although labor-saving technology is employed, it is not necessarily labor displacing.

Yields of rice per acre are also presented in table 1. In the IADP area yields per acre of improved swamp rice are more than double yields on traditional upland rice and 37% higher than under traditional swamp rice. In the Bolilands yields per acre are slightly higher on mechanically cultivated farms, but regression analysis of yield data indicated that this was due to higher fertilizer applications on mechanically cultivated fields and not due to any effect of mechanization per se.[4]

Enterprise budgets for each farming system are constructed in table 2. In the IADP area, returns per acre are increased on improved swamp rice farms compared with traditional systems. However, returns per man-hour of labor input are lower on improved swamp rice compared with traditional swamp rice production, although 50% higher than on upland rice production. Adoption of the IADP package to improve swamp rice has resulted in

[3] Equation estimated directly through nonlinear maximum likelihood regression approach following Ramsey and Zarembka. R^2 for the estimation was 0.73. This function was chosen because, unlike the Cobb-Douglas function, it allows the elasticity of substitution to range from zero to infinity and can thus better reflect the extent to which factors can be substituted for one another.

[4] The function fitted was $Ya = 7.40 + \underset{[0.07]}{0.15}\,Fa + \underset{[0.006]}{0.014}\,La$, where Ya is yield per acre (bushels), Fa is fertilizer per acre (pounds), and La is labor per acre (hours). Standard errors are bracketed, and the R^2 is 0.50. A variable representing method of ploughing (hand or mechanical) had no significant effect. However, mechanical farms use 60 pounds of fertilizer per acre compared with 37 pounds per acre on hand cultivation.

Table 2. Enterprise Budgets for Different Systems of Rice Production in Sierra Leone, 1974–75

	IADP Area			Bolilands	
	Traditional Upland	Traditional Swamp	Improved Swamp[f]	Hand Cultivation	Mechanical Cultivation
	Average/Acre				
Output-value (Le)[a]	67.0	105.0	144.0	61.4	72.1
Variable costs (Le)					
Land payment	0	0	0.7	0.3	2.1
Seed	5.3	4.4	5.1	4.5	3.8
Fertilizer	0	0	1.5	0.8	1.2
Mechanical service	0	0	0	0	6.8
Hired labor[b]	6.5	4.7	23.9	3.1	3.1
Others	0	0	2.2	0	0
Total variable cost	11.8	9.1	33.4	8.6	16.9
Interest on total costs[c]	2.3	1.8	6.7	1.7	3.4
Enterprise gross margins[d]					
Per acre	52.6	94.1	103.3	51.1	51.9
Per hour of family labor	0.06	0.13	0.10	0.18	0.34
Gross margins per hour family labor with unsubsidized costs[e]	0.06	0.13	0.09	0.18	0.06

[a] Le 1.00 = $1.10 U.S. in 1974–75.
[b] Valued at wage rate specific to the area.
[c] Assumes 20% opportunity cost.
[d] Output value less variable costs less interest on variable cost.
[e] Assumes fertilizer subsidy of 67% and mechanical ploughing subsidy of 85%.
[f] IADP package of seed, fertilizer, and water control.

increased returns to land, but because of the added labor, returns per unit of labor are lower than under traditional swamp cultivation systems.

In the Bolilands returns per unit of land are virtually the same for both hand and mechanical cultivation. However, returns per unit of labor are substantially higher under mechanical cultivation.[5] Moreover the marginal value product of labor estimated from the constant elasticity of substitution production function fitted above is Le 0.19 per hour—almost identical to average returns to labor on hand cultivated fields. (The Sierra Leone monetary unit, the Leone [Le], was valued at $1.10 U.S. in 1974–75.)

In Sierra Leone mechanical services and fertilizer are both heavily subsidized. To assess the economic returns in both projects, returns to labor were recomputed using unsubsidized prices.[6] For the IADP area, returns are virtually unchanged, but in the Bolilands hand cultivation is now considerably more profitable than mechanical cultivation. In fact, the previously high returns to labor under mechanical cultivation are reduced to a level below that of improved swamp cultivation in the IADP area. The results indicate that neither the biological-chemical technology of the IADP nor the mechanical technology of the Bolilands is particularly successful as measured by returns to the limiting factor—labor. If returns are to be increased in the IADP area, either labor inputs must be reduced or yields increased.[7] In the Bolilands the increase in cultivated area resulting from mechanization has occurred at substantial cost given the current high cost of operating the government tractor hire scheme.

The relationships observed here are consistent with theoretical expectations. The mechanical technology has increased labor productivity, while the biological-chemical technology has increased land productivity. However in each case only one technology among a range of potential alternatives was evaluated. Biological-chemical technologies employing only improved seed and fertilizer but not water control measures may be more appropriate than the IADP package considered here. In fact, elsewhere Spencer has shown that investment in improved seed and fertilizer in upland rice has greater potential for increasing returns to labor than either of the two technologies evaluated here. Likewise, tractor cultivation represents only one form of mechanization. In Ghana, Winch has investigated several technological alternatives for rice production and concluded that a combination of tractor hire for cultivation and improved seed was most profitable, although hand cultivation was not considered as an alternative.

Technological Change and Total Household Labor Use

In assessing the impact of technological change on total family labor use, it is necessary to consider all household production activities, since labor may be shifted between rice production and other crops and between farm and nonfarm activities at different seasons of the year. In addition, it is also important to analyze how the introduction of technological change affects the division of labor by sex. In fact, several writers (e.g., Boserup and Tinker) assert that new agricultural technologies have an adverse effect on women, since they lead to an increase in women's work loads, while the work loads of men are reduced.

The seasonal profile of total hours worked each month by family members in farm and nonfarm work (excluding domestic duties, such as cooking) for the two survey sites are shown in table 3. In the IADP area, households were divided into three groups: nonparticipants or households who had not joined the IADP, households who were participating in the project for the first year, and households who were second-year participants in the project. Boliland households are grouped into households using primarily hand cultivation, households using mixed hand and mechanical cultivation, and households using primarily mechanical cultivation.

Of course, with cross-sectional data, we cannot always be sure that the difference among groups are the result of the technological adoption or the cause of the adoption. In

[5] In fact, part of this difference is the result of higher inputs of fertilizer on mechanical farms. If hand cultivation fields use the same level of fertilizer, returns per man-hour are Le 0.22.

[6] It is estimated that current subsidy levels are 67% for fertilizer and 85% for mechanical services.

[7] Yields of improved rice in the area are below the potential for the area partly because farmers did not follow recommended practices especially in the second year of participation when the level of extension advice was reduced, cultural practices were poor, and the rate of fertilizer was reduced. Also, labor inputs are high partly because farmers are still engaging in land improvement even in the second year of the project.

Table 3. Seasonality of Labor Inputs for Adult Family Members in Sierra Leone Rural Households Using Differing Agricultural Technologies

Type of Household	Sample Size	Month[a] May	June	July	Aug.	Sep.	Oct.	Nov.	Dec.	Jan.	Feb.	March	April	May	Total Hours for Year[b]

[a] Survey from May 1974 to April 1975 in IADP area and June 1974 to May 1975 in Bolilands.
[b] Differences between groups significant at 5% level for males in IADP and for females in Bolilands.

the following comparison among groups observed differences are assumed to be the result of the technological change. Boliland households with and without mechanical cultivation exhibit similar characteristics with respect to age and sex composition of family members. However, in the IADP area heads of nonparticipant households are older than for participant groups, so that a priori we expect their labor inputs to be somewhat lower.

There are definite seasonal peaks in labor use at planting time in June to August and harvest time in December and January and well-defined slack periods—in October and November and in the dry season from February to May. In the peak month, male adults consistently work over 200 hours per month. The one exception is the nonparticipant group in the IADP area with a peak monthly average of 147 hours. However, this in part reflects the heterogeneity of this group with respect to crops, so that the peak month varies from household to household. When this average is computed using the peak month for each household, the male labor input is 190 hours per month.

The high labor input at the peak season is accomplished through working both more days and longer hours per day. For example, in the Bolilands at the peak month of August, male adults worked twenty-eight days at an average of 8.4 hours per day. Moreover, the number of people who did any work in a month changed over the season through the participation of older people and short-term visitors who are (presumably in response to seasonal labor constraints) concentrated at the peak seasons of harvesting and planting. Work is concentrated on farming activities at the peak season. In the Bolilands the percentage of time of male adults spent on nonfarm activities such as blacksmithing, trading, and construction is only 1.6% in the peak months (July to September) compared to 40% in the slack period (March to May). These results strongly underline the magnitude of the labor constraint at the peak season. The maximum number of people are working in agriculture almost every day for long hours each day during this period.

The technologies examined here have had relatively little impact on the "spread" of labor inputs over the year. In every case the peak season occurs at planting (July through September) with a subsidiary peak at harvest (December and January). In the IADP area, first-year participants in the project have less pronounced slack periods partly because they are still producing some traditional upland rice, which has different seasonal labor demands than swamp rice (Spencer and Byerlee). In the Bolilands labor inputs of households with mechanical cultivation are slightly less in the slack period, since this is the time of mechanized land preparation.

The introduction of improved technologies

has a significant impact on the use of household labor by sex. In the IADP project male adults increase their labor inputs by at least 50% when they join the project. In the first year of participation in the project when most land development is undertaken, male adults worked over 2,000 hours per year. In contrast, female labor input is not significantly changed by participation in the IADP project.

In the Bolilands, the effect of mechanical technology on labor use by sex is quite different. The mean hours of work per adult male decrease slightly as mechanical cultivation is substituted for hand cultivation (the difference is not statistically significant even at the 30% level). However, the hours worked increase significantly for female adults, so that in households using primarily mechanical cultivation, females work 50% more than in those using primarily hand cultivation. Also, at the peak season, women in households using mechanical cultivation work the same number of hours in farm activities as men.

The key to these differential effects of varying technologies on male and female labor inputs lies in the sex-specific nature of some farm activities in Sierra Leone. In the Bolilands mechanization almost completely eliminates the land preparation undertaken by men but increases farm size so that there is an increase in the demand for labor for planting and harvesting where women traditionally play an important role. In the IADP area, the substantial land development required in the early years of the project places the burden of the work primarily on men.[8]

This analysis of total work hours for adults shows that the number of hours worked for both men and women nearly always exceeds the 1,000 hours per year noted by Cleave in a review of several African surveys. In most cases, this labor input exceeds 1,200 hours per year stated by Brandt as the maximum number of hours worked by male adults in rural households of tropical Africa.

Finally, in this paper we have not examined buying and selling of labor, although this is clearly an important activity in both project areas. However, in the Bolilands areas the wage rate for men and women was almost identical, while in the IADP area, as in most other areas of Sierra Leone, the daily wage rate for men was about one-third higher than women.[9] This observation supports earlier findings with respect to the relatively important role of women in the Bolilands compared to the IADP area. Interestingly, there is considerable hiring of labor at harvest in both areas, although household members work less at this time than in the peak planting season. With cash in hand at harvest time and an available supply of labor, some farmers are apparently willing to hire labor and reduce their own labor inputs.

Conclusions

Examination of the impact of two technological packages representing biological-chemical technology and mechanical technology in rice production in Sierra Leone has illustrated some of the interrelationships between improved technology and labor use. In a situation of a high land-labor ratio, mechanical technology can overcome peak season labor constraints and increase the acreage cultivated. Under these conditions mechanization is not labor displacing, since the increased acreage resulting from mechanization requires added labor for planting and harvesting.

Private returns to family labor are substantially increased by mechanization, but because of a large subsidy for the use of tractors the economic returns are low. The biological-chemical technology increases returns to land, but because of a large increase in labor requirements the returns to labor are below that for traditional swamp rice cultivation. These results have significant implications for policy in Sierra Leone. Under present costs and factor endowments both technologies have low economic returns. Other technologies that have higher returns to peak season labor such as improved seed and fertilizer for upland rice should be given greater emphasis (Spencer).

Analysis of total family labor inputs in the various systems demonstrated that peak season labor demand is indeed a constraint to increased production since farm families are working at capacity during this period. Moreover, there is relatively little underutilized labor among the sample of farmers, even if 2,000 hours per year are taken as an upper

[8] We should raise a note of caution that the two areas compared here include two different ethnic groups. Work is now underway to examine the role of women in different production systems and ethnic groups in Sierra Leone.

[9] Based on 551 observations in IADP and 407 observations in the Bolilands, an analysis of variance showed significant seasonal differences in wage rates in both areas at the 1% level and significant sex differences in the IADP area only.

bound for labor use. Finally, the results suggest some important interrelationships between use of improved technology and division of labor by sex. Biological-chemical technologies increased the male labor input but did not affect female labor inputs, while mechanical technology increased female labor inputs but male labor slightly declined.

Finally, this analysis demonstrates the need for detailed information to evaluate the impact of new agricultural technologies on the demand and supply of labor. Under the conditions examined, clearly the use of labor in the peak season should be a priority consideration in the development of technological packages for small farmers.

A View of the Plan Puebla: An Application of Hierarchical Decision Models

Christina H. Gladwin

What does a decision-making study tell project planners in developing countries about designing a rural development project for small farmers? The results, summarized here, of a study of farmers' decisions regarding the recommendations of the Plan Puebla should begin to answer this question. The Plan Puebla is an agricultural development project that was started by Centro Internacional de Majoramiento de Maiz y Trigo (CIMMYT) in 1967 and is now run by the secretariat of agriculture in Puebla, Mexico. Its aim is to increase yields of maize on rainfed farms. Initially, the project's breeding program attempted to find improved maize varieties or hybrids that performed appreciably better than the local variety (*criollo*). When the program found none, the project focused on deriving recommendations about fertilizer use and timing and plant population for the local variety (CIMMYT).

The aim of this study was to view the Plan Puebla through the eyes of the proposed adopters of the new technology—the farmers. The study focused on the decision-making processes of a small sample of farmers in one village concerning the recommendations of the plan in order to identify the factors limiting adoption of the recommendations. The recommendations for the village in 1973–74 were to get credit for fertilizer, to increase plant population, to increase the number of fertilizer applications, and to use a recommended level of fertilizer per hectare. Since farmers seemed to decide to adopt each of the first three recommendations independently of the other two, separate models of the first three adoption decisions were developed. In order to identify the factors limiting adoption of the fourth recommendation, a simulation model of the quantity of fertilizer per hectare demanded by individual farmers was developed. Since farmers first adopted fertilizer in 1962, the model focuses not on the decision to adopt fertilizer, which occurred long enough ago to cause problems in modeling and data collection, but on the decision to increase or decrease fertilizer use since then.

Before particular decision models and results are presented, a discussion of the form of the decision model used is in order. Recently, social scientists have argued that people, in choosing one alternative over other available alternatives, do not make complex calculations of the overall utility of each alternative. Rather, people tend to use procedures that simplify their decision-making calculations (Simon, Cyert and March, Tversky, Quinn). Hierarchical models or trees, with decision criteria at the nodes or branching points of the tree, can represent such procedures. The tree form of the decision model is the product of a theory of the choice process that takes into account the simplifying procedures people use in "real-life" decision making.

A Hierarchical Theory of Choice

The theory assumes, following Lancaster and Tversky, that an alternative is a set of characteristics or aspects. An aspect is a dimension or feature of an alternative. For example, the aspects of a car (in a hypothetical choice between alternative used cars to buy) could be its cost, miles per gallon, shape, and outside appearance. Furthermore, the theory assumes that all aspects are discrete. Thus, when decision makers use a continuous quantitative dimension such as cost, they either treat it as a constraint (e.g., is cost $\leq$ \$4,000?) or they categorize it such that only an ordering or a semiordering with noticeable differences of the alternatives on the aspect ($cost_{car\ 1} < cost_{car\ 2}$) will influence the choice. An algebraic representation of the choice process follows from this assumption.

Christina H. Gladwin is at the International Fertilizer Development Center, Florence, Alabama.

The author is grateful for the help received from C. P. Timmer, B. Johnston, W. Falcon, H. Gladwin, A. Thomson, Soledad Coyotl, Candé Chantes, and Benjamín Coyotl.

The theory tries to explain how people in everyday life make choices over a large number of objects. A car buyer, in trying to decide which used cars to look at today, might pick up a newspaper with several hundred cars listed and arrive at three used cars that interest him after fifteen minutes of scanning the page. This theory says that the person has gone through the first of two stages in the choice process. In stage I, identical to Tversky's choice process of elimination by aspects, the decision maker has eliminated rapidly and often unconsciously all cars that have some aspect that he does not want: he does not want a truck, van, convertible, or two-door sedan; he does not want a car more than four years old. He is then left with a small, manageable number of alternatives (two or three) that he can see and decide about in a more detailed way.

The latter, "hard-core" decision process occurs in stage II. People typically go through stage I quickly and think that the real decision process is stage II. In that stage, the decision maker chooses among the two or three alternatives by first listing all aspects of the alternatives and then eliminating aspects on which alternatives have equal or equivalent values. For example, if the two alternative cars in the choice both satisfy a cost constraint, i.e., they are both under $4,000, then the car buyer eliminates the aspect "is cost ≤ $4,000?" and makes no further use of it in the decision process. Then, when aspects of the two or three alternatives are themselves narrowed down to a manageable subset, the decision maker picks one of the aspects to order the alternatives on; e.g., miles per $\text{gallon}_{\text{car 1}} >$ miles per $\text{gallon}_{\text{car 2}}$. Then he formulates constraints from the remaining aspects and passes the ordered alternatives through the constraints. If the alternative ordered first on miles per gallon does not satisfy all the constraints, the alternative ordered second on miles per gallon gets a chance at them. If no alternative passes all the constraints, another strategy is employed. Therefore, the "hard-core" choice process is essentially an algebraic version of "maximization subject to constraints," a choice principle found in any microeconomics text (Henderson and Quandt). The "hard-core" choice process is algebraic, since there is an ordering of alternatives on an aspect rather than maximization of a continuous aspect. Therefore, the process may be represented by an algorithm, a decision tree, or a set of decision rules.

Methodology

Given a theory of "real-life" choice, a plan to apply the theory to a particular decision is necessary if one is interested in more than the psychological processes underlying choice. The major methodological concern is to find the specific aspects and constraints decision makers are using. One must determine what information is actually used in making decisions, as opposed to information unused in decision making that may nevertheless be given in response to interview questions.

Producing a decision-process model can be considered to have five steps.

Step 1. Observe the decisions made by a small sample of twenty to thirty decision makers. Given their decision behavior, observe and elicit the decision criteria that decision makers use in their "rules of thumb" or decision rules. Discovering decision criteria is the most difficult part of the model-building process and is described in depth elsewhere (Gladwin). Essentially, the method involves going back and forth between controlled interviewing (and acquiring information by direct observation) to produce a hypothesis about the specification of the decision criteria and testing of the hypothesized criteria against the choice behavior of the sample of decision makers.

Step 2. Using the language and categories that the decision makers themselves use, put the decision criteria into a flowchart.

Step 3. To be sure that the flowchart is descriptively adequate, test its predictions against the decisions made by the sample of decision makers used to build the flowchart.

Step 4. Model the flowchart, i.e., give an economic interpretation to the language and categories decision makers use. From the flowchart, a purely descriptive statement of the decision process, the researcher must find the underlying ordering aspect and constraints of the theory. Depending on what the flowchart says, the alternatives can be ordered on any aspect: profit, cost, risk, welfare of the group, etc.

Step 5. Test the model by using it to predict the decisions made by a new, different (if possible, random) sample of decision makers.

In the process of building the models of the decisions to adopt the recommendations of the Plan Puebla, twenty-five farmers were interviewed; in the process of testing the models, another sample of thirty-four farmers in the

same village were interviewed. In the test, each node or decision criteria in a model was a question in a questionnaire. Therefore, given a farmer's responses to the questionnaire, the model predicts what the farmer's choices will be. For example, in figure 1, the decision to increase fertilizer use, the decision maker must pass, i.e., satisfy, all the criteria on the left-hand path of the tree in order for the model to predict that he choose the outcome in the box at the end of that path, i.e., "increase q_f/ha." The six errors on that path are farmers who pass all the criteria on the path but did not try an increase in fertilizer use at that time. Since the aim of a decision model is to predict the farmer's decisions, the proper test of the model is percentage predictability, i.e., the ratio of correct predictions of farmers' choices divided by the total number of farmers who made the choice.[1] For brevity, the results of the test of each decision model will be presented along with the explanation of the model.

Decision to Increase (Decrease) Fertilizer Use

The main subroutine in the model of individual demand for fertilizer is the decision to increase (decrease) fertilizer use in figure 1. A farmer is sent to subroutine INCQF if at any time in the period after adoption of fertilizer he has a reason to change fertilizer use. A farmer may make up to four changes in fertilizer use during the period, which varies across farmers from one to eleven years. A farmer has a reason to change fertilizer use if external factors change (e.g., the bank gives him credit for more fertilizer, the available fertilizer technology changes, or the relative price of fertilizer to corn changes) or the farmer changes his production technology (e.g., he increases plant population or the number of applications of fertilizer). In subroutine INCQF, a farmer will increase the quantity of fertilizer per hectare (q_f/ha) at time t (i.e., he will go down the left-hand path to the box "increase q_f/ha") if he thinks that more fertilizer is profitable (the value of the marginal product of fertilizer

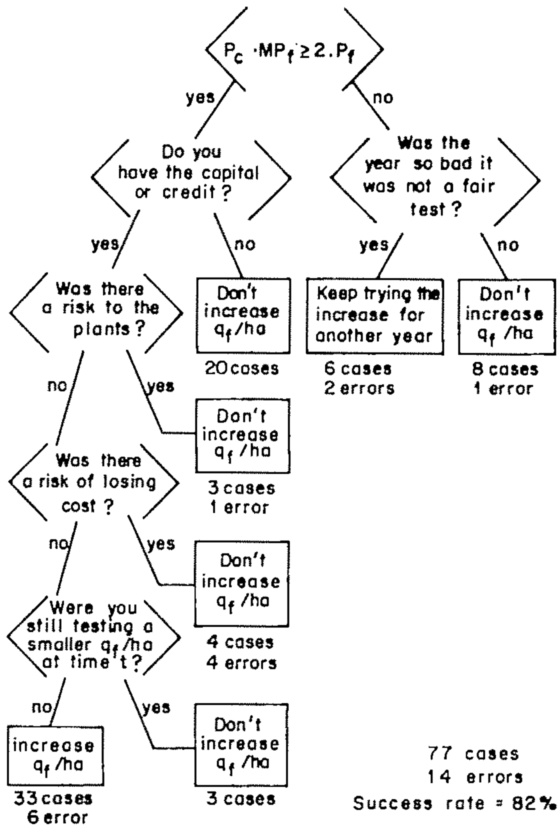

Figure 1. Subroutine INCQF

(MP_f) is at least two times its marginal cost or price ($p_c MP_f \geq 2p_f$)[2]), he can also pass a capital or credit constraint and risk of loss of plants and input costs constraints, he is not still experimenting with a smaller amount of fertilizer at that time. If the farmer fails one of any of the constraints, then the model predicts that he does not increase fertilizer use, i.e., he goes down a path leading to the outcome "Don't increase q_f/ha." The exception of this rule, on the right-hand path, occurs when the farmer finds an increase not profitable because bad weather made a fair test of more fertilizer impossible. In that case, the model says to repeat the trial for another year.

[1] The problem of the statistical significance of each path on a tree can be thought of as a quality-control problem: the farmers are passing through quality criteria designed to weed out the noninnovators. Then, on each path, one can use a t-statistic to see if the number of errors on the path is significantly different from zero. Therefore, one should interpret the t-statistic on a path in terms of the number of observations on that path. The size of the sample in this study is too small to adequately test for the significance of each path.

[2] The price of corn and fertilizer are p_c and p_f. The number 2 was chosen as a threshold value of the net return per dollar spent for fertilizer ($p_c MP_f/p_f$) because it is a number that has popped up repeatedly in the literature (Timmer, p. 200) and in interviews with farmers in the village. Its value is higher than that for the profit-maximizing farmer because the profitability question asked for a judgment given conditions of good weather and good labor (quality). The model assumes that one simplifying procedure farmers use is to look at one side of the coin, the profitability of more fertilizer under good conditions, and then at the other side of the coin, the risk of possible losses under bad conditions. Expected profit is not used as the profitability criteria because it is too complicated a calculation to be a decision criteria.

Data about seventy-seven past actual or contemplated changes in fertilizer use tested figure 1; of these forty were actual increases and two were decreases. Of the thirty-five cases in which the farmer did not try more fertilizer, twenty were cases in which the farmer did not have the necessary capital or credit. (Most of these twenty contemplated changes occurred before credit was introduced to the village in 1969–70, when the Plan Puebla started.) Hence, lack of capital or credit and not riskiness or nonprofitability was the main factor limiting fertilizer use in the past.

Figure 1 predicts 82% of the seventy-seven test cases successfully. As one can see by looking at figure 1, the main error in the model is found in the specification of the risk of losing input costs constraint. Farmers said yes, there was a danger of losing the added costs of more fertilizer, but they were willing to take the risk and increase fertilizer use anyway, whereas the risk constraint in figure 1 allows the farmer to take no perceived risks, however small. The failure of this risk constraint in all of the adoption decision models led to a reformulation of both the risk of losing plants and input costs constraints (Gladwin). The failure of this risk constraint does show, however, the advantage that a tree model has over other decision models in pinpointing exactly where the errors of the model are.

Decision to Increase Plant Population

Traditionally, farmers in Puebla plant three or four seeds per hill (*mata*) of corn with hills 70 centimeters apart. Thus, they have a seed population of 55,000 per hectare and a plant population of 36,630 plants per hectare if two-thirds of the seeds germinate. The agronomists of Plan Puebla recommend, for the village, 3,2,2 seeds per hill with hills 40 centimeters apart or 64,000 seeds per hectare or 42,624 plants per hectare if two-thirds of the seeds germinate, an increase of 6,000 plants per hectare. Most farmers in the village in 1974 knew that the plan's recommendation was to plant the hills closer (at 40 rather than at 70 centimeters), but they did not know that the recommendation called for fewer seeds per hill. They thought that the recommendation was to plant at 40 centimers with three or four seeds per hill or 96,200 seeds per hectare or 64,165 plants per hectare if two-thirds of the seeds germinate, an increase of 27,500 plants per hectare. However, the plan's agronomists say that this is too high a plant population given the soils and rainfall in the area and adopting 40 centimeters at 3,4,3,4 seeds per hill will decrease rather than increase yields. Instead, the recommendation is to distribute the plants more evenly with only 3,2,2 seeds per hill.

Therefore, the top node in the decision to increase plant population is a knowledge constraint that divides the sample of farmers into two subsets. (The flowchart is omitted for brevity.) One set of farmers decides about adopting 40 centimeters at 3,2,2 seeds per hill, the real recommendation. The other set of farmers decides about adopting "the wrong" recommendation, 40 centimeters at 3,4,3,4 seeds per hill. Both sets of farmers, in deciding between 40 and 70 centimeters, maximize gross returns (yields-cash costs) subject to the risk of losing plants and input costs constraints and a capital or credit constraint. Data from decisions made by twenty-six farmers tested the model. Lack of knowledge of the real recommendation was clearly the main factor limiting adoption of the recommendation, since fourteen out of twenty-six farmers failed the knowledge constraint. Of the remaining twelve decisions, three farmers were ready to try (or did try) the recommendation. The model successfully predicts 85% of the farmers' decisions about plant population.

Decision to Fertilize Two Times Instead of Once

Traditionally, farmers in Puebla fertilize once, at the first weeding, which occurs when the plants are 10 to 20 centimeters high, or about twenty days after planting. The Plan Puebla, however, recommends fertilizing twice, at planting and at the second weeding, which occurs when the plants are 50 centimeters high or about forty days after planting. However, no farmer in the village in 1973–74 fertilized at planting in all his fields, and few farmers fertilized at planting in one field.[3] (Most farmers in the village have one or two irrigated fields and three or four unirrigated fields.)

The decision model in figure 2 states that farmers will try to fertilize twice, at planting

[3] Although no official numerical estimates were available, unofficial estimates from extension agents were that only a small percentage of farmers in the entire region served by the Plan Puebla fertilized at planting.

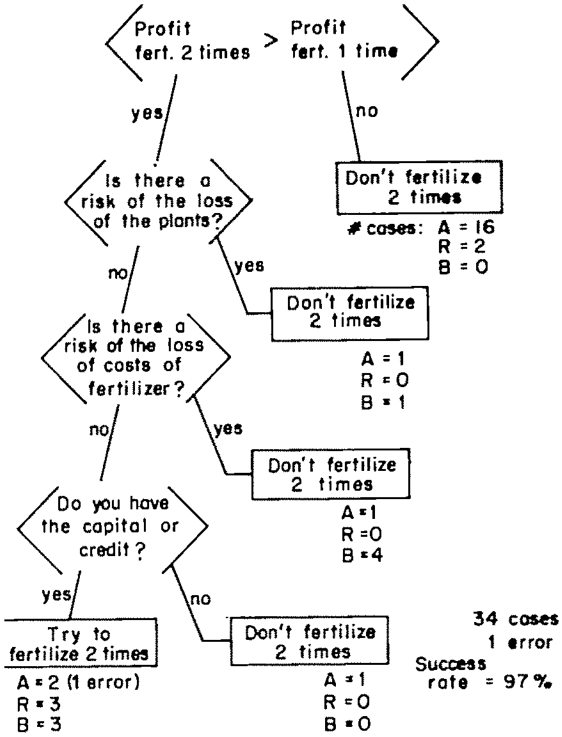

Figure 2. Decision to fertilize twice, at planting and the second weeding

and the second weeding, if they think fertilizing at planting is profitable, and they can pass the risk of loss of plants and input costs constraints and a capital or credit constraint. The model is more complicated than shown, as the profitability criteria is itself a set of criteria or logical statements of the form: If you do X in a field of type Y, then fertilizing at planting is profitable. The criteria forming a profitability judgment are different for different types of fields. In the village, there are roughly three types of fields: type R, fields with irrigation; type A, fields without irrigation but with enough moisture in the soil if plowed correctly after the preceding harvest so that the farmer can plant early in April; and type B, fields without irrigation and without moisture in April so that the farmer must wait for the first "regular" rain to plant, which may occur in April or May or as late as June. Usually there is sprinkling (*lloviznitas*) in April but no regular rain. Type A soils are called "*suelos de arena*" and contain volcanic ash; type B soils are "*suelos de barro*" or sodiclike soils (CIMMYT, pp. 2–4).

The profitability criteria for type A soils say that, if a farmer plants early in April "in dryness" (*en seco*) and does the first weeding before the first regular rain, then it is not profitable to fertilize at planting. The soil is too dry at planting to let the fertilizer dissolve, so that it just sits there on top of the ground until the first regular rain. A good farmer, i.e., one who follows the best set of observed practices to grow corn in the village, should do the first weeding (and fertilize the corn) before the first regular rain anyway.[4] There is no head start for the plants with fertilizer at planting for a good farmer with type A soils. The profitability criteria for R and B soil types say that it is profitable to fertilize at planting in fields that are moist at planting (soils wet by irrigation or by a previous regular rain) because the fertilizer will dissolve at planting and give the plants a head start. (Plants in type B soils, because of later planting, can use a fast start if they are to withstand too much water from the heavy rains (*los aguacerros*) that come in the middle to end of June.)

Data from thirty-four farmers were used to test the model. The main factor limiting adoption of the recommendation on type A soils was nonprofitability—sixteen out of twenty-one farmers with type A soils did not think it was worth the effort to fertilize at planting. On type R soils, three out of five farmers were willing to try (or did try) fertilizing twice. For five out of eight farmers with type B soils, the factor limiting adoption was risk of loss of plants or input costs. The model successfully predicts 97% of the farmers' decisions about fertilizing at planting.

Conclusion

The question initially posed about the usefulness of a decision study can now be answered. Only a study of farmers' adoption decisions can pinpoint the critical factors or intervention points in the decision process that policy makers can affect. Clearly, knowledge of the main factors limiting adoption is a necessary but not sufficient condition for speeding up the adoption process. The two aims of a decision study

[4] The best set of observed practices to grow corn in the village involves early planting in April so that the first weeding and fertilizing can be done before the first regular rain and the second weeding can be done before the first heavy rain (*aguacerro*), which is expected after 13 June. If it pours before the second weeding is done, the ground may be too muddy for the animals and plow to enter the field. Later, the plants may grow too tall for the animals to fit between the rows of corn. If the hilling-up operation in the second weeding is not done, there is more possibility of the plants' lodging later in the season in a wind.

should be to identify decision factors amenable to policy variation and to recommend changes that will speed up adoption of a project's recommendations.

This is not always an easy task, as demonstrated by the previous studies of the Plan Puebla that attempted to show that farmers' risk aversion is a factor limiting adoption. Whereas results obtained by Martín del Campo and Winkelmann do not support the argument that risk plays a prominent role in farmer decision making, results obtained by Moscardi do. However, Moscardi's results are clouded by the fact that he derives what he assumes is a risk measure, but he does not test how important risk is as a limiting factor to adoption, or if what he calls risk aversion is really nonprofitability or lack of credit or knowledge. In my judgment, one can only see how important risk is to adoption by formulating a risk constraint and including it with other factors, e.g., profit and availability of credit and inputs, in a model of an adoption decision that can be tested directly.

Because a decision model with profit, risk, capital, and knowledge as decision criteria was built for each recommendation of Plan Puebla, this study was able to pinpoint a critical node or main factor limiting adoption of each recommendation in the village. In the decision to increase fertilizer use it was lack of credit; in the decision to increase plant population, lack of knowledge of the real recommendation; and in the decision to fertilize twice, nonprofitability of the recommendation on type A soils. These results show that the critical factor or intervention point in the decision to adopt one recommendation in "the package" is not necessarily the factor limiting adoption of another recommendation. This finding differs from that of previous studies done in Puebla because those studies combined the three adoption decisions under one behavioral assumption. Thus, the methodology used precluded their finding different critical factors for different recommendations and their suggesting policy changes specific to each recommendation. The results of this study suggested the following changes in policy: increase the amount of fertilizer per hectare given to farmers on credit in the village, improve communication between extension agents and farmers in the village, especially about the topic of plant population, and drop the recommendation to fertilize at planting on type A soils. Obviously, the more practical and detailed the proposed policy changes are, the more relevance they will have for project coordinators.

The study presented here was undertaken *ex post*. Ideally, within the context of policy planning, this type of decision study should be undertaken at an earlier stage in the design of a project, e.g., after the pretest or first trial of an innovation on farmers' fields. At that stage, one can look at the decision processes of early adopters with the aim of speeding up the diffusion process. It may be possible, however, to do an *ex ante* study of farmers' choices between "the old way" and a hypothetical recommendation with the aim of eliminating "bad" recommendations. ("Bad" recommendations cause "bad" demonstrations of new techniques and much laughter among older and wiser farmers.) Another possible direction for future research lies in broadening the base of a decision study from a village to a regional level. Although the results from this study are not generalizable to the region, it should be possible to conduct a similar type of study on a regional basis.

Impediments to Technical Progress on Small versus Large Farms

Richard Perrin and Don Winkelmann

During the past four years, Centro Internacional de Mejoramiento de Maiz y Trigo (CIMMYT) has been associated with a number of farm-level studies of the adoption of new wheat and maize varieties and fertilizer use. Most of these studies have now been published, and it is our purpose here to summarize some of the findings with respect to impediments to farmer adoption of new varieties.

Farm-to-farm differences in the date of adoption or the extent of adoption of new technology might be explained by a number of considerations. The studies reviewed here considered farm-to-farm differences in the cost of acquiring and processing information, differences in the physical productivity of the new technology, differences in incentives due to tenure arrangements, differences in the cost of inputs, differences in prices received for the product, differential aversion to risk among farmers, and scale effects associated with farm or enterprise size. Policies to stimulate more rapid or more extensive adoption will vary in their success depending upon which of these factors are the most important in limiting the rate and extent of adoption. Of particular relevance is the extent to which small farmers lag behind large farmers in adoption and which of the above factors might account for that lag.

The studies were directed toward factors explaining differences in adoption of new varieties and fertilizer among farmers surveyed in a number of countries in 1972 and 1973. Since seeds and fertilizer are nearly completely divisible, one might ask why farm-size effects might be expected at all. First, there are likely to be economies of size in transaction costs. It takes about the same effort for the small and large farmers to acquire and evaluate information about a new technique, to learn how to use it, and to make the purchase transaction. For an increase in net returns of $20 per hectare, the effort might be quite worthwhile for a 10-hectare farmer but not for a 1-hectare farmer. These transaction costs will fall as community experience with and information about the new technique becomes more common. Because of this, the phenomenon of economies of size in transaction costs can lead to a lag in small farmer adoption even though ultimate adoption levels may be the same as on large farms. Hence, we will more likely observe size effects during the early phases of the adoption cycle.

Furthermore, experimentation with new techniques involves the risks of the unknown, usually involving additional investment, and small farmers may be less able to undertake such risks. This risk effect can lead to lower equilibrium levels of adoption or to a lag in adoption by smaller farmers until the risks of the unknown are reduced with experience in the area. A third potential source of size effects is that smaller farmers may face higher input costs—i.e., quantity discounts might be available or government subsidies of information, credit, or inputs may favor larger farmers.

The Study Areas

CIMMYT has been associated with maize adoption studies in Kenya (Gerhart), Colombia (Colmenares), El Salvador (Cutié), and Mexico (Perrin) and with wheat adoption studies in Tunisia (Gafsi) and Turkey (Demir). In addition, Vyas undertook, at CIMMYT's request, a review of the studies of wheat adoption that had been conducted in India. While the primary focus of these studies was the adoption of improved varieties, fertilizer use was also examined to some extent in each. The percentage of surveyed farmers who had

adopted improved varieties at the time of the studies ranged from 20% among Colombian maize growers to 67% among Kenyan maize growers (though adoption rates for subregions were as high as 100%).

The adoption trends shown in figure 1 help to provide the dynamic contexts of the adoption processes at the time the studies were conducted. Adoption of hybrid maize in western Kenya shows the most stable growth pattern, with use increasing steadily at the rate of an additional 8% of the farmers adopting each year after the hybrids were introduced in 1964. This rate slackened somewhat in the year immediately preceding the survey. Increases in the adoption of hybrid maize in El Salvador and Colombia have been both more modest and more irregular. While the earliest hybrids were introduced into El Salvador in the late 1950s, not until after the introduction of H3 and H5 (after 1966) did the increase in use of hybrids become steady. In Colombia, on the other hand, the level of hybrid use has been relatively static in the past ten years.

High-yielding varieties of wheat were first introduced commercially in India in 1966–67. There followed a rapid adoption of these varieties by about 30% of the farmers within two years. The adoption level began to rise again after 1970, as irrigation facilities were extended and improved, until nearly 60% of Indian wheat was in new varieties by 1973. The data reported by Vyas were largely gathered in 1969–71, after the initial surge of adoption had slowed. In the coastal spring wheat areas of Turkey, very rapid adoption of Mexican varieties occurred the first two years following their introduction in 1967. A second very rapid rise in the use of new varieties occurred in 1972 and 1973 after the introduction of the Russian winter variety Bezostaya into the winter wheat-producing areas of Thrace and Marmara. In Tunisia, on the other hand, adoption of the Mexican bread wheat varieties increased only slowly from their introduction in 1968 until 1970, after which adoption fell, reportedly due to problems with seed quality. The majority of new varieties adopted there

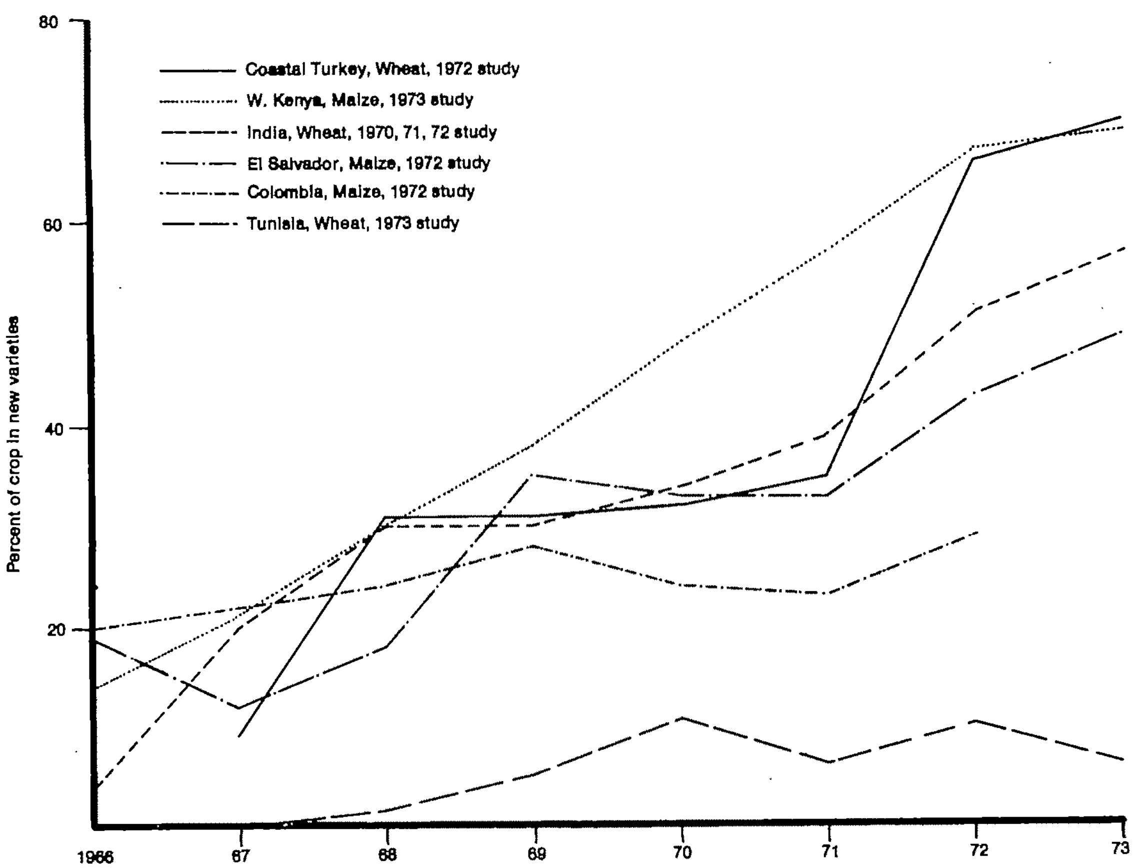

Figure 1. Trends in adoption of new varieties in the study areas

are high-yielding varieties of durum wheats (durums constitute three-fourths of the national wheat acreage).

In each of the survey studies, the population to be studied was prestratified by an agroclimatic zone as determined in collaboration with agricultural scientists. The samples were later poststratified into size groupings. Analytical procedures included both multivariate analyses and interpretation of two-way tables. This summary is restricted to a general interpretation of the results of somewhat diverse analytical approaches to a similar issue.

The Effects of Farm Size and Other Factors on Variety Adoption

In table 1 is presented the levels of adoption of new varieties by farm-size groupings within agroclimatic zones of the study areas. In about half of these situations, there appears to be little relationship between farm size and adoption, occurring in areas of Kenya, India, and Turkey, where adequate time has elapsed since introduction and nearly all farmers have adopted regardless of size, and in the medium and high valleys of Colombia, where few farmers have adopted but little additional diffusion has been taking place (figure 1). In these areas equilibrium levels of adoption appear to have been realized, and little correlation between farm size and adoption decisions is expected.

The multivariate analyses in the cited studies offer some insight into which factors are important in explaining farm-to-farm differences in adoption behavior in areas where equilibrium adoption levels have not been

Table 1. Farm Size and Percentage of Farmers Adopting New Varieties

realized. The factors considered varied from study to study but included zone and topographic variables to capture differences from farm to farm in yield superiority of the new varieties, plus variables representing differences in farmer incentives arising from input and product prices, differences in farmer perceptions of or reactions to risk, and farm-size effects. Due to the differences from study to study in variables used and analytical techniques, only a brief summary (table 2) of the results of these multivariate analyses is presented. For each factor included in the analysis, either a yes or a no is entered in table 2, yes if the factor was significant statistically (t-ratios of 1.5 or more) with a coefficient sufficiently large to be of practical significance, and no otherwise.

A cursory glance at table 2 shows that productivity factors—agroclimatic zone and topography—are the most consistent in explaining why some farmers adopt new varieties and others do not. While these factors were generally far more important in explaining behavior than any others, we are convinced that much more of farmers' adoption behavior could have been explained by productivity considerations had more accurate measurement of agroclimatic factors as related to productivity been possible. This became clear in retrospect, for example, as some villages within a few miles of one another in the Aegean area of Turkey where farmer adoption patterns seemed to make little sense were reexamined. The elevation of one valley village was just enough higher than the others that frost problems precluded the use of new varieties, and no farmers were using them, though some had tried. Within a lower valley village, the land parcels were divided between two types of valley land—a lower alluvial terrace and an upper alluvial terrace. The upper terrace soils were shallower and lighter than those of the lower terrace, and soil water capacity was so low that farmers preferred the local varieties, which yield as well as the new varieties under limited rainfall conditions where little fertilizer is used.

Thus, within a small geographic area, we had observed three villages, ostensibly similar, with markedly different patterns of adoption: no adopters in one village, nearly all adopters in a second, and a mixed pattern of adoption in a third. Yet with a better insight into agroclimatic factors affecting the productivity of new varieties versus the old, this pattern of behavior was understandable apart from considerations of information, prices,

Table 2. Factors Explaining Within-Region Variability in Farmer Decisions to Adopt Improved Varieties

	Maize				Wheat	
	Kenya	Colombia	El Salvador	Veracruz	Tunisia	Turkey

[a] Market participation was important in one of four Turkish regions.
[b] Farm size was important in one of three Colombian and in two of four Turkish regions.

and risks. It was not that agroclimatic factors were not considered prior to the study but rather that relatively subtle agroclimatic gradients can lead to dramatic changes in farmer behavior. Gerhart's Kenya study and an as yet unfinished maize study in Pakistan reinforce this observation, as do studies with rice (Barker). It is also stressed by Evenson (p. 201) and his coworkers. Gerhart concluded that "if anything, this study shows how very site-specific agricultural technology is, even within one region of one (admittedly very diverse) country" (p. 26).

These experiences force the recognition that, within any farming area, there exists a wide range of expected yield increments from a given new variety or new technology. The differences can be the result of gradients in soil depth, texture, or other characteristics, differences in quantity of rainfall or irrigation water, differences in nighttime low or daytime high temperatures in certain seasons, differences in disease incidence related to these factors, and so on. In a truly homogeneous agroclimatic zone, the frequency distribution of expected yield increments across farmers' fields would be bunched rather tightly about the mean. For practical purposes, however, either for developing and recommending new technologies or for analyzing farmer behavior, we must deal with groups of farmers for whom the frequency distribution of expected yield increments will not be very compact due to agroclimatic variability. Because of this, identification of the extent to which productivity factors are affecting farmers' decisions versus differences in economic factors, such as information, tenure, input and product markets, scale economies, etc., will be difficult.

Turning now to the effect of these economic factors in the six studies, with some exceptions farmer behavior was not found to be significantly or consistently related to them. One exception was the availability or use of credit. In four of the six studies in which it was considered, this variable was significantly related to the adoption of high-yielding varieties. However, even though farmers using credit were more likely to be using new varieties (44% more likely in Columbia for example), this does not necessarily imply that the existence of credit programs is critical to farmer adoption decisions. Where a new variety or new technology is marginally profitable, the subsidies implied by government credit programs could be expected to affect many farmers' decisions. But if the new technology is profitable even at unsubsidized capital and input prices, farmers could be expected to adopt the technology and to purchase the inputs through the credit program if it in fact provided capital and inputs at subsidized prices. In the latter case, we would see a high correlation between the use of credit and adoption, even though the credit program itself had little effect on the adoption decision.

Market conditions accounted for very little of observed adoption behavior. Differences in price discounts for new wheat varieties from village to village in Tunisia were significant in explaining farmer adoption decisions, but this was the only case in which product market circumstances or market participation were related significantly to new variety adoption. The availability of seed appeared to be a limiting factor in adoption of winter wheats in Turkey and durum wheats in Tunisia, where the introduction of new varieties was fairly recent and seed multiplication had not kept pace with farmer demand.

Differences in the cost of acquiring and processing information as measured by extension activity and schooling had only a slight relationship to adoption. Extension visits or demonstration attendance appeared to increase the probability of adoption by 10% to 15% in certain subregions of Colombia and Turkey, less or none in other areas. Each additional year of schooling increased the probability of adoption by an estimated 8% in Colombia, less in other areas.

The question of whether risk aversion is affecting adoption decisions was not really very satisfactorily addressed in these studies, and it is difficult to imagine how one can do so. In three studies, farmer perception of the risk of low crop yields was used as an index of farmers' risk aversion, while in Kenya the existence of drought resistant "famine" crops was used. While these indexes were in general correlated with adoption, the interpretation of this result is not straightforward. It is true that where crop failures are more common, risks are greater. But it is also true that where crop failures are more common, average yields will be lower. Where farmers perceive high risks of crop failure, reluctance to adopt could be evidence of risk aversion or simply evidence that the average returns to adoption are too low. To determine which of these factors are contributing to the observed correlation, more specific information is needed than was avail-

able about farmer perceptions of expected yields versus yield risks for both new and old varieties.

This brings us again to the question of the relationship between farm size and adoption decisions. In about half of the agroclimatic situations of table 1, farm size appeared to have an important effect on adoption. Yet in the multivariate analyses, farm size was not correlated with adoption decisions in some of these areas. In the low elevation areas of Colombia, where table 1 indicates an important size effect, the multivariate analysis showed that once credit and extension contacts are considered the residual effect of size was minor, with each hectare increase in size being associated with only 0.1% increase in the probability of adoption. After a careful consideration of extension and credit activities, Colmenares concluded that the orientation of these programs toward larger farmers contributed substantially to the greater adoption rate among larger farmers. In Tunisia, it appears that smaller farms' lower adoption rates are due to differences in topography, credit use, and local price discounts rather than to factors related to farm size per se. The multivariate analyses of hybrid maize adoption in El Salvador likewise fail to show any effect of farm size per se, though it is not clear yet what factors may be contributing to the apparent size effect revealed in table 1. In India, Vyas reported that most of the observed differences in variety adoption by farm size were due to differences in the availability of irrigation water and to a seed distribution policy that initially favored larger farmers.

In the remaining areas in which size effects are notable in table 1, variety introductions were quite recent in Veracruz and Mexico (maize) and in the South Marmara and Thrace areas of Turkey, and the multivariate analyses indicated definite size effects associated with adoption even when other factors were considered. Thus, of all the areas considered, only in the Aegean area of Turkey did there appear to be significant size effects in adoption that were not plausibly explained by differences in productivity, differences in effective market prices for inputs or products, or by the early stage of adoption in which small farms can be expected to lag behind larger farmers because of economies of size in transaction costs in evaluating and acquiring the new varieties.

By contrast, the scale effect in fertilizer adoption in these studies was more pronounced. Space precludes a summary of the analyses of fertilizer adoption decisions, but there were significant size effects in fertilizer adoption in nearly half of the agroclimatic situations considered. Apparently, fertilizer use is more heavily influenced by farm size than is variety use, as might be expected due to the greater investment at risk with fertilizer.

Conclusions

The adoption studies with which CIMMYT has been associated have shown that to a limited extent differences in farmer adoption behavior can be explained by differences in information, in the availability of inputs, in market opportunities for the crop, and differences in farm size and farmer risk aversion or risk perception. The pattern of adoption among large and small farms is generally consistent with the proposition that small farms may lag behind larger farms in the early stages of adoption but soon catch up. The impression from these studies is that the most pervasive explanation of why some farmers do not adopt new varieties and fertilizer while others do is that the expected increase in yield for some farmers is small or nil, while for others it is significant, due to differences (sometimes subtle) in soils, climate, water availability, or other biological factors.

Agricultural technology is more site-specific than we were led to believe by some of the early successes with wheat and rice varieties. The early high-yielding wheat varieties were adapted to extensive production areas and were widely adopted. It seems that these early successes will not be easily duplicated on such a scale. In the areas not already dominated by new varieties, the factors limiting yields are so disparate and complex as to make it unlikely that any single new variety can repeat the success of the early releases from international breeding programs.

Government policies to reduce the cost of information, the cost of inputs, or the impact of risk could be expected to influence the decisions of those farmers whose expected yield increases are now marginal. But the experience in the areas of these studies suggests that these policies are not likely to have a large impact in increasing the number of farmers who adopt new technologies. Significant advances in adoption will not occur until signifi-

cant advances are made in technologies that will increase yields in the agroclimatic environment of those farmers not presently adopting. This will require greater attention to the environment for which technologies are being developed than was necessary for the early successes in cereal breeding.

Land Use Planning: An Institutional Overview

Raymond J. Supalla

The environmental concerns of the 1970s have spawned an extensive institutional maze designed to achieve a multiplicity of environmental goals. Land use planning occupies an important but ill-defined role within this configuration of institutions, that is, ill-defined with reference to both what land use planning is and what it can accomplish. The result is a confusion, a misallocation of research resources and planning impotence.

Land use planning is ill-defined primarily because the relationships, powers, and responsibilities of the many people involved in planning are changing rapidly (institutional change) and because there exists no theory of planning that adequately integrates the market and political aspects of land use decision making. Rapid institutional change makes it extremely difficult for analysts to maintain realistic and relevant perspectives. Similarly, the absence of a comprehensive theory of planning leaves analysts without an adequate basis for conceptualizing problems and selecting appropriate analytical concepts. This paper constitutes an attempt to improve understanding of what land use planning is and what it can accomplish by examining conceptual issues and reviewing current institutional trends. Attention is also given to assessing the reasons for institutional change and the significance of recent trends with reference to social welfare and research needs.

Discussants for this session were Orville E. Krause of the Economic Research Service, U.S. Department of Agriculture, and Daniel W. Bromley of the University of Wisconsin.

Raymond J. Supalla is an associate professor of agricultural economics, University of Nebraska.

New Mexico Agricultural Experiment Station Journal Article No. 607, New Mexico State University, Las Cruces, New Mexico. The author gratefully acknowledges the helpful comments received from Dave Aiken, G. Dawson, Loyd D. Fisher, J. Gray, Paul Gessaman, Bruce Johnson, and Duane Olson.

Conceptual View of Planning

According to the conventional definition, planning is a public decision-making process involving the evaluation of land use alternatives and the implementation of direct or indirect land use control programs. This broad definition is widely accepted, but attempts to specify the planning process in greater detail reveal vastly different perspectives and are fraught with conceptual problems. Thus, it is necessary to examine some of the major conceptual problems before presenting a more detailed conceptual framework that can serve as a basis for discussing planning institutions.

Perhaps the most significant problem is the persistent belief that land use planning can be and ought to be comprehensive. Comprehensiveness calls for determining the land use pattern that maximizes social welfare. Defined in this manner, comprehensive planning can be achieved only if two conditions are met: decision makers thoroughly understand the welfare implications of all land use outputs for all the people involved and analysts are able to clearly specify the production relationships between land and social outputs, such as clean air, clean water, efficient public utility systems, aesthetic enhancement, etc. Neither of these conditions can be met at the present time, and, thus, comprehensiveness is and will probably remain an elusive and impossible goal. (For a more complete treatment of why comprehensive land use planning is an impossibility, with emphasis on the difficulties inherent in the political process, see Libby, pp. 106–8.) The major consequence of attempting comprehensiveness is production of a document that achieves nothing. Planners who attempt to do all things find themselves without

the resources to sell the public on any one of them, even though they may have acquired the data to convince themselves.

Another conceptual problem is the tendency to view land use patterns as an output or end in itself instead of an input or method of achieving desired social goals. When a given change in land use patterns is viewed as the desired objective instead of in terms of the difference made to society if the land is used differently, attention is diverted from the real purpose of planning, leading to the ignorance of methods other than land use planning as the means for achieving desired ends. For example, property damages due to flooding can be reduced by land use planning actions that discourage development of flood plains, but perhaps retention dams could achieve the same end with a more desirable cost-benefit distribution.

A third conceptual problem results from failure to understand the meaning and/or importance of analytical institutional economics. A recent article by Seagraves illustrates both the confusion surrounding the analysis of environmental institutions and the persistent tendency of many economists to succumb to the conservative bias that requires a positivistic approach and deemphasis of distributional issues. The appraisal of environmental institutions, of which land use planning institutions are a subset, demands an assessment of what difference will be made if the rules are changed and who will be affected by the impacts (Schmid, Bromley, Randall). The focus on efficiency questions, strongly advocated by economists with a conservative bias, ignores the question of whose efficiency. The ideal land use pattern (highest value output per unit of input) may be quite different for poor inner city residents than for rich suburban dwellers. Perhaps many land use plans continue to gather dust because they are designed by and for one group, planners and community activists, but must be sold to the public at large.

The foregoing discussion only touches on the myriad of conceptual problems associated with the land use planning process, but it does provide a starting point for presenting a relatively detailed conceptual perspective that is consistent with institutional reality.

Land use planning can be viewed as a process of establishing and operating public institutions that modify the market allocation of land consistent with the wishes of the people involved.[1] The process begins when groups of individuals become dissatisfied with the existing or projected market allocation of land resources and set out to change the rules (establish planning institutions) in order to allocate land resources in a manner more consistent with their wishes. The objective is not to optimize the use of land (comprehensive planning) but to use land use modifications as a means of achieving a narrow subset of social goals. Once the rules have been established, including the choice of the decision maker, the distribution of power over land use, provisions for citizen recourse, and provisions for financing planning efforts, the operational phase of planning begins. This phase consists of analysis of the difference made if land is used in different ways, selection of desired land uses, analysis of how land use patterns change with the implementation of control alternatives, and actual implementation of control programs. More precisely, land use planning can be thought of as a process of determining property right distributions at two levels. First, the rules establish whose preferences count. Second, property rights are changed to encourage land use patterns more consistent with the wishes of those whose preferences matter.

When land use planning is viewed in the above manner, it permits perception of the process as but one means of achieving desired goals. It also facilitates recognition that the outcome of land use planning depends on the distribution of rights or liability rules, contrary to those who believe that optimum land use patterns could be determined if only enough data was available. The importance of property rights means that any evaluation of planning performance must focus on how decisions vary with differences in institutional arrangements and how successful a given institution is in achieving the objectives of the people whose preferences matter. Planning performance can be evaluated with reference to the perspective of given publics, but the normative aspect of property rights makes it impossible to evaluate with reference to the total public interest.

[1] It is helpful to distinguish between land use planning and public land management, where land use planning involves public controls over private lands and public land management involves public decisions regarding public lands. Public land management is essentially a subset of land use planning where the market is rejected in favor of public ownership as a means of land use control.

Current Institutional Trends

The current state of land use planning activity can usefully be divided into two components, input-oriented and output-oriented. Input-oriented efforts include all planning institutions established for the express purpose of modifying land use patterns. Output-oriented efforts include those institutions established to pursue an express purpose other than land use planning but that employ land use planning as one of several means for achieving their goals (e.g., the Environmental Protection Agency).[2]

Since federal land use legislation succumbed to impeachment politics and the fears of the agricultural sector in 1974, the push to establish input-oriented planning institutions at a state level has abated considerably. A review of *Land Use Planning Reports* reveals that only one state, Wyoming, passed broad based input-oriented land use planning legislation during the past eighteen months and that it is being seriously considered in only one other state, Michigan. County and municipal programs are still being established, but such programs continue to be almost exclusively dependent on zoning, a control technique that is only marginally effective (Babcock, p. 123).

The real action in the land use planning arena appears increasingly to involve output-oriented efforts. Some of the more significant land planning institutions include highway departments, fish and wildlife bureaus, parks and recreation agencies, housing agencies, and, last but not least, the Environmental Protection Agency. All of these institutions engage in land use planning as one means of achieving their objectives.

Highway departments engage directly in land use planning when they set out to determine highway routes and designate arterials. This process involves analyzing the impact of highways on land use patterns. Fish and wildlife, parks and recreation, and housing agencies are involved in the management of agency-owned lands and in the control of lands owned by others as a means of insuring the availability of wildlife habitat, recreation facilities, and aesthetically pleasing housing, respectively. The Environmental Protection Agency (EPA) is involved in land use planning in many ways and is emerging as the most important of all output-oriented land planning institutions. The activities associated with implementation of the Federal Air Quality Act (PL 91-604) and Water Quality Act (PL 92-500) are perhaps the most important land related EPA programs. Implementation of the Federal Air Quality Act involves determination of where industrial and public facilities can be located, which constitutes land use planning in its purest form.

The most significant water quality program, in terms of land use, is section 208 of Public Law 92-500. Section 208, as recently interpreted by a U.S. District Court for the District of Columbia, requires a statewide program, including rural as well as urban areas. Under draft guidelines issued by the EPA, section 208 programs must, among other things, have accurate land use growth projections in order to plan for adequate waste-water management facilities and anticipated nonpoint source runoff (U.S. Environmental Protection Agency). The guidelines essentially say that section 208 planning must examine, evaluate, and make recommendations on the existing land use regulatory system and land management practices, particularly as they relate to nonpoint source control (Nebraska Natural Resources Commission, p. 3).

This brief summary of what is currently transpiring in the land use planning arena indicates that land use planning is occurring at an increasingly intensive pace in rural as well as urban America. But, the major programs are not the traditional land input-oriented programs with the multiple objectives and political decision making that is usually envisioned in state or federal land use bills. Instead, land use planning is being done by output-oriented institutions where land use decisions are made by bureaucrats and viewed as a means of achieving a single objective. Some of the reasons for this phenomenon are perhaps obvious, but it might be useful to explore them before examining the policy and research implications of this changing institutional scene.

Factors Affecting the Development of Land Use Institutions

Factors affecting the development of land use planning institutions fall into two categories:

[2] It is important to carefully distinguish between institutions that engage in making decisions about land uses for the purpose of achieving particular goals or outputs (output-oriented planning) and those who merely establish rules that incidentally influence land use. For example, tax rules influence land use, but the Internal Revenue Service does not engage in land use deliberations. The Environmental Protection Agency, in contrast, engages in both rule making and in deliberations regarding desired land use patterns.

those that create a demand for outputs affected by land use patterns and those that influence the type of institutions that emerge for the purpose of providing the outputs demanded. Each category is discussed in turn below.

The land use planning outputs that have enjoyed the greatest increase in demand are primarily environmental in character, e.g., preservation of open space, improved air and water quality, protection of wildlife habitat, and preservation of wilderness areas. The demand for these environmental products has apparently increased due to greater affluence, population pressures, improved knowledge regarding the ecological implications of man's activities, and changing life styles. There is probably no question about the general validity of these forces, but what is not well understood is the extent to which such forces vary by geographical and social dimensions. To what extent and for what reasons, for example, is the demand for environmental products different in urban versus rural communities? Casual observation indicates that the political pressures for environmental products are greatest in the more affluent urbanized regions, but little is known about why such differences exist. Are they due to different preferences (values) or to different levels of knowledge regarding ecological factors?

Analyses of public attitudes indicate that preferences or value differences explain more of the variance in demand than differences in knowledge (Comer, p. 40). If these preliminary results prove to be valid, a number of land use and other environmental programs are doomed to fail. Most notedly, land use education efforts directed at making planning in rural areas politically acceptable are not likely to succeed if the public does not want what land use planning will provide, as opposed to not understanding what the outcomes will be.

The factors influencing the type of institutions being established to provide environmental outputs are more difficult to discern, but at least three plausible forces come to mind: the relative ability of the public to identify with broad goals as opposed to techniques for achieving goals, the fact that oblique changes in property rights are more politically acceptable than direct and obvious changes, and the difficulty that politicians find both conceptually and politically in providing specific policy directions.

In this election year it appears to be particularly evident that the public identifies much more readily with goals than with techniques for achieving them. Much as Governor Carter finds it more persuasive to speak of goals rather than of programs to achieve goals, the general public is more apt to support pristine water quality than they are to support land use planning, which is usually equated with zoning. If this phenomenon is as pervasive as it appears, it would come as no surprise when Congress adopts environmental goals that require land use planning to achieve them but turns down land use planning bills.

Much of the resistance to input-oriented land use planning can be attributed to the obvious changes in property rights that occur when plans are implemented. Property rights are viewed by many lay people as being absolute and inviolate such that any change threatens the very foundations of the social structure. However, opposition to changing property rights is intense only when changes are direct and obvious. Perhaps this is due to the fact that one cannot oppose something unless one recognizes that it is occurring, or perhaps it is due to the implicit acceptance of property right changes when the resulting outcomes clearly warrant it. In either case, it is clear that oblique property rights changes, such as giving a farmer's neighbor the right to be free of the dust associated with grain storage via an Air Quality Act, are much more acceptable than a direct change such as zoning cropland agricultural.

A third important factor contributing to development of output-oriented land use planning institutions is the difficulty of making specific political decisions when the issues involved are extremely complex and controversial. Politicians at all levels of government cope with complexity by making broad policy decisions and assigning to bureaucrats and to the courts the task of working out the details and the conflicts. This phenomenon is evidenced quite clearly in the evolution of environmental law. The National Environmental Policy Act, the Water Quality Act, and the Air Quality Act were all so broad that no one knew what they meant until bureaucrats drafted guidelines (administrative law) and the courts approved or disapproved such guidelines, given their view of congressional intent. If this approach continues, and there does not appear to be a viable alternative, input-oriented land use planning efforts that

call for detailed political decision making are likely to remain insignificant.

The output-oriented land use planning institutions that emerged in recent years appear destined to continue their domination of the land use planning arena, given the nature of the forces underlying such developments. Assuming this view is correct, several critical social welfare and research issues merit attention.

Social Welfare Effects

What appears to be quite clear from the emerging pattern of land use planning institutions is that market-directed land use patterns are being drastically modified but not in the manner envisioned by many advocates of land use planning. Instead of planning efforts that seek to balance multiple objectives, the scene is being increasingly dominated by single-objective programs, e.g., water quality. Land use decisions are being made by bureaucrats and the courts instead of by the elected representatives of the people. Similarly, the emergence of strong output-oriented programs has successfully removed most of the important decisions from the local control so strongly advocated by many input-oriented planners.

The principal welfare consequence of these developments appears to be the danger that particular objectives will dominate to the exclusion of others or, more broadly, the danger that many publics will not be adequately represented as land use decisions are made. At the present time, for example, people concerned about air quality, water quality, automobile transportation systems, and the preservation of historical sites, wilderness areas, and wildlife are quite well represented, as contrasted to those publics who are interested in preservation of agricultural land, quality mass transit systems, lower-cost housing, and efficient public utility systems. Perhaps what is needed is an Agricultural Land Act, a Mass Transit Act, a Private Housing Act, and a Public Utilities Act comparable in impact to the Wilderness Act, the Air Quality Act, and the Federal Highway Act. One could then permit the courts to adjudicate the increased conflicts that result or to establish additional adjudicating bodies called something other than land use planning boards.

In considering the social welfare effects of the evolving pattern of land use planning institutions, it soon becomes clear that what has been, is being, or could be produced by alternative institutional arrangements remains largely unknown. There exists little empirical evidence to either refute or support deductive conclusions.

Research Needs

The increased emphasis on output-oriented planning efforts calls for quite different research programs than those currently being emphasized by land use planning economists. Current research programs, to the best of my knowledge, focus on property value effects of public land use decisions; the impact of incentive-based policies on land use patterns; measurement of public land use preferences; development of land use data systems; explanations for the spatial distribution of economic activity; and identification of prime agricultural lands. (This summary of current research emphasis is based on published output and inferences that can be drawn from the work of the National Task Force on Research Related to Land Use Planning and Policy.) Suggested changes in research priorities are discussed below with reference to three major recommendations.

(*a*) Additional research is needed on the outcomes associated with different institutional arrangements. With land use planning institutions in a rapid state of evolution, it is imperative for society to closely examine what differences result from alternative institutional arrangements. For example, what differences are likely to result from decisions made by elected officials, bureaucrats, and judges? To what extent do land use decisions resulting from output-oriented institutions differ from input-oriented pursuits? Does citizen participation in planning change decisions or does it simply legitimize what would have been done anyway? Answers to these and numerous related questions are essential if there is to be any hope of anything more than random achievement of land use goals.

(*b*) Additional research is needed on the relationships between land use and quality of life variables. At the present time little is known about the all important relationships between land use and quality of life variables. Specific examples that merit attention include the relationship between a sprawled urban land use

pattern and air quality; the effect of prohibiting urban development of agricultural land on the quantity, quality, and cost of available housing; and the relationship between use of inorganic compounds on cropland and the impact on potable water supplies and water-based recreation. Input-oriented planning efforts have often failed because they did not consider relevant outputs, and output-oriented efforts can succeed only if asking output-oriented questions results in credible answers.

(*c*) Increased emphasis should be placed on the efficient collection of the types of data that influence land use decisions. Perhaps the most serious malallocation of research resources occurs with reference to the collection and analysis of data for all lands, when it is relevant to decisions on only a small part of the total acreage. For example, detailed data on the physical suitability of soils for urban use are needed for areas where urban development is likely but are a waste of effort for areas where it is clear that urban development will not occur. A better more general illustration might be land resource inventories. Most land resource inventory systems call for collection of the same data for all lands within a jurisdiction, despite the fact that land use changes occur only on a small and predictable portion of the total land base.

Another malallocation occurs when researchers collect data and analyze issues that they believe important but that decision makers choose to ignore. This factor is becoming increasingly important as narrowly focused output-oriented planning institutions increase in prominence.

Summary

This institutional overview reveals that land use planning must be conceived of as a subcomprehensive public decision-making process that focuses on modifying land use patterns to produce desired outputs, with decisions made on the basis of distributional impacts, not economic efficiency. When land use planning is conceived of in this broad context, it becomes clear that the public decisions regarding land use are increasingly being made by output-oriented planning institutions such as EPA and not by conventional planning commissions. Output-oriented planning institutions can be expected to continue their rapid growth, due to the relative ability of the public to identify with specific instead of general goals, the higher acceptability of oblique changes in property rights than direct and obvious changes, and the increasing difficulty that politicians find in making detailed resources use decisions, such as those required with input-oriented planning.

Current trends in the evolution of land use planning institutions mean that increasingly it is the bureaucrats and the courts instead of politicians who are making land use decisions and that the distribution of power over land use is shifting from the local to state and federal governments. These developments pose an increased danger that particular planning objectives will dominate to the exclusion of others and that the divergent interests of different localities will not be adequately represented.

The high priority research needs associated with the changing institutional scene include evaluation of the outcomes associated with different institutional arrangements and estimates of the relationships between land use and quality of life variables. In addition, research planning needs to involve a greater emphasis on determining the data and research results most relevant to the decision-making process.

Information Needs and Models for Land Use Planning

James A. Gibson and John F. Timmons

Public concern about the use of land resources has increased in recent years. One explanation stems from accelerating changes occurring in population patterns and life styles.[1] Simultaneously, tight world food supplies combined with environmental pressures[2] and possible changes in future technological progress[3] have led to an increased realization that land resources are relatively scarce and require improved management. Land use is closely linked to such important issues as food supply, energy resources, environmental quality, and rural and urban development.

This paper presents information needs and models for U.S. land use planning. The following steps are followed. First, U.S. land use planning is briefly reviewed in retrospect. Second, present land use information needs are discussed. Third, the concept of land use viewed as a process is introduced. Fourth, models for land use planning, based on methodologies utilized in recent land use research undertaken in Iowa and which seem to have applications in other states, are presented. Selected research findings obtained from application of these models are presented. Finally, utilization of land use information and further land use research needs are discussed.

Land Use Planning in Retrospect

During the depression years in the early 1930s, land use research and planning became evident by the establishment of the National Planning Board in 1934 and the subsequent establishment of state planning boards in most states and of county land use planning in most counties. Land use research during the first part of the 1940s was directed toward increasing agricultural production. In the postwar part of the decade, effort was directed toward land use adjustments necessitated by declining demand for agricultural products and by urban growth. During the 1950s land use research efforts extended to problems of irrigation and water rights as water use became more competitive among the major uses within the more humid areas. World land problems, aggravated by increasing world population pressures, became major concerns of land use research during the 1960s. During the late 1960s and the 1970s land use efforts were extended to environmental problems associated with soils, water, air, congestion, technology, and land resource use conflicts.

Many weaknesses experienced in land use research and planning efforts of earlier decades could now be avoided. A popular area of earlier land use research encompassed development and application of land classification techniques. As stated by Kelso, "The intent was to map geographically the patterns of physical and biological characteristics of the environment. Often the problem-solving relevance of these classifications was vague, and in most cases their economic interpretation was more vague" (p. 3). Land use research lacked defined goals and defined data needs consistent with state and national goals. There was an absence of rigorous analyses and quantitative modeling. Today, there still exists an absence of clearly defined land use goals, land use information (needed for an informed and participating citizenry), and policy tools adequate and acceptable to implement land use programs.[4]

[4] Infanger and Bordeaux's recent assessment of extension land use educational publications found a paucity of information trac-

Information Needs for Land Use Planning

Currently, governmental entities, recognizing the need for land use planning, are enacting land use legislation at both state and national levels. But current land use planning efforts are being thwarted and confused by vague and conflicting goals. Among such goals are orderly development of land uses, preservation of prime agricultural land, and protection of property rights.

Any land use planning system requires an information support system. Land use legislation pending at the state and national levels is likely to demand new levels of capability within the technical area of economic analysis, particularly in regard to systematic analysis of land use data. Proposed federal legislation explicitly requires states to forecast their land use requirements.[5] Both state and federally proposed legislation provide significant incentives for developing quantitative land use analysis models.

Information systems serving land resource programs have direct bearing upon the effectiveness of identifying and satisfying land use policy, planning, and program objectives. A reduction of uncertainty through land use information and projection can improve the social allocative efficiency of the land market and can improve public land use decisions with respect to land resource allocation over time.

Applied research is a necessary basis for planning future uses of land. Land use research needed in the United States includes articulation and analysis of public land use goals, inventory of present land uses and projections of future land uses, and identification and development of alternative means for achieving articulated land use goals.

No land use program can be made effective without appropriate implementation. Policy tools designed to meet the needs of an earlier era are still relied on today. Current zoning ordinances, for example, are based on a model enabling law proposed in 1922 by a U.S. Commerce Commission Advisory Committee on Zoning (Berger). Research is needed to analyze and design appropriate policy tools to guide land uses toward current goals.

Land Use Viewed as a Process

Significant progress cannot be made in land use planning until the land use process is better understood. The land use process concept views land use not as a random process but subject to causal factors that are dynamic, predictive, and normative in nature. This concept implies change in land uses over time. Each land use has an immediate impact on the adjacent land uses and also has impacts on succeeding land uses over time. Effective public land use programs require accurate understanding of past and present land uses and their interrelationships.

The predictive element of the land use process implicitly hypothesizes the existence of identifiable causal factors affecting the use of land. Current land uses have evolved through processes involving decisions and actions in both the market place and the political arena. Land use does not just happen; rather, there is a rationale for present uses of land that requires understanding and analysis. Finally, normative elements of the land use process assume that land use goals can be articulated by society and implemented by institutions, taking into account identified causal factors.

Recent Iowa land use research, divided into three highly interrelated segments, has begun to apply the land use process concept. The first segment focuses on identifying land use planning goals of residents within a multicounty planning area. The second focuses on inventorying present land uses and projecting future land uses, while the third analyzes policy tools available to guide land uses toward identified goals. A comparison of results from the first segment with the second forms the basis for detecting potential land use problematic situations. Through this approach, the need for institutions to resolve the problematic gap becomes obvious and is treated within the third segment.

Multigoal Land Use Model

Recent land use research in Iowa develops and applies methodology in the identification

ing the development of present state land use patterns. They also found that, while publications related to present control techniques (mostly zoning) are plentiful, available material on proposed new land use controls is sparse.

[5] Both S.632 and S.3175 included provisions for states to qualify for federal land use planning assistance (U.S. Congress, Senate 1971, 1972). Subsequent bills introduced in Congress—S.268, H.R.10294, and S.984—contained smaller provisions (U.S. Congress, Senate 1973, 1975; House 1974). Under Section 701 of the Federal Housing and Community Development Act of 1974, HUD 701 grants for comprehensive planning will not be approved after August 1977 unless the comprehensive plan contains a land use component (U.S. Congress).

and formulation of goals for land use planning preferred by citizens within a multicounty region (Lundeen). A model was developed that uses U.S. Water Resources Council goals for land use planning.[6] Agricultural, industrial, residential, recreation, mining, and transportation land uses are involved in achievement of these goals.

Through interviews with a modified random sample of respondents designed to reflect their age, sex, education, and occupation, in-depth interrogation of respondents revealed the identification and ordering of the following land use goals: increased environmental quality and conservation of resources, increased economic development of the region, and improved social well-being in terms of income distribution and levels of living. A paired-comparison model was used to provide an estimate of each goal's numerical position on a scale in addition to an ordinal ranking of the goals (Edwards).

Land Use Inventory Model

In order to have meaningful land use planning, accurate data on land uses are essential. In the United States, land use data have evolved gradually and piecemeal to meet specific needs. No comprehensive system of collection, analysis, publication, and retrieval of land use data has ever been developed. Federal, state, regional, county, and local governments collect and maintain data largely independent of each other. There is little uniformity of coordination in organizing and disseminating basic kinds of land use data among planning jurisdictions and little agreement and consistency concerning land use definitions and projection dates.

Because of the lack of land use data, there has been an absence of quantitative land use analysis. Methodological approaches already exist for the development of techniques to analyze land use data. The challenging step is to obtain and present needed data in a quantitative analysis format that will be comparable and useful to land use policy makers at national, state, region, and county levels.

Recent pilot land use research in Iowa has begun to respond to these needs for land use information by public agencies engaged in planning for the use, management, and development of Iowa's land resources (Gibson). Although this research has been limited to Iowa, the analytical methods seem applicable in other states.

The Iowa land use inventory model focuses on two general categories of land use—agricultural and nonagricultural—and their respective subsets of uses. Agricultural land uses are disaggregated by major crops, while nonagricultural land uses are disaggregated by subcategories. Both agricultural and nonagricultural land uses are analyzed in terms of extensive (acres) and intensive (density measures) use classifications within specified spatial units including incorporated place, county, multicounty planning region, and state.

To determine past and present land uses and to provide a data base for projections, relevant available land use data were obtained from state and federal government agencies and published data sources (see appendix A, part 7, in the *List of Agencies Contacted for Land Use Data,* Gibson). Also, mail surveys were used in obtaining land use data and information from Iowa incorporated places, county extension agents, and multicounty planning entities. Sampling techniques were used to make data adjustments. A multiple regression model was used to identify the major economic determinants affecting past and present demands for Iowa urban land uses.[7]

Land Use Projection Model

Land use research in Iowa has developed a model for projecting future nonagricultural and agricultural land uses under varying assumptions and alternative public policies. Initially, baseline projections were made for land uses expected to materialize if there are no demand, supply, or institutional changes of an unusual and unforeseen nature or magnitude in the causal factors that have been changing over time. The baseline projections provide these functions: an assessment of future land resource needs, an indicator of a potential land resource use problematic situation in terms of a divergence between future and desired land resource uses, and a framework for evaluating

[6] The U.S. Water Resources Council establishment of principles and standards for planning water and land resources is an example of an administrative order illustrating both clarity of wording and differentiation between means and goals.

[7] Urban land use includes nonagricultural land uses within Iowa incorporated places. Agricultural land within Iowa incorporated places is defined as land of ten acres or more that has not been planted and is preferentially taxed as agricultural land.

(*a*) alternative projections reflecting possible exogenous shocks and normative changes and (*b*) projections under public policy land use constraints as a measure of the effects of policy changes.

There are two general parts to the land use projection model—projected noncropland uses and projected cropland uses. With regard to the noncropland segment, regression analysis and trend extrapolations were used to project quantities (acres) of nonagricultural land resource uses (urban, highways, airports, public recreation, private recreation, and extractive land uses) and noncropland agricultural land resource uses (pasture, forest, and other land in farms). Projections of qualities of nonagricultural land absorption and noncropland agricultural land uses were made by extrapolations from the initial inventory data according to rules specific to the subcategory of land resource under consideration.[8]

With regard to the cropland segment of the land use projection model, the study evaluated the significance of U.S. Department of Agriculture OBERS crop requirement projections for Iowa (USDA and U.S. Dep. Commerce). OBERS (Office of Business Economics [U.S. Department of Commerce] and Economic Research Service [USDA]) projects Iowa crop requirements by using the state's historic contribution record as a basis for disaggregation. Iowa regional crop requirements were projected by allocating projected ranges of Iowa statewide crop requirements to each of the economic planning regions according to the region's historical percentage distribution. Given ranges of projections of future crop yields by land qualities within Iowa regions, projections of the acreage required for crop production were made. These projections were compared with projections of the supply of land services for cropland purposes (given projections of nonagricultural land absorption by quantities and qualities and noncropland agricultural land uses) to protect a surplus or deficit of regional cropland acres. Thus, the implied baseline norm for evaluating the land use projections of this model is that Iowa regions can continue to supply their historic trend contribution of U.S. crop requirements. These baseline projections provide a framework for evaluation purposes between this norm and the projected land use situation and alternative projections reflecting possible public policy changes.

Various ranges of assumptions of nonagricultural land use absorption and noncropland agricultural land use conversion to cropland uses were considered. The assumptions and policy shocks were introduced into the land use projection model in various combinations to estimate the sensitivity of changes in each exogenous land resource variable to the agricultural development potential, with respect to land constraints, within each region.

The Iowa land use research makes maximum use of secondary published data and primary data survey methodologies available to all states. The land use projection model provides an internally consistent set of regionalized land use projections for the state that are comprehensive in coverage of major land use classes and provide uniformity of base and projection target dates. The land use projection model is dynamic since different solutions can readily be computer derived under different policy programs. The land use projection model is consistent with the framework of national OBERS projections, which are periodically updated.

Utilization of Research Results

Empirical results of the multigoal land use model revealed the ranking and intensity of first, second, and third goal choices of respondents within a multicounty planning region (Lundeen). Results of this study indicate that land use planning can no longer be considered to be single purpose; multiple goals must be considered when constructing land use plans. Although citizens may not be able to participate in the technical aspects of land use planning, articulation of goals is one essential means for citizens to participate in land use planning. If citizens realize that technicians are directing land use planning toward their preferred goals, then they may be better motivated to execute the plans.

Systematic information on Iowa's past, present, and projected land resources would be a valuable input into the development of a land use policy for the state and aid county and multicounty planning entities and land use planning educational programs. Although many of the results of these pilot studies are more suggestive than definitive, some of the

[8] The 1967 Conservation Needs Inventory (CNI) data, available for all states, were used as the data source for land qualities (land capability classes) (USDA).

more salient statistical conclusions and projection model results are summarized. Policy implications are also indicated.

Research effort was devoted to developing a regionalized set of land absorption coefficients for Iowa (Gibson). Between 1960 and 1970, urban population density declined or Iowa incorporated-place urban area per capita increased for every population size class incorporated place and for every region considered. On a statewide average basis, urban land per capita increased from 0.26 to 0.28 acres per capita from 1960 to 1970. Derivation of urban land absorption coefficients revealed that Iowa's incorporated-place land absorption per capita is higher than the corn belt average and much higher than the national average. Iowa incorporated places of greater than 50,000 people were found to absorb more than double the land per employee compared with the national average, reflecting a relative surplus of Iowa land.[9] These land absorption trends provide valuable information in formulating future land use policy. For example, if zoning is to be effective in directing land use development, officials must recognize the amount of area that may be absorbed by various land uses.

An analysis was made of urban land absorption coefficients for different population size Iowa incorporated places. Iowa's average urban land absorption coefficients generally increased, moving from large population size classes of incorporated places to smaller population size classes of incorporated places. Per capita land absorption differentials between different population size classes of incorporated places have important policy implications. If population migration is at a turning point (Beale) in the long movement from rural to urban dwelling, then this could lead to significant increases in urban land absorption per capita.

Between 1960 and 1970, the amount of agricultural land within Iowa incorporated places increased 17% (63,000 acres); at the same time nonagricultural incorporated-place acres per capita increased. Growth in population of Iowa incorporated places was found to be associated with incorporated-place land annexation in spite of large amounts of agricultural land presently existing within Iowa incorporated places.[10] Between 1960 and 1970, less than 2% of all Iowa's incorporated places had an actual net decline in land area, indicating the apparent irreversible nature of the urban land use process, even though there is much agricultural land within Iowa incorporated places that is not physically urbanized.

The relatively large stocks of agricultural land within incorporated places in Iowa comprise a potential land resource of considerable value in terms of accommodating additional urban land use needs. Projections of future Iowa urban land use needs revealed enough existing agricultural land within Iowa incorporated places in 1970 to accommodate these needs for all sixteen of Iowa's economic regions to the year 1990 and for fourteen of the sixteen Iowa economic regions to the year 2000.[11]

The multiple regression study of urban growth in Iowa found that change in urban population explained 80% of the variation of change in urban land use (Gibson). Neither change in income nor change in average value of agricultural land and buildings explained much of the variation of change in urban land use. Over the ranges observed, demand for total new Iowa urban land implicitly seemed both price and income inelastic. A policy implication is that present prices of agricultural land in Iowa are not sufficiently high, relative to urban demand, to play any significant role in rationing agricultural land to urban uses.

Major conclusions of the Iowa land use projection model are summarized on a statewide basis as follows. Alternative projections of Iowa land use found that the public policy alternative of preserving highly productive Iowa cropland (corresponds to CNI land capability classes I to III) from nonagricultural land use conversion had a negligible (compared with similar baseline projections) effect on increasing Iowa's cropland resource

[9] This was found for both manufacturing and associated land uses per manufacturing employee and wholesale trade, retail trade, and services and associated land uses per wholesale trade, retail trade, and services employee.

[10] In 1970, there was 430,000 acres of agricultural land within Iowa incorporated places.

[11] These projections ignore any land quality constraints, such as slope and drainage, on the use of these lands for urban uses. However, twelve of the sixteen Iowa economic regions were each projected to have more than 1,000 remaining acres of agricultural land within incorporated places in the year 2000. These projections also ignore possible individual incorporated-place deviations between urban land use needs and agricultural land availability within the incorporated place. Projections at the county level found that seventy-eight of Iowa's ninety-nine counties could meet their projected future urban land use needs to the year 1990 by utilizing the amount of agricultural land existing within their incorporated places in 1970.

use capacity in the near-, medium-, or long-term given ranges of projected yields and crop requirements.[12] The differential regional impact of such a policy was also found to be small. An empirical investigation of a possible Iowa cropland resource capacity contingency demand was alternative projections of accelerated nonagricultural land absorption. Only for high trend crop requirements (high export assumptions) and low trend yields combination of projections in the long term did accelerated nonagricultural land absorption cause a deficit of Iowa statewide cropland acres from comparable baseline projections. The public benefits of prime cropland preservation in Iowa may be small in terms of significant increases in output of food and fiber. But this conclusion ignores other possible public benefits from prime cropland preservation, such as those associated with increased environmental quality and with option demand benefits resulting from uncertainty in both the supply and demand of future food and fibers.

The public policy alternative of improving the quality of the environment by removing fragile Iowa cropland (corresponds to CNI land capability classes IV to VIII) from production did not place undue stress on the general productive capacity of Iowa statewide cropland, except in the long term under high-trend crop requirements and low-trend yields combination of projections. Not all regions in Iowa were affected equally by such a policy. Public costs of removing private Iowa fragile lands from production must be measured against the public benefits of such a policy, taking account of regional distributions of costs and benefits.

Further Land Use Research Needs

The Iowa land use research has been more of a reconnaissance survey than a definitive analysis. Further land use research needs, summarized below, will be incorporated into ongoing Iowa land use research.

With regard to the multigoal land use model, information is needed on the technical relationships between means and goals of the model. For example, an acre of land used for industry may contribute to achieving environmental quality, economic development, or social well-being. With these coefficients and weightings of land use goals, a multiobjective goal program could be developed.

Analysis is needed on land use interrelationships among different population size classes of incorporated places and spatial regions. The following kinds of questions need answers. Do different population size classes of incorporated places have different per capita and per employee land absorption relationships? How is this related to urban hierarchies? Why do incorporated places continue annexing agricultural land when there is ample existing land already within them? Is this a means whereby the incorporated place can gain future control over these land uses through development regulations? By annexing new land is the incorporated place gaining a higher proportion of middle income residences, thereby alleviating fiscal difficulties but creating land use inefficiences? Do annexation laws overly encourage substantial agricultural land annexation? Do preferential tax laws lead to a premature incorporation of agricultural land because agricultural land within the city perimeter is taxed more favorably than the same agricultural land just outside the city limits? Do speculative expectations of increased land values within incorporated places promote annexation? What are the forces behind the supply decisions of land owners that influence the pattern of urban development? Is nonagricultural land use just outside incorporated places taxed more favorably than nonagricultural land just inside incorporated places, and does this lead to urban sprawl? How do public investments influence land use shifts particularly in rural-urban fringe areas? In general, more information needs to be known about the forces behind the land-transfer process before effective land use policy tools can be developed to control land use.

Research is needed on economic decision rules that incorporate social risk aversion, interdependent decisions, and irreversibilities. These rules could be incorporated in cost-benefit analysis to evaluate the decision to preserve "prime" agricultural land.

What are the implications of the effectiveness and economics of land use approaches rather than structural or technological abatement techniques in controlling agricultural pollution?

Alternative land use projections based on

[12] Land use projections for the years 1980, 2000, and 2020 can be considered near-, medium-, and long-term projections, respectively. These projection dates correspond to those used by the U.S. Department of Commerce in making economic projections (USDA and U.S. Dep. Commerce).

alternative methodologies should be made and compared. Projecting different land uses over the long run is not susceptible to any single method or model. Probably more can be learned from accommodating differing projections based on different approaches, premises, and data, as from sequential manipulations of a single method undertaken independently.

Finally, much investigative study needs to be undertaken in the area of land use policy tools. This research should be closely coordinated with land use goals derivation because policy tools become meaningless without valid objectives to achieve. Selection of policy tools should be analyzed in terms of the objective function derived and the needs and characteristics of the region under consideration.

Prime Lands—Definition and Policy Problems

William W. Wood, Jr.

> The preservation of agricultural land is of paramount interest to the welfare of the state of California in that the preservation of such land, especially prime agricultural land, is critically important in order to assure and to maximize the food, fiber, open space and employment opportunities which are necessary for present and future generations of the state and the nation.
>
> Warren (section 67701)

As a proposed policy statement authored by an urban legislator, this quotation from proposed California Assembly Bill 15 seems to epitomize the increasingly popular cry to save or preserve prime agricultural land. Since prime connotates first in importance in terms of quality or value, intuitive support of such cries seems most appropriate.

Mature reflection suggests that efforts to save prime agricultural land must mean that market allocation is not achieving the objectives of such observers. This being the case, a substitute for market allocation must be developed, the assumption on which this paper is presented. The alternative is a public policy capable of implementation to insure that a specific resource such as prime agricultural land will be utilized so as to accomplish stated objectives. Simply stating as public policy that we shall save or preserve prime agricultural land is not capable of implementation; a positive action policy must be identified with specific applicability. At this juncture some very serious definitional difficulties as well as policy conflicts arise. Simply stated, prime in a nebulous sense may be universally acceptable; prime in a specific policy implementation sense no longer is as universally acceptable and in fact may not be acceptable to anything approaching a majority position.

The basic policy problem involved in the issue of prime lands centers on the inability or unwillingness to separate the scientific classification function from the policy-making function. If the word agriculture consistently follows prime, then it may be scientifically possible to define prime agricultural lands, i.e., those most appropriate for the production of agricultural commodities, and ignore the more generic definition of prime lands. Simply to define lands as prime, as in fact a number of scientists as well as urban observers tend to do, avoids the fact that land prime for agriculture is likewise apt to be prime for other societal uses. Thus, the scientific responsibility is to identify and analyze as many of the alternatives as can be found, while the policy-making responsibility is to select alternatives for specific parcels of land. Even with regard to agricultural land, however, we may have fallen into the trap of confusing classification or taxonomic approaches with policy making (Wood, p. 151).

Definitional Criteria

There appears to be an implicit assumption on the part of many observers that, given the objective of preserving prime agricultural land, the criteria for defining such land are objectively identifiable and capable of uniform application. Unfortunately, this implied assumption seems to lead full circle in that the selection of appropriate criteria depends upon the definition of prime, which in turn depends upon the criteria selected. The development of soil classification criteria has been a matter of interest and attention on the part of soil scientists and perhaps agronomists. Fenton gives an excellent and concise review of the development of land classification systems in the United States. The development of criteria for definitions of prime agricultural land now involves not only soil scientists but also economists, planners, engineers, and, for that matter, the general public. As a result, there is no longer an easy consensus as to what the

---

William W. Wood, Jr., is an economist with the Cooperative Extension, University of California, Riverside, and an associate in the Giannini Foundation of Agricultural Economics.

objective may be with regard to a classification system (House, pp. 2–3).

This expansion of interest is a relatively recent and continuing matter. For example, the *LIM Task Force Report* in November 1974 listed nine criteria (see Fenton) for prime agricultural land relating exclusively to soil-water-topographical characteristics (USDA 1974). In an unpublished preliminary draft of a potential cropland study by the Soil Conservation Service (SCS) in May 1976, additional characteristics were included such as the size of ownership unit, the size of tracts, and the extent to which the area was isolated (USDA 1976a). Even Fenton recognizes that energy utilization and its relationship to productivity may be an important consideration in soil classification (p. 142).

The technical criteria as used in the Land Inventory and Monitoring System (LIM) provide either a range of values within or a specific value above or below which land will qualify as prime. Once so classified, the applicable value for that variable is lost for future policy decisions; the system is completely static. For example, a pH between 4.5 and 8.4 in the appropriate zone will qualify. However, in many agricultural operations over time, there may be significant differences between soil that has a 4.6 pH and that with an 8.3 pH. The same lack of specification will apply to moisture, temperature, conductivity, erodibility, permeability, and texture. Unless measurements made for site-specific classification are stored in a retrievable manner, aggregate designation as prime precludes flexibility for future decisions.

Another serious definitional problem evolves from the use of the word agriculture. From a public policy standpoint most observers are concerned with either agricultural products or perhaps more specifically food and fiber. Pragmatically, however, land is not used to produce food and fiber but rather to produce crops that have different characteristics; these may depend upon whether the perspective is that of a market economist, a nutritionist, or a social psychologist. With several hundred commodities involved, it is obvious that agriculture is not homogeneous in this respect.

Futhermore, different commodities require a wide range of characteristics in terms of soil, climate, and other conditions for effective production. Thus, a particular classification of land that is appropriate for the production of corn or soybeans may not be as appropriate for the production of rice or cotton. As a result, a national definition of prime agricultural land assumes some relationship to appropriate commodity production. Thus, land appropriate for the production of avocados in Southern California or blueberries in New England is presumed to be less significant to a national interest than is land for the production of corn in Iowa. While this may ultimately be the case, it is not at all clear that the classification effort for prime agricultural land is licensed to make policy decisions as to which commodities should make up the total food supply. This would infer priorities in terms of continued commodity availability.

A basic economic contradiction arises. If one accepts the assumption that market allocation of land does not meet societal objectives for future food supply, dependence upon market allocation of commodities does not appear consistent. Ultimately nonmarket, i.e., public policy, allocations of commodities (food), and other land-oriented economic activities, would be a natural consequence.

Calories, Commodities, and Climate

A definition of criteria for prime agricultural land either assumes the inclusion of a variable relating to flexibility—the ability of a given parcel of land to be utilized for the production of a large number of differing commodities—or that some other prioritization system has been utilized. Such a system might well be the number of calories provided for human consumption, or it might be some measure of the net additional energy produced over the energy required in the production process itself. In fact, one senses an increasing urban concern toward reserving commodity production for those in which caloric content of the final product for human consumption exceeds the caloric input in the production process. This is particularly true for energy from fossil fuels. This consideration has led many areas to seriously examine their position with regard to continuing food supply. The Commonwealth of Massachusetts, for example, has developed a report entitled "Policy for Food and Agriculture," which attempts to deal with a number of policy issues (Congressional Record, pp. S.589–91). Included in this document is a recommendation for identification and mapping of prime farm land. From a defin-

itional standpoint the question arises as to whether Massachusetts' prime farm land is the same as that envisioned for a U.S. definition under more general criteria.

Relativity and Local Interest

Definitions of prime, by their very nature, are relative to some defined population. Prime from the standpoint of the total United States is apt to be considerably different than prime from the standpoint of the Commonwealth of Massachusetts or from the standpoint of a country or local community (although this difference is entirely ignored in the Secretary's Memorandum No. 1827, Supplement 1 [USDA 1976b]). The Government Code, State of California, defines prime lands for purposes of California. Land may be classified prime by meeting any one of five categories. Three of those categories are technical in nature.[1] However, two of the classifications for prime land are economic, i.e. "land which has returned from the production of unprocessed agricultural plant products an annual gross value of not less than $200 per acre for three of the previous five years" (chap. 7, art. 1, sec. 51201). From a policy standpoint California presumably considers the economic contribution of agriculture as significant a factor as the technical definition of land categories that are able to produce food and fiber over time.[2] A definition of prime land such as contained in the LIM project for the United States is not apt to be completely satisfactory for those states and/or communities that have other objectives in mind with regard to prime farm land preservation.

Much of the urban support for prime agricultural land preservation may well stem from quite different factors than those that more traditional agricultural analysts examine. Recent increases in retail food prices may be a triggering mechanism. However, factors such as open space, aesthetic appearance, environmental quality, and romantic notions seem implicit, particularly if achieved with minimal urban cost. The appeal of cattle grazing near residential areas may convert even marginal land into prime in the minds of urban residents. The agricultural findings and policies of the *California Coastal Plan* recommend preservation of thousands of acres on the basis of its importance to agriculture, although such land is marginal in terms of animal carrying capacity and certainly not "prime" on any productivity rating (California Coastal Zone Conservation Commission).

A further conflict exists relating solely to land that may be technically class I under the SCS classification system but located in an urban area. As Peterson and Yampolsky observe, land in an urban area may be technically capable of agricultural production but be incompatible for practical purposes due to a variety of social, environmental, legal, and economic reasons (pp. 13–15). This suggests the need for including definitional criteria beyond those presently utilized.

Alternative Approaches

One alternative under consideration is to rely upon what amounts to a semantic cop-out. This alternative would simply eliminate the use of the word prime in any of the definitional approaches to land classification and rely on some substitute word that would not have some of the connotations currently attributed to the word prime.[3] Unfortunately, this does not solve the dilemma of classifying land areas that are of critical long-run national or local concern; it remains static. The primary reasons are a failure to distinguish among identification, analysis, and classification (essentially scientific responsibilities), policy making (essentially allocative), and persistent inflexibility. While the word prime may well be one source of the present dilemma, criteria rather than names are at issue.

A second alternative is to rely on the technique currently used in the LIM project of identifying a prime land definition on technical criteria and relegating other significant portions of land area that are important for commodity production to a classification called unique. Two difficulties arise with this approach. The first is that since unique has no objective criteria, the inclusion of any land in this category is a policy decision. If such in-

[1] These technical categories include classes I and II under the SCS Soil Classification System, 80 to 100 under the Storie Index, and one animal unit carrying capacity per acre.

[2] An interesting contradiction in that market allocations of commodities are used to provide a basis for replacing the market in the allocation of the major production input, land.

[3] For example, there was a tentative proposal in the 1976 Session of the California Legislature to substitute "commercial" for "prime."

clusion is specified by those developing classification and criteria measurement, the scientific and policy-making roles are intermixed. The second difficulty is the psychological impact, particularly on citizens of communities and regions, of having their farm land excluded from prime. While unique may have positive psychological values, these tend to diminish as awareness rises that any land not in the prime category is eligible for unique. Furthermore, under this system inclusion of specific criteria for prime implies that commodity and/or caloric priorities have been included.

A third alternative explicitly recognizes the separation of scientific analysis from policy decisions and attempts to set up a series of criteria by which land may be classified (Wood). Under this proposed system any parcel of land can be evaluated for all significant variables, perhaps as many as twenty or twenty-five, and given a cardinal number on a scale of zero to ten in such a manner that the values for each variable are additive.[4] If the total possible points from all variables is, say, 200, then the policy maker is in a position to define prime agricultural land as that land with a rating of over a given number such as 150 or 175.

A further advantage of this system is that with the use of computer sciences, a program can evolve in which particular values for any given variable can be specified in order to identify the amount of land that is capable of producing a given commodity with very specific requirements. A quite common cry in California, for example, is that prime agricultural land must be preserved in order to guarantee continued production of brussels sprouts; this production is limited to a very small portion of two counties on the California coast. Most of the land involved in such production is not technically prime land under current classification systems, except as it qualifies under the economic category in the California definition. However, under a matrix analysis if one or two variables such as temperature extremes or hours of sunlight and cooling fog are particularly significant, identification of that land susceptible to the production of brussels sprouts could quite easily be identified.

This classification system allows flexibility. Since specific values for each variable are retained, changes for any parcel can be made as circumstances alter. Changes in water availability, adjacent land uses, or technology can be instantly included to reflect current conditions. Thus, the system does not become outdated for policy purposes. In this manner, the classification system shifts from completely static to partially dynamic.

As suggested above, the waters have been muddied considerably in the matter of attempting to define and inventory prime farm land or prime agricultural land in the United States. This confusion arises from a number of sources: the multidisciplinary perceptions of prime, the confusion between taxonomy and policy making, and perhaps most importantly the fact that local and national objectives do not completely coincide. The seminar conducted by the U.S. Department of Agriculture at Airlie House in July 1975 was an exceptional step in attempting to reconcile the problems with productive agricultural land in the United States. Unfortunately, for a variety of reasons the follow-through from that seminar seems not to have been as productive as might have been hoped.

Not only are there institutional factors involved, but also vested interests on a geographic, political, and even professional basis. The nonmarket allocation of productive lands for future food and fiber supplies cannot be accomplished by either agricultural economists or soil scientists working in isolation. Furthermore, if a national definition of land classifications is the approach that seems politically feasible, then it seems appropriate for that definition to be sufficiently flexible to permit state and local entities to interpret within guidelines established at the national level.

At present, California, for example, is using some of the traditional national definitions with some expansion. My concern is that California, in its infinite (or infinitesimal, as the case may be) wisdom, may decide that national guidelines and definitions for prime agricultural land are not sufficiently applicable and develop its own system as has so frequently happened in public policy in the past. The same sort of danger exists with regard to many areas of the United States with the possible exception of the Corn Belt, for which the

[4] For additive purposes, undesirable variables can be ranked on an inverse scale of ten to zero. Subjective variables, on an ordinal scale, can be converted to cardinal numbers while cardinal values, pH, for example, can be included directly. In addition, proximity to urban services with excess capacity or other nonagricultural variables can be included.

current approach to prime land definitions seems most appropriate.

As commonly used, prime seems also to be a function of time. A static definition will not pertain under all future conditions. Changing conditions—population, technology, and weather—very likely will alter criteria for selecting optimum land allocations.

Conclusion and Recommendation

It seems appropriate for representatives of the legislative branches of government to call for preserving prime farm land; it may also be appropriate for top level members of the executive branches of government. However, it is not appropriate and in fact counterproductive for similar appeals from the scientific community without clearly delineated criteria for definitional purposes. Therefore, much of the energy and resources currently devoted to advocacy should be redirected to developing a land classification system useful to policy makers. Such a system cannot be solely technical—from soil science and agronomy—but must also include aesthetic, economic, environmental, and social variables. With such a system, the extramarket land allocation decisions can be made if politically feasible.

Rural Development, Poverty, and Regional Growth
(Eldon Smith, University of Kentucky, Chairman)

The Political Economy of Rural Development: Theoretical Perspectives

Clark Edwards

The rural and urban sectors of the economy are strongly interlinked. Growth in one sector impacts on the other. The growth process does not appear to be an equilibrium one in which marginal adjustments to opportunity costs eliminate disparities. The two sectors grow in an unbalanced way. So far, the economic advantages appear to have favored the urban sector.

The income gap between the rural and urban sectors continues to widen; rural income per capita is around three-fourths of urban income. The incidence of rural poverty is twice as high as urban poverty. Rural people have relatively limited access to health facilities, they are more likely than urban dwellers to live in substandard housing, and they attain lower levels of education.

Some conditions in the rural sector have improved recently relative to earlier decades as well as relative to the urban sector. Between World War II and 1970 rural to urban migration flourished, but since 1970 it appears to have reversed direction. Even so, the symptoms of imbalance continue. In a number of rural counties, social and economic opportunities are limited and outmigration continues.

This rural-urban imbalance is of national concern. It appears to have resulted in relatively densely populated cities and sparsely populated countryside. Rural development can increase economic efficiency, add to the nation's goods and services, and enhance the social and economic well-being of both the rural and the urban sectors.

A need has been felt by society to do something as a nation to improve the social and economic well-being of rural people. Some actions aim at improving efficiency and increasing aggregate well-being; others aim at equity and improving the distribution of income. Frequently, it is assumed that accelerating rural growth will, as a side effect, alleviate rural poverty. Empirical evidence raises doubts about this assumption.

A correct theory is not essential to problem solving. For example, 3,000 years ago, long before the laws governing motion in our solar system were sought, the Babylonians accurately predicted the apparent motions of stars and planets and knew when to expect an eclipse. Later, "incorrect" theories, in which it was assumed the sun is in orbit around a stationary earth, did not interfere with the accuracy of celestial forecasts. Now we have the "correct" theory, which jointly explains celestial motion and terrestrial tides. But the tide tables appearing in our daily newspapers continue to make no use of this theory. The rise and fall of tides is still predicted by empirical methods *sans* theory. No, a correct theory is not essential to describe and forecast events. This explains why so many people have accomplished so much of value in rural development while claiming that there is not an adequate growth theory.

But theory helps if we seek to understand events or to influence their outcome. We need to probe deeper into theories of change if we expect to understand the rural development problem and to seek public and private policies to ameliorate it. We have several growth theories, all of them partial, most of them helpful, but none complete. Together, they cast considerable light on rural development and can serve as guides to formulation of public policy.

Temporal and geographic variations in population, income, and employment have been

---

The discussants for this session were James Hite of Clemson University, David L. Debertin of the University of Kentucky, and Burl R. Long of Virginia Polytechnic Institute and State University.

Clark Edwards is an economist with the Economic Research Service, U.S. Department of Agriculture, Washington.

explained in a number of ways. Some explanations, upon examination, turn out instead to be descriptions of history. Other explanations assert that everything in the economic system is functionally interrelated and that one must analyze the total system before one can begin to understand how it grows.

This paper is organized around five key factors that have each been considered in economic literature as the basis for regional growth. Public and private programs and policies are in place that influence each basis. The five alternative bases for growth are increasing resource availabilities, advancing technology, expanding markets, conquering space, and building institutions. A considerable portion of the literature on economic development refers to none of these bases; such literature is descriptive rather than analytic. For example, the "stages of growth" literature describes growth over time, while the "diffusion" literature describes cross-sectional patterns of geographic change. Occasionally, an author will be found who discusses several, or possibly all, of the five bases for growth. In such cases, there is a tendency to consider only one of the five as "basic." When an author considers two or more of these five bases equally, we may classify that theory as a "systems approach."

Increasing Resource Availabilities

More input induces more output. Classical and neoclassical theories explain regional variations in growth by regional availability of land, labor, and/or capital. If there is a single most popular basis for growth in the literature of economics, beginning with Ricardo, surely it is the accumulation of capital. The theories of Harrod and of Domar treat capital accumulation as the key. Romans notes that, "from colonial times to the present day, statesmen and economists have assumed interregional capital movements to be a major variable affecting the economic growth and welfare of regions in the United States" (p. 3). Hirschman discusses many factors influencing growth but funnels them all through "the ability to invest" (p. 177).

There is a chicken-and-egg argument in the literature as to which is cause and which is effect in economic development—public or private capital. Hirschman favors a relative scarcity of public capital. Others argue that public capital in the form of schools, roads, hospitals, sewer and water, and industrial parks is causal.

Natural resources have been seen as a limit to growth since Malthus suggested that population is limited by the capacity to produce food. Ricardo viewed the supply of land as perfectly inelastic. Later, Turner attributed rapid growth in the United States to the availability of cheap land on the frontier. The modern view is that increased services from natural resources can be made available through applications of capital. Perloff and Wingo relate regional availability of natural resources to what they call "the geography of national economic expansion" (p. 191). They trace the role of deep water ports and agricultural hinterlands in the early agricultural period, of minerals during our industrial expansion, and of amenities of climate, land, coastline, and water during the "services" era.

Growth in population was seen by Smith as a stimulant to the wealth of nations. Now we find two views toward the role of population in economic growth. Hirschman, following Smith, says that more people add to both the incentive to consume and the capacity to produce, while Schumpeter says that more people may mean more mouths to feed and a reduced level of living. Migration tends to override the effects of natural population increase in regional growth. As with population, one finds two views: inmigration adds to the size of markets as well as the capacity to produce or inmigration is a burden adding to congestion and welfare rolls. Labor force participation tends to be smaller in slower-growing regions; growth depends on the proportion of the region's population at work. The quality of the labor force is as important as quantity.

The policy implication of neoclassical growth theory is: to develop rural America, we need to provide it with more resources. Rural development programs frequently emphasize capital. For example, the model implicit in the Rural Development Act of 1972 is: outmigration would be stopped, or even reversed, if more jobs were created; jobs are created if output is increased; and output is increased if plant and equipment are expanded. Therefore, supply rural areas with more public and private capital. Tax incentives and low interest guaranteed loans to plants locating in rural areas are further examples of capital accumulation policies.

The Departments of Agriculture and Interior operate natural resource development programs that increase the availability of energy, minerals, water, and agricultural land. Friedmann noted that, "until the late 1950's, most people understood regional planning to mean the purposeful development of a region's natural resources" (p. 792), a view much narrower than is held today.

The recent emphasis of public and private population programs has been one of limiting birth rates. The Labor Department recently revived its experimental program to relocate people from areas of limited economic opportunity to areas with greater prospects. Labor force expansion programs equip people with specific job skills and/or with freedom to join the labor force.

Advancing Technology

Advancement through science and innovation is probably the most widely held basis for growth outside of economics, that is, among historians, philosophers, scientists, anthropologists, and others. The idea is also one of the oldest. In Sophocles' *Antigone*, the chorus comments that man has always helped himself and faces no future helplessly. He has learned to cross the sea in a winter storm, to plow the fields with mules, to snare birds, net beasts and fish, ride horses, provide shelter from cold and rain, and has even taught himself a language. Each of these advances led to an increase in the availability of things valued by man per unit of input.

Among modern economists, technology follows resource availabilities as the most often cited basis for growth. As Leven put it, "the driving force behind economic growth is productivity" (p. 80). Kuznets asserts "modern economic growth is distinguished by the fact that the rise in per capita product was due primarily to improvements in *quality*, not quantity, of inputs" (p. 491). Schumpeter said "development consists primarily in employing existing resources in a different way, in doing new things with them" (p. 68).

Technological advance concerns the productivity of labor as well as capital. Kunkel sees human development and the analysis of behavior as the basis for social change and economic growth. Schultz finds "a strong connection between the investment in human capital and the secular rise in the economic value of man" (p. 1113). Much of economic growth, says Schultz, cannot be explained by additional inputs of conventional types.

The policy implication of advancing technology as a basis for growth was illustrated during the 1960s by extensive public and private efforts to modernize rural plants, provide on-the-job training, reduce underemployment, and improve productivity. These efforts were abetted by federal programs to provide orientation, counseling, education, skill training, and other services to help qualify individuals. Productivity gains in the nonmetropolitan sector during the 1960s were greater than in the metropolitan sector, which helps explain the recent surge in rural growth.

Expanding Markets

Expanding the market for products of a region as a basis for growth has been traced by Spengler at least back to the mercantilists. The idea has been suitably captured in the following quote from a presidential advisory commission: "The ability of a community to grow depends upon its success in attracting additional spending within its confines—whether this be personal consumption, business investment, or government outlays" (Advisory Commission on Intergovernmental Relations, p. 37). The commission might well have added "net exports." Expanding rural markets may include exports to abroad, such as wheat to Russia; shipments to urban areas, such as textiles; or local consumption. Each region can grow while the nation as a whole grows.

Alternatively, emphasis may be on expanding the derived demand for local resources by, for example, industry location. This view is frequently coupled with the notion that regional growth is a zero-sum game; growth in one region must be at the expense of another. Such thinking leads to antipirating clauses in rural development legislation.

The idea that nations or regions can mutually gain through exchange was developed by Ricardo and by Mill. Comparative advantage, which is based not only on markets but also on internal resource availabilities, technology, and economic structure, implies that two trading regions can produce a greater total product than if there was no trade.

The potential for economic gain through international or regional trade can be exploited by residents of one region, at the expense of other regions, through increased exports or reduced imports. Economic base theory is a popular version of this narrow view. Growth is explained in terms of the market for a region's main export or staple. Total employment is allocated between base industries, in which the product is destined for export, and nonbase residentiary industries, in which the product is destined for local use. The critical assumption is that residentiary employment is a function of base employment. It follows that total employment grows as base jobs are created through expansion of net exports. Greenhut argues that the unfortunate and widespread belief that export base is extremely important has helped promote abandonment of classical economic principles. He finds the internal structure of a region important and calls for "a return to the classics" (p. 461).

Keynes revived the idea of Malthus and others that aggregate demand is the basis for growth. He recognized both internal and external sources. Keynes was concerned with the short run. He asserted that at full employment his general theory is the same as neoclassical theory. Short-term growth of a partially idle economy may depend on expanding aggregate demand, as Keynes suggests, but long-term growth may depend on expanding capacity. This view was expressed by Borts: "Over long periods of time, it appears that the demand hypothesis does not play a role in explaining regional economic growth . . . supply factors appeared to have been very important in explaining regional growth differentials" (p. 133).

Expanding aggregate demand is a vague and general notion; some theorists, such as Rostow, demand more precision and seek to locate the origin of growth in a single sector. This turns attention toward a leading industry. Perroux emphasized that some industries are driving forces in an economy; the type of industry varies from region to region. This agrees with the views of Hirschman and Myrdal that growth is inherently not balanced. Some elements necessarily change prior to others and in different proportions. These disequilibrium views raise concern for conflicts between efficiency and equity.

The policy implication of market expansion as a basis for growth is illustrated by federal programs to increase or maintain exports to abroad. Many commodities benefiting from these programs are produced in rural areas. Increased government purchases or reduced taxes are frequently justified, in part, by their contribution to aggregate demand. State and local product promotion in the United States tends to be operated at the state or local level. Most market expansion programs are in the private rather than public sector.

Conquering Space

Geographic space has been overlooked as a dimension of economic space in much of economic theory. This was so even though Smith and Ricardo recognized the importance of location in their rent theories, and Von Thunen developed his seminal approach to location of economic activity some century and a half ago. During the last three decades, spatial relationships have been incorporated in economic analyses and are seen by some as the basis for growth. Richardson observed, "Growth rates vary with location . . . because the relative strength of agglomeration and dispersion factors alters over space" (p. 2).

Integration of location theory with the conventional theory of the firm leads to the conclusion that equilibrium in the space economy requires that marginal cost equals marginal revenue in spatial as well as nonspatial dimensions. Uncertainty tends to send plants to the obvious or safe location—the center of the market. Webber shows that this may result in concentrated patterns that would be suboptimal under perfect knowledge. From society's point of view, the profit-maximizing location of a plant need not be optimal with respect to, for example, providing jobs to residents of a slower-growing region.

Von Thunen had in mind a central place with agricultural hinterlands and was concerned with the spatial pattern of a region. Weber emphasized the importance of agglomeration. Christaller's central place theory incorporated the idea that the growth of a city depends on specialization in various functions and on the demand of the region it serves. Losch studied spatial relationships for noncompetitive markets and extended the analysis to general location patterns and the network of economic regions.

The central place provides jobs, shopping, and cultural attractions to residents of the entire region. The hinterland, on the other hand, provides rural-oriented goods, such as food, textiles, minerals, and timber products. It also provides workers to fill central place jobs and may provide residential and recreational sites and sites for decentralization of central place activities. The economic fortunes of a region depend on the interplay between its central place and hinterland as well as on its relationships with other regions.

The theories of Von Thunen, Weber, Christaller, Losch, and others suggest that a nation can be delineated into a number of regions, each with a central place and a hinterland. A hierarchy is formed in which some regions are fairly urban in character and provide central city services to others. Some regions are fairly rural in character and perform hinterland functions for the more urban-oriented regions. Commuting and trade patterns suggest that the United States is probably comprised of some 500 functional economic areas that are relatively closed with respect to trading and commuting. About half of these contain cities larger than 50,000 persons; the other half are relatively rural.

Prospects for development of a particular rural area depend in part on where it is located. A rural community in the hinterland of an urban-oriented region has different prospects for growth than a community in an isolated, rural-oriented region. Alonso suggests that "the path of fastest economic growth may imply sharp geographic inequalities concentrating wealth and power in a few advanced centers and condemning backward areas to lengthy periods of poverty" (p. 2).

The policy implication of spatial relationships as a basis for growth is illustrated by multicounty programs and by growth center strategies. Substate planning and development districts have been delineated for 527 districts in forty-five states for the purpose of coordinating federal programs. Other multicounty efforts, some of which are coterminous with substate planning and development districts, include councils of governments, economic development districts, resource conservation and development districts, and nonmetropolitan districts funded by the Department of Housing and Urban Development.

A number of federal programs, particularly those operated through the Economic Development Administration, accounted for spatial relationships through growth centers. The concept of a growth center is not so clearly defined as that of central place. Some authors apparently use the term to mean any urban place that grew recently. Hansen associates growth centers with places in excess of 250,000 persons. The Economic Development Administration's programs recognized smaller centers and were based on the theory that "accelerating the creation of employment opportunities in or near such centers was believed the most effective and timely approach to providing jobs for residents of neighboring depressed areas" (U.S. Dep. Commerce, p. 10). This became popularly known as the "trickle-down" theory.

The U.S. Department of Agriculture inverted this theory when it encouraged plant location in the hinterlands. Weitzell explains: "The basic theory underlying these . . . efforts is that rural industry can bring about sufficient economic growth to resolve problems of unemployment, underemployment, and low income. . . . the growth center concept should not be overemphasized. . . . modern communication and transportation . . . make decentralized development entirely practical" (p. 6). In contrast to the Economic Development Administration's trickle-down approach, this seems to imply that beneficial effects would trickle up.

The multipliers in the above approaches are variable and not too reliable according to subsequent evaluations by Milkman, Stewart and Benson, and Lewis and Prescott. Beneficial effects claimed from both the trickle-down and trickle-up theories have not been substantiated as a general rule. Programs aimed directly at a target group appear more likely to succeed than those that seek to accomplish their ends indirectly through a multiplier effect. An explanation of how to conquer space will likely never be arrived at by reducing spatial theory to simple multiplier relationships. The problems of communication and transportation over space, and their contributions to growth, are proving to be more complicated than that.

Federal programs to enhance transportation have had considerable impact on rural development. Interstate highways have frequently been cited as a prime example, but we must not overlook programs related to air, rail, and water transportation. Highway development policies have been associated with the rapid

suburbanization of major cities and concurrent depopulation of both the central cities and the more distant countryside.

Building Institutions

Man is a goal-oriented animal. He may seek to reach his goals as an individual or as a member of a group. A group of individuals organized to attain a goal has been described as an institution. Institutional arrangements can affect economic development.

In neoclassical theory, institutional arrangements to organize firms and households are assumed to evolve as needed to absorb increased demand, accumulate resources, innovate, and conquer space as firms and families take appropriate actions to reach individual goals in the growing economy. Samuelson has shown that this view implies that man need concentrate only on private firm and household goals; the free market will automatically organize firms and households into an efficient, equitable economy.

Contrary to the view that requisite institutions will always materialize as needed is Baran's view that "economic development has always meant a far-reaching transformation of society's economic, social, and political structure of the dominant organization of production, distribution and consumption" (p. 3). Authors with a relatively long-term view tend to pay far more attention to institutional change than those taking a short-term view. Perhaps this is because the pace of change in institutions is relatively slow and the impact negligible over shorter time periods.

North and Thomas find "efficient organization is the key to growth" (p. 1). They discuss the institutional change involved in the delivery of public goods, such as justice and protection; growth of the money economy; transactions; specialization; and, particularly, institutions related to private property rights.

There are several situations in which purposive institution building may be required to produce desired economic development.

(*a*) A competitive equilibrium situation may be held to be inequitable. An example may be taken from Keynesian economics where institutions are created to intervene with fiscal and monetary policies.

(*b*) The economy may not be converging on an equilibrium but may be observed, in fact, to be diverging. Myrdal identified what he called the principle of circular and cumulative causation as a cause of inequity, with the rich getting richer and the poor getting poorer. Institutions may be built to guide or redirect various strands of the economy toward a socially acceptable balance among diverging sectors.

(*c*) Monopoly power may override competitive forces. Antitrust legislation is an example of institution building to express dissatisfaction with the invisible, guiding hand.

(*d*) Uncertainty, or imperfect knowledge, may interfere with competitive choice. Schmid sees a relationship between insitutions and uncertainty. He states a need for research on how institutions might perform a hedging function. Imperfect knowledge creates the need for institutions for research, education, extension, market news, and insurance.

(*e*) Market failure may occur for public goods, goods that are consumed jointly by two or more users. Buchanan has shown that the rules for optimizing behavior are different for public goods than for private goods. Institutions required to deliver services of public goods, such as hospitals, roads, and symphony orchestras, need not evolve spontaneously, as market institutions for private goods do; sometimes they must be built purposively. Interjurisdictional conflicts among local governments are symptomatic of the institutional breakdown associated with market failure.

(*f*) Not all conflict is resolved in the market. Roboch describes how nonmarket institutions may cope with conflict and promote regional growth. Neale points out that goals of acquiring and exercising power came into conflict with economic goals in India. Ladd cites a conflict between parochial and cosmopolitan goals in Connecticut. Okano discusses conflicts between indigenous residents of a region and newcomers. Strong outlines a conflict between landowners along the banks of Brandywine Creek, who stood to gain from economic development, and residents of nearby townships, who preferred the status quo.

Policy implications of institution building as a basis for growth can be classed into two groups: those that facilitate other bases for growth discussed above and those that serve vital functions independently of those bases. Examples in the former category include financial institutions to provide capital, manpower training institutions to increase productivity, news services to expand markets, and zoning regulations to control spatial activity.

Other programs have resulted in formation of institutions for regional planning, identification of local leadership, and establishment and valuation of local ends. These institutions promote multicounty organizations and employ local coordinators to work with lay leaders in establishing priority needs and carrying out plans for community development. There is an emphasis on institution building to deliver public goods, such as health and education, to rural areas.

Conclusion

Five theoretical bases for growth have been considered. Policies for which laws and appropriations exist and which are directed toward each of the several bases, thereby influencing regional growth and rural-urban balance, were noted. The question is: if we know the bases for growth, and if we already have policies acting on each basis, why do the problems persist?

Economic theorists have not integrated the five bases conceptually. In fact, defenders of one basis frequently skirmish with defenders of others as to which favorite is really the key to growth. The neoclassical marginalists, the Keynesians, the regionalists, and the institutionalists continue to regard one another as misguided.

Policy makers have not waited for a fully developed growth theory before implementing programs that influence growth, evidence that a correct theory is not essential to problem solving. However, they have failed to integrate their several policies.

Most government programs that have impact on regional growth and rural-urban balance are created and operated with other ends in view. Adverse side effects on the rural economy may go unnoticed because such effects were not the purpose of the program. Noticed or not, the effects occur; government programs can unwittingly contribute to the problem.

Government programs that are explicitly focused on rural development tend to be fragmented rather than integrated. With each agency operating such programs, single purpose thrusts are focused on specific targets. Such targets may be met, but it may not be the responsibility of the persons involved to be aware of unintended side effects.

Economic theorists need to look again at theories that explain change over time and space. They need to provide policy makers with a more clear understanding of the disparate effects of policies. Policy makers need to be more clear about rural development goals and about the impacts of existing and proposed legislation and appropriations that act on the several bases for growth.

We have the theoretical and practical potential to develop rural areas and achieve rural-urban balance, but we have not yet learned to put it together.

Rural Development Research: Conceptualizing and Measuring Key Concepts

J. Dean Jansma and Frank M. Goode

In a paper presented at the 1974 annual meetings of the American Agricultural Economics Association, Back argued that "the unsatisfactory state . . . of rural development policy reflects in part either an inadequate or inaccessible knowledge base" (p. 1125). Basically, he was arguing that research in rural development had not provided policy makers with the information necessary to formulate a cohesive national rural development policy. In addition, he argued that the institutional arrangements for conducting rural development research have helped create this knowledge gap.

Edwards suggests an alternative reason for the knowledge gap. He argues that the rural development researcher is faced with a host of partial theories of economic development but has no general theory to guide his empirical work. Although Edwards does not make the point explicitly, an implication is that the knowledge gap will remain until a comprehensive theory of rural development is forthcoming.

In this paper, a third reason for the continued existence of a knowledge gap is suggested. It is argued that rural development researchers have not done a good job of operationalizing and measuring the relevant concepts in the rural development process. The institutional arrangements for conducting rural development research can be improved, but additional conceptual work is needed. Significant progress can be made in bridging the knowledge gap given existing institutions and conceptual frameworks if more resources are devoted to operationalizing and measuring the relevant concepts. The objective of this paper is to present suggestions concerning how one might improve the operationalization and measurement of rural development research.

In his 1975 presidential address, Bonnen provided a useful framework for discussing these issues. He argued that a good information system must satisfy three conditions. First, it must have a good conceptual base. Second, special attention must be given to operationalizing the concepts; that is, the phenomena being measured in reality must be highly correlated with the concept. Third, the real world phenomena involved must be measured accurately. Each of these three conditions will be addressed below in the context of rural economic development.

Conceptualizing Rural Economic Development

In this section Bonnen's first criteria, namely, the conceptual basis for rural economic development, is discussed. In an attempt to narrow and focus, rural economic development is assumed to be reflected by increases in employment and/or income. The major determinants of income and employment in a given economic space (a rural community) are the quantity of the goods and services sold to and inputs purchased from outside the community and the extent to which dollars entering the local area are "recirculated" within the local economy. Conceptually, the economic development of an area involves explaining the economic forces affecting the geographical location of firms producing goods and services or sales outside the area and the complexity of the local economy in terms of retail trade and service activities.

Edwards has surveyed and classified the theoretical literature that addresses these two questions and concludes that the suggested determinants of economic development are (*a*)

J. Dean Jansma is a professor and Frank M. Goode is an associate professor of agricultural economics, Pennsylvania State University.

Paper No. 5169 of the Pennsylvania State Agricultural Experiment Station. The authors wish to acknowledge the contribution of James Fink, now with Chilton Research Services, Philadelphia, for his contribution to the research work discussed in this paper.

supply, (*b*) demand, (*c*) space, (*d*) institutions, and (*e*) technology.

The difficulty is that little if any of the literature explicitly addresses these five factors simultaneously; however, the common theme in this literature is that private firms locate where they can maximize profits. The concept of spatial profit maximization can be used to integrate the five types of variables used in location theory for explaining the action of individual firms.

Briefly, an example of this integration is as follows. In the context of rural communities, it is realistic to assume that firms are price takers in the output market. The firms will be primarily concerned with the transportation cost to its market (spatial factors) because the market price net of transportation cost determines the demand curve faced by the firm (demand factors). On the other hand, the firms may be large enough to influence the price of the inputs they purchase in the rural communities. Thus, the supply of locally purchased inputs is of prime importance to a prospective firm (supply factors). In addition, a prospective firm's profits can be sensitive to state or local laws (institutional factors) regulating permissible, productive processes (technological factors).

In addition to economic factors, issues such as informal contacts and community attitudes toward economic development may be important in the firm's location decision. Rural sociologists are trained to deal with these issues, and their input is needed if our analysis of the rural development activities is to be complete.

In essence, the underlying assumption of location theory, as detailed in the five types of factors suggested by Edwards, is spatial profit maximization. This, it seems, is a widely accepted theoretical framework that provides an adequate base for empirical work concerning the location of firms.

The second issue concerns the extent to which the income generated by the exporting firm is "recirculated" through the local economy. The essence of this issue is what types of service and trade activities are located in the community. Conceptually, the location of these types of activity is similar to export activities. The issues are treated separately here because of the traditional separation in empirical and theoretical works. If asked the question, What will be the secondary income and employment effects of a new plant?, the typical response would be: conduct an input-output or export base study. In many cases this may be appropriate; however, in rural communities a new plant may result in significant changes in the local economic structure and trade patterns. Since trade patterns and economic structure are assumed not to change in the typical input-output and export base approaches, these techniques are not directly applicable. Fortunately, Losch (and to some extent Christaller) has provided a solid conceptualization that explicitly addresses community economic structure and trade.

One can argue that there is an adequate theoretical model to explain the geographic location of economic activity. Though it is in need of improvement, this model does satisfy Bonnen's first criterion.

Operationalizing Key Concepts

The general theoretical model outlined above has been of limited usefulness to policy makers because the relationships in the model have been subjected to very limited empirical testing. One of the major reasons for this is that the concepts (or variables) in the model have not been carefully operationalized and measured (Bonnen's second and third criteria).

The general model suggests that the supply of labor at a potential plant site affects the profit function of a firm. Empirical information indicates that many of the firms that locate in rural areas are labor intensive. Thus, one can hypothesize that there should be a strong positive relationship, *ceteris paribus,* between available labor supply and the location of new firms. To test this relationship one must, among other things, operationalize and measure the concept of "labor supply." An example of how to operationalize and measure this part of the general theoretical model is discussed in the remainder of this paper.

How can the concept "supply of labor" be operationalized? The optimum would be to develop estimates of the "labor supply" function at alternative points in space. However, this is unwieldy if not impossible. An alternative is to employ an adaptation of the method used by firms to test the availability of labor at potential sites, namely, a "blind" advertisement soliciting job applications. As a rule of thumb a firm should obtain three to four applications for each position. In terms of the gen-

eral model, the firm's managers are attempting to establish that they are facing a highly elastic supply of labor. If firms make decisions based on this operationalization of the concept of labor supply, then it can also serve as a starting point for research.

In essence, the firm's blind advertisement is asking the question: If we create a specific number of jobs of a particular type at a point in space, how many additional people in the surrounding area will participate in the labor force and will commute to the new job? The three central issues involved are commuting behavior, labor force participation, and the type of jobs being created.

The first of these issues, commuting behavior, has received some attention in urban areas but little if any in rural areas. However, there is a substantial amount of literature in the general area of economic and social interaction over space. The most popular methodology in this area is the gravity model that holds that the interaction between two points in space is positively related to the mass at the two points and negatively related to the distance between the points. Applying this general model to rural commuting behavior results in a regression model:

$$(1) \quad V_{ij} = a + b_1 ELF_i + b_2 EMP_j - b_3 D_{ij},$$

where V_{ij} is volume of work trips from i to j, ELF_i is employed labor force at i, EMP_j is employment at j, and D_{ij} is distance between i and j. If such a model could be empirically implemented and the relationship were strong, we would have a method to predict commuter flows in rural areas.

The second issue (labor force participation) has received some attention in urban areas but very little in rural areas. Labor force participation is believed to be a function of the social and economic characteristics of the population. However, in the rural setting, labor force participation may depend on the geographic access to employment. A regression model of the following nature could be used to investigate labor force participation rates:

$$(2) \quad LFPR_i = c_0 + c_1 GAE_i + \sum_{k=2}^{m} c_k SEC_{ik},$$

where $LFPR_i$ is labor participation rate in area i, GAE is geographic access of people in i to employment opportunities, and SEC_{ik} is social and economic characteristic of people in i. Again, if such a model could be empirically implemented and the relationship were strong, we could predict labor force participation rates.

These two regression models could be used in pursuing the original question of how to operationalize the concept of labor availability. For example, if a firm locates in area j, the geographic access to employment for area i is increased by some amount ΔGAE_i. From equation (2) the predicted change in labor force participation will be $c_1(\Delta GAE_i)$. The change in employment in area i is the change in the labor force participation rate multiplied by the population in area i: $c_1(\Delta GAE_i)(Population_i) = \Delta ELF$. Substituting this estimate of ΔELF into equation (1) yields an estimate of the change in the number of people commuting from i to j, namely, $b_1 \Delta ELF_i$. If this procedure is repeated for all of the areas surrounding j and the results summed, we have an estimate of the change in the number of people commuting to area j as a result of the new firm.

The regression models, equations (1) and (2), can be improved by using more detailed employment categories. For example, labor participation rates depend on an interaction between the social and economic characteristics of the people and the geographic access to specific types of employment, not employment in general. Likewise, commuting behavior is conditioned by occupational characteristics interacting with specific types of employment. Once the specific types of employment are incorporated into the model, the three issues mentioned above, type of employment generated, labor force participation, and commuting behavior, are included in the procedure for estimating labor availability. We now consider methods of empirically implementing this procedure.

Measurement of the Labor Availability Concept

The operationalization of the concept of labor availability discussed above involves substantial data requirements. In general, data requirements are a major reason why rural development researchers have done a poor job of operationalizing concepts. They have been unwilling or unable to collect the data necessary to empirically implement good operationalizations of concepts. In this section examples of how some of the measurement problems can be overcome are provided.

The first issue involved in the opera-

tionalization of labor supply was commuting behavior. A study by Fink of the trip distribution process in two specific rural areas provides an important first step for analyzing the commuting question. His analysis provides insights into the factors underlying the trip-making behavior of individuals in rural areas. The empirical model designed to measure the volume of trips between an origin and a destination was based on (*a*) the employed labor force at the origin, (*b*) the level of employment at the destination, (*c*) the commuting distance, and (*d*) the presence of intervening or competing employment alternatives between the origin and the destination.

The study areas were two rural counties in Pennsylvania. The units of observation were the minor civil divisions (MCD's)—townships and boroughs—in these counties. Imaginary points of trip productions (population centroids) and trip attractions (employment centroids) were established for each MCD (figure 1). These centroids were derived in a manner analogous to that of determining center of mass. Trip volumes moving between MCD pairs were calculated from school census data obtained from school districts in each of the two counties. (See the Fink study for complete description of the data sources referred to in this paper.) A 30 × 30 work trip distribution matrix was compiled for one county and a 26 × 26 matrix was prepared for the other, so that there are 900 MCD origin-destination trip pairs in the first county and 676 trip pairs in the second. Data on the employed labor force were obtained from the U.S. Census of Population (Fink). Employment data were obtained from Dun and Bradstreet data files (Fink). The commuting distance used for each trip pair was the straight-line distance between the population and employment centroids.

The construction of the intervening opportunity (IO) and competing opportunity (CO) variables was as follows. If the employment centroid for a MCD fell within the intervening opportunity triangle (figure 1), that MCD was taken to be an intervening opportunity. The IO variable was defined as the employment at the destination divided by the sum of the employment at all intervening opportunities plus the employment at the destination. Thus, the IO variable takes on a value of one when there are no intervening opportunities and approaches zero as the number of intervening opportunities increase. The competing opportunity variable is constructed in a similar manner using the remaining area in the circle in figure 1.

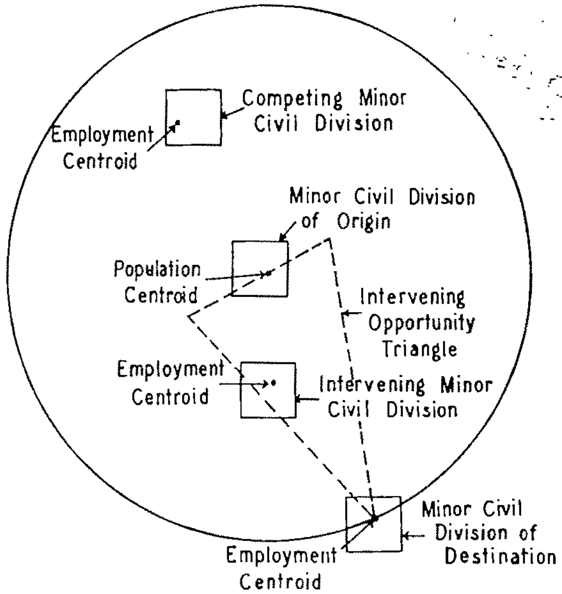

Figure 1. Spatial arrangement of population and employment centers

The basic approach followed in developing the trip distribution model was to estimate various models utilizing the data from the first study area. After a final trip distribution model was developed, it was tested with data from the second study area. The first model estimated was a crude three variable linear model that used commuting distance and aggregate measures for the activity systems of the origin and destination. The results in terms of the "signs" of the coefficients were consistent with those hypothesized. However, the low R^2 of the model indicated that a more complex model that takes account of the influence of alternative employment opportunities would be required to explain trip distribution. Thus, a new three variable model was developed in which the intervening and competing opportunity variables were entered into multiplicative interaction with the total available labor force at the origin and with the aggregate employment at the destination. Commuting distance was the third variable. The R^2 of this interaction model was 0.88. The results of this model when compared with those of the crude model suggest that trip distribution is conditioned by alternative employment opportunities.

Two additional sets of runs were made modifying the interaction model. In the first set of

runs, the IO and CO components were selectively removed from interaction with the aggregate employment at the destination. The resulting model appeared to be just as adequate for determining the distribution of work trips, i.e., R^2 remained essentially unchanged. Thus, the variation in trip volume explained by destination system interaction is negligible.

In the final set of runs, the IO and CO components were selectively removed from interaction with the total available labor force at the origin but retained with the destination. This reduced the R^2 from 0.88 to 0.26. The results of these runs indicated that the interaction between the origin activity system and the alternative employment opportunities was extremely important to determining work trip distribution. In fact, the results of all of the analysis indicate that the interaction of competing opportunities and intervening opportunity and the available labor force is the single most important factor determining the distribution of work trips.

From those runs a three variable model was selected as the final model. The variables include the available labor force at the origin in interaction with the IO and CO variables, the commuting distance, and the aggregate employment at the destination.

The final step of the analysis was to test this three variable model on a data set from the second study area. Substantial differences were found to exist in the distance and employment parameters of the models for the two areas. However, the interaction of the origin activity system and the IO and CO variables was even more pronounced in the second study area. Hence, it was concluded that the differences in the coefficients on the other variables for the two study areas were probably due to basic differences in the occupational structures in the origins or difference in the economic structure at the destination. Two additional studies—one on the characteristics of the labor force at the origin and a second on the economic structure at the destination—are now being undertaken.

A study designed to develop more specific and accurate measures of the labor force available at the origins is based on primary data from a mail questionnaire. The first objective of the study is to empirically estimate the relationships between various factors in a specific MCD and its labor force participation rate (LFPR). Further, the procedure is designed to permit comparisons of the LFPR for residents in various occupational categories. Implicit in this first objective is the determination of the relationship between the occupational structure and the trade-off between increases in income (wages) and commuting distance.

The second objective of this research is to integrate these results into the trip distribution model. Effectively, this will permit one to determine with a great deal more confidence the specific factors that affect the spatial supply of labor in these rural communities. One would hypothesize, for example, that the blue collar service worker would probably have a quite different set of factors explaining the economic space in which his services are available than would the college professor who "wants to get away from it all and probably even pretend he's a farmer." Again, the emphasis in this study is on the supply of labor as one component in the spatial profit-maximizing function.

The second follow-up study will emphasize certain aspects of the spatial demand for labor at the employment destination. The objective of this research will be determined by what occupational-employment combinations are most relevant in terms of labor force participation and commuting. The basic task will be to develop employment categories. The employment variable in the commuting and labor force participation models will be replaced with a set of variables reflecting employment levels in the various "disaggregated" categories. In addition, this study, using the tenants of central place theory, will help identify basic trade patterns that are hypothesized to be related to trip-making behavior.

These three studies represent our attempt to empirically implement the operationalization of the concept of labor availability. We are aware of several shortcomings of the procedure but believe the measure of labor availability to be superior to commonly used measures such as county unemployment rates. The latter are poor operationalizations and unemployment statistics in rural areas are poor measures.

Summary

The position taken in this paper is that rural development research should and can be compatible with the criteria outlined by Bonnen for good information systems—a satisfactory

conceptual base, operationalized concepts, and accurate measurement.

The location of economic activity, excluding location decisions by the public sector, is basically explained by a spatial profit-maximization model; that is, traditional micro theory, with particular emphasis on spatial input and output prices, provides a less than desirable but adequate conceptual base.

Labor inputs as a spatial supply factor—including the determination of the labor force participation rate—were discussed as an example of the implementation of Bonnen's operationalization-and-measurement criteria.

There is a knowledge gap that needs to be fulfilled in rural development research. But, one could argue that "matches and candles" are available so why curse the darkness.

Analytical Institutional Economics and Rural Development Research: Opportunities for a New Synergism

Larry C. Morgan

During the past five years, the popularity of the rural development movement has waned considerably. The reasons for diminished rural development support among both public officials and researchers are numerous and complex, but the failure to adequately incorporate institutional change into research on community resource allocation must be regarded as one of the movement's major disappointments.

The economist's traditional inclination to study community decision-making processes, given a particular institutional setting, has resulted in a wide variety of powerful, market-oriented economic tools being applied in rural development research without much demonstrable evidence of success. Any researcher who has attended a public forum on rural development research results understands local citizens' frustrations with applied economic analyses where few, if any, parameters can be manipulated in support of community objectives.

A reorientation of perspectives is needed to bridge the gap between the market-oriented approach to rural development by most economists and the emphasis on the economic basis of collective action by analytical institutional economists. Both groups can make valuable contributions to rural development by synergizing their respective competencies in the development of a more precise theory of institutional change.

The Legacy of Oversimplification

Rural development research has suffered from the inertia of past approaches to rural development problems. Many of the initial perceptions of problems and analytical approaches to these problems were oversimplifications that have too often become a part of the rural development conventional wisdom.

The Problem of Rural Outmigration

Unfortunately, the publicity that influenced enactment of the Rural Development Act of 1972 portrayed outmigration and community decline as the major problems facing rural America. Countless public officials insisted that outmigration would have to be stopped or reversed if the quality of life in rural areas was to be improved. Not only has the wisdom of that assessment of problem priorities been questioned but it detracted attention away from the more fundamental and obstinate problem of conflicts among private and collective actions in small-area economies.

While rural development efforts were being organized to cope with rural decline, outmigration was apparently less severe than the popular impression. A new study of nonmetropolitan population patterns concludes that a majority of small towns and cities were not losing population during the 1950–70 period (Fugitt and Beale). Since 1970, metropolitan population has grown at a slower rate than nonmetropolitan population, leading to another popular, though oversimplified, impression of rural optimism and metropolitan pessimism.

The recent reversal of migration rates in many rural areas has been due almost entirely to factors other than rural development efforts. If increased rural industrialization and energy resource exploitation had not occurred, a "stop outmigration" policy would have further impoverished rural areas. Instead, a simulation study of seventeen popular rural development strategies indicates that a desirable strategy should be multifaceted, in-

Larry C. Morgan is an assistant professor of agricultural economics at Texas A&M University.

cluding a combination of job creation, labor force expansion, and improved resource productivity and capital utilization (Edwards and DePass). Such a strategy requires a major program to develop alternative institutional arrangements to assist where market processes have been unsuccessful.

The Importance of Self-Interest

The shortcomings of rural development efforts seem especially acute when compared with the contributions of economic research to commercial agriculture. But that comparison, however popular, is not an appropriate basis for evaluation.

Microeconomic theory holds a special reverence for the assumption that people will pursue their self-interest. In a market economy, self-interest is obviously a central feature of the resource allocation process. Beyond firm and household units, group action often supersedes the role of self-interest in community resource allocation processes. The allocation of public goods raises problems of free riders and technical externalities that are beyond the firm or household's control. Even the voting process often obscures individuals' community preferences and permits or invites the intervention of political institutions that may discourage the individual pursuit of self-interest to the detriment of community welfare.

Rural development research has been strongly influenced by the accomplishments in production economics. Studies dealing with the optimum size of cities, regional approximations of firm growth models, and the demand for public services are of limited value if market-oriented models are used with no provision for the influence of public goods effects. It is not much comfort to officials to learn that their town is either too small or too large in terms of per capita public service costs unless they have a method of comparing alternative schemes to achieve a size that meets the community's goals.

Institutional Change as an Economic Process

Criticism of the economist's failure to incorporate institutional change in the economic process is not entirely fair. The long-standing plea for a theory of institutional change remains essentially unanswered. I would expect sociologists to be leading the search for a concise theory, but recent writings by some of their leading scholars offer little encouragement (Blau). Among economists, the so-called "neo-institutionalists" are not much more advanced than the sociologists (Grunchy).

Davis and North have made a valuable contribution to institutional economics. The central role of self-interest in their theory of institutional change should help justify the study of institutional change as an economic process. Their theory is closely related to market activities and consequently may not attract much attention from noneconomists. The challenge of research in institutional change is to develop a theory that applies to both market and nonmarket activity.

Economic Rationality and the Institutional Setting

Hirschman's treatment of exit and voice offers a unique approach to the study of institutional change. Exit from a firm or organization is viewed as a traditional economic process. Failure to correct the cause of exit ultimately threatens the firm with extinction. Voice consists of efforts to modify the firm or organization without resorting to anything so drastic as exit. Voice might be classified as a noneconomic activity, but I regard it as activity to reduce uncertainty, extend or modify property rights, reduce or shift transaction costs and liabilities, and acquire rents, windfall gains, or other pecuniary or nonpecuniary benefits.

Voice falls within the scope of economic rationality since even random or nonmaximizing behavior conforms to basic economic theorems in response to changes in production and consumption opportunity sets (Becker 1962). Voice is thus a part of the institutionalizing process, an economic process where the "sets of ordered relationships among people which define their rights, exposure to the rights of others, privileges, and responsibilities" are modified to permit new production and consumption opportunities (Schmid, p. 893). This view of institutionalization rejects Georgescu-Roegen's argument that economics is not a theoretical science because the content of its fundamental principles is determined by the institutional setting (Georgescu-Roegen, p. 324).

The New Consumer Economics

The notion of "noneconomic" activity has been revised by the works of Becker (1965) and Lancaster on the economics of time. Any activity requires an allocation of time, which has an opportunity cost in some other use. Such a noneconomic institution as the family results from the allocation of time to maintain and enforce its working rules. The willingness of society to allocate time for such purposes ultimately reflects part of the social value of that institution.

The nonpecuniary nature of many activities does not justify classifying them as noneconomic. The task of measuring time costs (value) is formidable, but it promises to explain in economic terms why actions are taken to create, modify, or abandon institutions.

Information

Members of institutions or social movements frequently have to influence some other institution or individual in order to successfully establish working rules (Breton and Breton, Goldberg). The creation of influence involves not only time but the production and distribution of special types of information that is allocated according to its marginal value and marginal cost.

The cost of information is therefore an indirect measure of the value that members of an institution place upon either preserving it in its present state or modifying the working rules to enjoy new production or consumption opportunities. Lobbying efforts by the National Rifle Association against antifirearm laws are an ample demonstration of the great value its members place on the right to own firearms.

The Bureaucratic Perspective

Organizations form to gain the benefits of collective action. The bureaucracy, contrary to its popular image of inefficiency, is highly efficient at protecting itself from budget cuts (Downs, Niskanen). Government bureaucracies are particularly adept at lobbying to preserve their organizations' missions and their members' jobs. The bureaucrat's resistance to funding cuts is an economic action guided by self-interest, but it often results in political institutions being prolonged after they cease to serve a useful public purpose. The political institutions that have been created to support rural development are thus likely to drift into obsolescence as the bureaucracy's control and influence grow and emerge as impediments to further progress.

An Institutional Research Agenda for Rural Development

Among the many institutional problems that merit the attention of rural development researchers, those that pertain to political institutions created to support rural development are emphasized here. The premises that were cited to justify the creation of new laws need careful examination to determine whether they are still valid. The role of interest groups in lobbying for or against rural development legislation should be examined to estimate the value of their efforts to change the working rules. The bureaucracies administering the new laws should be scrutinized for evidence of atrophy and obsolescence of mission.

Area Planning and Development Districts

Multicounty planning districts have been created under the provisions of the Office of Management and Budget's Circular A-95. The districts were created to coordinate the flow of federal funds and render technical economic planning assistance to each member city and county. Serious doubts are now being raised about the organizational structure of the districts. Research is needed on the extent to which the district bureaucracies cooperate with other agencies to benefit their members. How effective are the members of their boards of directors in guiding the districts to accomplish community goals?

Health Service Areas

The National Health Planning and Resources Development Act of 1974 established multicounty health service planning areas, designed to form functional health service areas (HSA's), to coordinate the flow of federal funds to improve health services and to coordinate the construction of all new health care facilities that are intended to serve patients enrolled in federal health insurance programs. What methods were used to select the coun-

ties in each HSA? What interest groups attempt to influence the HSA's funding decisions and to what extent have they been successful?

The most fundamental research question on HSA's concerns their impact on the individual pursuit of self-interest to maintain adequate health care. How will voluntary associations and activities be affected by the HSA's decisions on whether new facilities can be constructed, even if a community raises the funds solely through voluntary contributions?

Title V Research

Title V of the Rural Development Act of 1972 provides for federal funding of rural development research. At least two aspects of the law should be studied from an institutional perspective. First, the law requires evaluation of each Title V research project to determine its effectiveness. Since evaluation is normally conducted by the project's researchers, there is ample opportunity to repeat one of the mistakes that has sparked intense criticism of the agricultural research establishment, i.e., producing trivial research results because trivial problems were proposed for investigation. The evaluation process should be studied to learn how rigorously and objectively it is conducted. The effect of evaluation on research performance should be analyzed to determine if new evaluation schemes are needed to stimulate more rigorous research and more challenging research problems.

Another feature of Title V that merits scrutiny is the role that state rural development boards play in setting research priorities and determining who does the research. Are projects approved in a manner that encourages low-risk research that has a correspondingly low value? Should competition for funding be opened to other research organizations outside the land grant, 1890 school group, such as the newly formed National Rural Center?

Concluding Comments

Most of the rural development research has had a strong empirical orientation. Until funding is available to provide incentives for more basic research on the economics of institutionalization, most of the applied research will have a limited payoff. The application of market models to community resource allocation problems often obscures the impact of collective action. More emphasis should be placed on developing a theory of institutional change that reconciles the market economist's perspective with that of the institutional economist. Unfortunately, far too many economists accept the rather obsequious notion that institutional change is an essence of the invisible hand's work and therefore inappropriate for further investigation.

Self-interest may not insure a Pareto-relevant solution, but it certainly should not be discouraged. The analytical institutional economist can make a valuable contribution to rural development research efforts by studying the extent to which political institutions that were designed to support rural development efforts are encouraging self-initiative and experimentation with new organizational arrangements. In this context, the accomplishments in environmental economics toward creating new institutions can make valuable contributions to other areas of rural development research.

Finally, the institutional arrangements that have supported rural development efforts need to be continuously evaluated for possible improvement. Agricultural economists have a rich tradition of offering alternative institutional arrangements in commercial agricultural policy. The challenges of institutional research will hopefully stimulate that same tradition in rural development research.

Organizational and Institutional Aspects of Community: Some Conceptual Perspectives

Donald M. Sorensen and L. M. Hartman

> The hope that the pursuit of goodness and virtue can be postponed until we have attained universal prosperity and that by the single-minded pursuit of wealth, without bothering our heads about spiritual and moral questions, we could establish peace on earth, is an unrealistic, unscientific, and irrational hope. The exclusion of wisdom from economics, science, and technology was something which we could perhaps get away with for a little while, as long as we were relatively unsuccessful; but now that we have become very successful, the problem of spiritual and moral truth moves into the central position.
>
> E. F. Schumacher (p. 30)

There is a need for social science researchers and community development practitioners to focus on the fundamental problem of the loss of a sense of community in American life (sense of community is defined as the existence of shared meaning and trust among individuals). We see the problems of environmental quality, provision of public services, and concerns about other factors considered to be in the rubric of quality of life as symptomatic of this fundamental breakdown in community. The erosion of community is being accompanied by increasing attempts to maintain or strengthen organizational-institutional structures. We see these attempts as furthering the destruction of community. Rather than serving community-determined needs, professionals often unwittingly further community breakdown by serving institutional and organizational interests that impinge upon the freedom and dignity of human beings. This paper suggests that a more responsible involvement by the professional can help reverse the trend toward structural decay.

The first part of the paper develops a brief conceptual framework for an analysis of the community development situation. The second part elaborates the insights from this framework in an analytic, descriptive, and illustrative way. We conclude with some recommendations for university people derived from the analysis.

A Conceptual Statement

The conceptual framework is based on an empirically testable proposition: the basis for democratic social action is through shared meaning. Shared meanings are the essence of what is meant when one speaks of the cultural tradition. The continuing development of shared meanings is the dynamic of human evolution. Weber, in his classic *Theory of Social and Economic Organization,* develops a conceptual framework for the analysis of social organization premised on the concept of *verstehen,* or intersubjective understanding. The possibility of communicating presumes that the communicators start with some level of shared meaning; otherwise, communication is impossible. The only alternative to shared meanings for the existence of human order is force and behavioral conditioning. Historical evidence indicates that use of force to maintain order is a very unstable state.

Fromm in his book *Escape From Freedom* views modern societies as moving toward authoritarianism and force as sharing of meaning deteriorates among members of those societies. The concept of freedom is inextricably interrelated with the concept of shared meaning. Like freedom, meanings cannot be imposed upon an individual but must grow out of his own experience. Individuals must be free to make choices so that experience leads to the development of subjective meaning. The possibility of freedom implies trust among individuals who are significant and important to each other, and trust implies shared mean-

Donald M. Sorensen is an associate professor and extension specialist and L. M. Hartman is a professor of economics at Colorado State University.

ing. This leads us to the concept of community. The sense of community is defined by the existence of shared meanings and trust between individuals. As we have developed the argument, the sense of community is basic to the possibility of freedom and democratic action. Conversely, the sense of community is developed by freedom and democratic action and is synonymous with the concepts of trust and shared meanings.

Interpreting the current state of affairs in terms of the above propositions, one observes that the sense of community in rural America is being destroyed by centralized organizational structures. Economic, governmental, educational, and other centralized organizations are extending into the local community and are taking over the local functional action prerogative. This structural phenomenon evolves in a dominant framework of meaning focused on efficiency and utilitarian ends. This framework of meaning is internal to organizational structure (i.e., it meets organizational needs) and is not developed in a sharing relationship with the organizations' clientele. The evolution of centralized organizational structure is analyzed below in terms of concepts derived from our empirically testable proposition. According to Weber's conceptual scheme, a structural order develops out of common agreement upon desired ends and the apparent means to achieve the end; that is, effective structural order evolves out of human interaction in which people share meanings. This formal, structural, or vertical (we use the terms interchangeably) order is legitimized by the value agreement based in community. One must assume that our modern organization-institutional system evolved out of communities where some degree of agreement on ends and means existed. These formal structures have now taken over and are destroying community because the community has lost control over them. What was the historical nature of this process? Sufficient for the analysis here is the assertion that the agreed-upon ends of a technoeconomic nature resulted in an urban-industrial society where communication and sharing of meaning broke down. Bell's new book, *The Cultural Contradictions of Capitalism,* contains an excellent treatment of this phenomenon. In the twentieth century, rural America is losing community. As communication and sharing of meanings break down, means become ends within the formal structure. When the sense of meanings associated with the ends are lost, then mere expediency becomes the rule for action. In the process, efficiency, rationality, etc., become the ends for the organization, and communication is closed in to the organization itself. Serving the needs of its clientele or the community is of secondary importance. When one says the system has taken over, what is implied is that the internal order of the organization or institution provides its own justification, and for individuals to survive, they must conform to that order.

Conforming to an order, i.e., an imposed set of arbitrary rules and criteria for action, precludes the individual from developing shared meanings, which is one meaning of alienation. Alienation occurs when people are unable to share in determining what the rules are going to be. The individual must repress his own feelings simply to conform, and he is thus shut off from development of his own sense of value and meaning. Destructive and competitive self-interest or apathy and cynicism are the inevitable result, as Fromm and other humanistic-existential psychologists have so clearly reported. Developing community implies revitalizing the communication process within people who are alienated, i.e., those who are suffering from repressed feelings that result in apathetic or cynical attitudes and characterized by "dropping out" or by destructive and competitive behaviors. Communication processes involve both shared meanings and trust. The development of this process is not spontaneous, as the analysis above would indicate, but must be brought about by self-conscious leadership. Therefore, development of effective communication requires a "third party" where alienation has occurred.

Some Historical and Systematic Processes in the Loss of Community

Man's adaptation to his environment has been and is a process of community development. Throughout this process, man has created institutions and organizations in response to mutually shared human needs. The structural order in our early towns and villages was based on functional needs of the community as determined by local people and therefore had legitimacy and purpose. Essentially, control, ownership, and operation of these institutions were at the local level. There was a real sense

of community integration as functional needs provided the basis for structural development. This integration of functional (i.e., the face-to-face exploration and sharing of meaning) and structural (i.e., action according to agreed-upon or traditional meanings) dimensions gave people a sense of identity within the local community and, having found meaning in their life relationships, afforded legitimacy to local institutions. Implicit in the above is the belief that people in local community had a sense of shared destiny in addition to their identification with the larger society.

The consensually determined goal of economic development provided overall societal organization, but continued pursuit of that goal and the tremendous growth of organizations born of it has resulted in systematization and has brought about profound changes in the nature of the relationship between the structural order and the local community in America. Through time, a highly complex private economic and public support system has evolved in which concentration of capital, centralization of decision making, specialization of labor, and bureaucratization of organization are the predominant features. Carried to its logical conclusion, pursuit of economic efficiency means that increased control and predictability of events is essential. This means concentration of decision making and control of as many variables as possible, thus creating power to reduce uncertainty. Pursuit of these rational, calculating ends means that institutions and organizations have become self-enclosed social systems with internal criteria for measuring performance. No longer is primary attention given to determining the needs of people or to measuring the effectiveness in meeting these needs. Rather, pursuit of their own organizational self-interest means that primary attention is given to internal efficiency and control. Internal efficiency means the organization must be able to influence or even determine demand to minimize risk and uncertainty. Controlling both production and demand assures the maximization of profits.

The problems at the local community level become almost impossible to resolve as business, government, religious, and other institutions/organizations become systematized and operate solely from a narrow self-interest perspective. In pursuit of self-interest, competition rather than cooperative endeavor becomes the dominant reality. Problems are identified in self-interest terms, and conflict ensues as, for example, one group feels a new sewer system is needed and another feels a new library would be the best use of public resources. The problem is resolved through the exercise of power by the dominant interest group with little concern for the impact of their action on other interests. The community is torn apart, and no one experiences full satisfaction with the result.

If the various interest groups of the community could turn outward in an open sense of sharing with others in the discovery and exploration of feelings, then community priorities that people feel good about could be worked out because they become a cooperating part of, not competitive to, community action. This kind of interpersonal communication has largely broken down in local communities. As a result meaningful sharing of meanings stops, resulting in alienation, loss of freedom, and the capacity to act. Unfortunately, government bureaucracies with their "top down" designed programs and professionals with their narrow specialized disciplinary expertise further exacerbate the problem by serving special interest groups in or outside the community without first determining what it is the community really needs.

Conclusions

If the above assessment represents an accurate description of the contemporary scene, then we are confronted with a desperate need for renewing the communicating process so that shared meanings again provide the basis for determining human values. Somehow leadership must function so as to help people begin to share meanings and thus to establish their own control over their lives.

Many concerned social scientists, community development practitioners, and other professionals want earnestly to be more effective in helping to bring about human and community development in America. Unfortunately, the only model they know to attempt this is the one demonstrated to them through the highly structured and formal training programs that provided their professional credentials. They have been taught to believe that they can define people's problems for them, tell people the appropriate solutions, and thereby solve problems for people. Thus, the professional, based on the only meaning he has, develops programs that he thinks the community needs. He becomes perplexed when his expertise

fails to become assimilated by the community. The professional finds the institution/organization that he serves unable to respond to the leadership challenge. Certainly the church could be suggested as a source of this vitally needed leadership, yet organized modern religion has itself tended to become systematized with emphasis on religious form. Having abdicated its mission to help people find and share meanings for their lives, the modern church has lost its position of developmental leadership for modern man. So long as the universities, social scientists, and community development practitioners continue to maintain primarily an associational and disciplinary orientation, our involvement in community is likely to further the alienation process rather than foster integrating forces. Again, this is so because we force our cognitive framework for analysis and action upon community people.

As noted above, the social scientist or community development practitioner already has his own preconceived way of viewing the world from the perspective of his own discipline and has decided what he can do for people before arriving in the community. Values are not something he has been taught to be concerned with because they are determined externally from his discipline. Therefore, the expertise he brings is an abstracted body of specialized knowledge he knows the people need. It is considered unnecessary and, in fact, bothersome to try to relate to people in a sharing, uncertain relationship in which both community people and the professional work out their meanings and establish need priorities. When people are unresponsive or openly hostile to outside intervention by professionals, the social scientist or the community development practitioner naively attaches such terms as apathetic, rural radicalism, provincialism, or stupidity to these reactions. However, the professional's lack of sensitivity is a result of his formal training and the expectations placed upon him. Therefore, he has not discovered how to free himself from the formal or vertical perspective that leaves him trapped and unable to make his expertise available for assimilation by the community. By remaining unresponsive, people in community are attempting only to protect themselves from further alienating forces represented by the professional. The professional often is not sufficiently integrated himself to feel secure in letting the problems of the community determine his participation and insists on staying securely within his formal professional role. Moreover, he expects people to relate to him at his level of cognition, which itself is alienating and grossly inadequate to addressing the fundamental needs of the community.

The professional who develops the knowledge, skill, and commitment necessary to human development can choose to initiate functional leadership necessary for helping people share meanings in an open atmosphere where values and cognitions evolve through mutual effort. The professional can begin by helping people communicate effectively so that their meanings are heard and shared by other members of the community. Individuals have to relate effectively in order to share, they must share in order to develop and know their own feelings, their feelings must provide the basis for human values, and they must have a sense of values that provides a basis for action and a fully integrating and functioning personality.

We suggest beginning by facilitating the sharing of meanings, including our own, in a mutual effort to establish structures for serving human ends. This means establishing a new methodology that transcends the traditional quantitative, technical and nonevaluative content of our relationship with people in community as the primary focus. This does not mean that the current structural order is of no use; it means that a more horizontal approach in which community people and organizational representatives and academic persons are mutually open to each other can lead to a reification of human relationships and to an enhanced organizational-institutional responsiveness for fostering development of creative human potential.

Private Property and the Development of American Agriculture, 1776–1976
(Wayne D. Rasmussen, Economic Research Service, USDA, Chairman)

The Role of Private Property in the History of American Agriculture, 1776–1976

Terry L. Anderson and Peter J. Hill

Two hundred years ago when Adam Smith described the way in which the invisible hand of the market place would organize society's output, he had no intention of implying that this invisible hand was to be unconstrained. On the contrary, Smith recognized that the rules under which buyers and sellers operated were crucial to the outcome. The structure of property rights has always played and will continue to play an important role in determining the way in which resources are organized for production, and the agricultural sector is no exception.

The history of agriculture contains many chapters on the methods of organization, ranging from communal to private, and the debate continues as to which system is "best." Recently, it has been argued that even the neolithic revolution that witnessed the switch from hunting and gathering to settled agriculture found its roots in the rules that governed production. In the words of North and Thomas,

> The solution to the common property dilemma in which prehistoric man found himself was the development of exclusive communal property rights. While animals and plants remained abundant relative to the demands of the human population, there was no incentive to incur the costs of establishing property rights over them. It is only during this transitional phase of increasing scarcity that it became worthwhile for man to incur the costs necessary to develop and enforce property rights that would limit the rate at which the resources were exploited (1975, p. 26).

Often the concept of private property rights is taken for granted in this country, but it should be recognized that the same evolutionary process to which North and Thomas attribute the "first economic revolution" is responsible for the current organizational structure (1975). Colonists landing on the shores of the New World found it necessary to adapt the rules they had known in their mother country. The founding fathers were faced with the problem of determining the proper federal land policy, while those who ventured into the western frontiers found it necessary to adjust those rules to their needs. When those frontiers closed, the farmers were faced with further adjustment to a more urban world. The rules governing economic organization have varied over time in the United States and will undoubtedly continue to do so.

Our purpose here is to explain the evolutionary process that has tempered the structure of property rights in the agricultural sector and discuss how these rules have affected resource allocation. To understand this process, we must first understand what is meant by property rights and what factors determine how these rights change. Within this context six periods in American agricultural history will be briefly examined: the adjustment to new conditions in colonial America, the formation of a national land policy, westward expansion, the closing of the frontier, the new role of government, and the recent environmental movement. An understanding of the factors influencing major changes in the institutional

---

Discussants for this session were A. Allan Schmid of Michigan State University and Robert D. Reinsel of the Economic Research Service, U.S. Department of Agriculture.

The authors wish to thank one of their students, Randy Rucker, for his valuable research assistance.

framework should provide insight into what lies ahead.

The Evolutionary Process

The rules that establish access to and use of both physical and human resources and the outputs therefrom are perhaps the most important determinants of the game's outcome. By assigning responsibility, private property rights force the self-interested individual to consider the costs and benefits of his decisions. In other words, the structure of property rights will determine how individuals or groups use resources, what goods they produce, and who bears the costs and reaps the benefits of actions. (For a more lengthy discussion of how rules evolved and how they influence activity, see Anderson and Hill, in press.) When exclusivity and transferability are insured through private property rights, resources move to their highest valued alternative subject to the constraint of positive transaction costs. Decision makers guided by the invisible hand and private property rights promote efficiency and raise society's output to its highest feasible level. When exclusivity and transferability are lacking, certain costs and benefits be externalized, and inefficient allocation will result.

From the above discussion it appears that efficiency is a simple matter of establishing private property rights, but this simplistic solution ignores the question of how such rules are established. The rules evolve through a process of interaction in which the rule makers assess the perceived benefits and costs of alternative rules and act accordingly. By determining the extent of access to and use of resources, the adopted rules influence society's as well as the individual's wealth position.

We have postulated elsewhere that "establishing and protecting property rights is very much a productive activity toward which resources can be devoted. But, like any other activity, the amount of this investment will depend upon the marginal benefits and costs to investors of allocating resources to these endeavors" (Anderson and Hill 1975, p. 165). Efforts to change the rules can be thought of as input into the production of an institutional structure. The demand for such input is determined by the value of the desired rule change as perceived by the decision maker and the likelihood that the proposed activities will achieve the desired change. The individual will be motivated by his perception of private benefits and costs, which may differ from those of society. In the case of establishing private rights, for example, the action may have "public good" aspects that result in an underinvestment in such activity from society's perspective. On the other hand, if desired rule changes merely transfer rights from one owner to another, net private benefits may exceed net social benefits, and too many resources will be devoted to these efforts. Nonetheless, an equilibrium will be established by the equalization of marginal benefits as described above and the marginal costs of activities, the latter being a function of the opportunity costs of resources involved.

To illustrate the use of this model, consider the example of recent efforts by various groups of Indians to reobtain title to their ancestral lands. Three factors fit into the explanation of this activity. First, the value of the lands has been rising over time and is likely to continue to do so. Second, a higher education level among the Indians has better equipped them to attempt the changes within the legal system. Finally, recent court decisions in favor of the Indian cause have significantly increased the probability of their success. These factors suggest an increase in the marginal benefits of rule change activity that should induce the observed efforts. These simple concepts are applied to the evolution of property rights in American agriculture.

Property Rights in Agriculture

In the course of American history there have been many changes in the structure of property rights as they pertain to the agricultural sector. At the same time, the inhabitants of this nation have been faced with many different combinations of factor endowments and different precedents within the legal system, which help explain the evolution of the existing property rights system and the impact the system has had upon output. The application of the above analysis to six periods in American history will shed light on the evolution of this system.

Adaptation in the Colonies

Since the early colonists came mostly from England, it is hardly surprising that the U.S.

property rights system bears a great deal of similarity to that of the mother country. After centuries of evolution, seventeenth-century English law was increasing its recognition of the private rights of citizens, especially with respect to land (North and Thomas 1974). Hence, "the institutions which the English settler brought with him provided a hospitable background for growth" (North, p. 48). Because actual conditions in the colonies differed from expectations, adaptation of the rules began almost immediately.

In both the Chesapeake Bay area and New England, initial settlements attempted some form of communal property system. The Virginia Charter, for example, required that all "fruits of their labours" as well as "all such other goods and commodities which shall be brought out of England" be put into one store and divided equally (Commager). But the results of such system spelled disaster for the colonists. "Its [common property's] strangeness, the fact that it was so contrary to the agricultural tradition they knew, was discomfiting. There were drones who idled while others labored, and in a land where every hand was needed to survive, there were women who would allege weakness and inability to avoid weeding and hoeing. There was a very human tendency to work less for the common good than one would work for one's own good" (Rutman, p. 6). To remedy the problem in Virginia, each man was given a small garden plot from which he was to provide his own food. This dispersement of land from the London Company marked the first form of private ownership in the colonies. In New England, where each family was granted an acre of land and the livestock were divided among the colonists at an early date, "the end of communal agriculture was a boon to the settlement" (Rutman, p. 12).

With time the system of private ownership in the colonies became better defined and enforced. Where good farm land was scarce, this evolution was more rapid. The New England geography, for example, combined with the commercial aspects of the economy meant that settlement was more likely to be concentrated. The potential for conflict over property rights raised the benefits from definition and enforcement, which in turn produced a system for surveying and recording land ownership. Farther south in the Chesapeake Bay region, however, this concern with the land system was much less intense. Land was more homogeneous and of good quality, transportation was available to most tide water land via rivers, and economies of scale were few, so the congestion and hence the potential for conflict were reduced. We should not be surprised, therefore, that well-defined and enforced property rights in land did not evolve as rapidly there.

When the colonies declared their independence of the mother country in 1776, colonial farmers had established the rights to alienate and inherit land, rights that were crucial to efficient agriculture. To be sure, there were some regulations of land use, and the government had retained the rights of eminent domain, police power, and taxation. Nonetheless, by the time of the Revolution the landowner had basically acquired the right to use his land as he saw fit with few restrictions and controls by the government.

The property rights structure that existed in 1776 was more than just the result of economic forces. The colonists inherited a strong philosophical ideology that adhered to the concept of natural law. Under this ideology individuals were vested with certain rights, and it was the states' function to codify and enforce these rights. Included in this package of vested rights was the right to private property, a right that the state could neither create nor destroy. The embodiment of these rights in the Constitution, with its emphasis on the importance and sanctity of the freedom of contract and the subsequent interpretations of that social contract by the Marshall Court, firmly established the principle of private property in the legal and economic system. Thus, from the very beginning of this nation a firm basis was laid for an efficient allocative mechanism in agriculture—a property system that provided strong incentives for increases in production.

Federal Land Policy

The nineteenth century was marked by the movement of agriculture across most of the continent, with large-scale increases in production coming from the settlement of new lands and from technological advance. In both of these, however, the ability of the farmer to capture all or most all of any output increases was crucial to the rising output that occurred. The property rights system internalized the benefits (and costs) of most decisions and thus led to efficient resource use. A major influence in determining what property rights

structure would prevail was the land policy of the federal government. Although by 1776 a set of institutions had developed that provided for private property in most of the settled land, formal property rights were not established over much of what is now the United States. The new nation was faced with some crucial decisions about the form those rights would take.

During the first half of the nineteenth century the government at both the state and national level moved rapidly towards a policy of establishing private rights in land. Such action was spurred on by a basic attitude that the energy of the unpopulated continent should be released, which could be best accomplished by the private actions of the citizenry. The impact of this land policy was felt most in the agricultural sector that dominated our early economy.

To be sure, the transfer of the public domain to private ownership entailed numerous costs, but those costs were lessened by two important developments early in the nation's history. In 1785 the Continental Congress passed the Rectangular Survey Act, which made establishment and enforcement of property rights much easier. Secondly, between 1781 and 1802 the various states ceded their claims to western lands to the federal government, again significantly lowering ajudication costs in establishing rights (Commager).

Initially, the federal government saw itself simply as a wholesaler of land, and disposed of large blocks of undeveloped territory to interested individuals and companies. Although the term "speculator" is often applied to these land purchasers in a pejorative sense, this policy did establish private rights very rapidly and quickly allowed the market to allocate land to its highest valued use. Because of a general disapprobation of "land speculator profits," the federal government gradually moved from being a wholesaler of land to being more of a retailer.

The growing concern for equity in land policy culminated in the Homestead Act of 1862, which, although it put severe restrictions on efficiency in land holdings particularly in the arid West, did embody community sentiment about appropriately sized land holdings. Although there were significant social costs to the Homestead Act and its various modifications, it did allow for the establishment of private property rights, albeit at a higher cost than previously. But perhaps of even greater significance was a general movement away from the establishment of individual rights to a policy of maintenance of group (governmental) rights in land. The twentieth century saw the government at both the state and federal levels move to more firmly establish its rights in the land that it held, in sharp contrast to the nineteenth century, which can be characterized as a period of rapid establishment of individual rights.

Westward Expansion

> The Easterner, with his background of forest and farm, could not always understand the man of the cattle kingdom. One went on foot, the other went on horseback; one carried his law in books, the other carried it strapped round his waist. One represented tradition, the other represented innovation; one responded to convention, the other responded to necessity and evolved his own conventions. Yet the man of the timber and the town made the law for the man of the plain; the plainsman, finding this law unsuited to his needs, broke it and was called lawless (Webb, p. 206).

By the time the first settlers were beginning to enter the American West, a system of defining and enforcing property rights in the productive agricultural inputs had evolved in the East. Surveys of the many small farms established the boundaries of each productive unit, positive identification by natural markings, combined with rail fences made from the available wood supplies provided for definition and enforcement of rights in livestock, and riparian rights determined access to and use of water in the streams. Just as the colonists of the New World imported a set of rules inherited from the mother country, the "colonists" of the American West borrowed from their eastern heritage. By the same analogy the western colonists were forced to adapt their rules to fit the resource endowments found in the new country.

Initial land endowments relative to the population in the West made the returns to the establishment of private property rights quite low. "There was room enough for all, and when a cattleman rode up some likely valley or across some well-grazed divide and found cattle thereon, he looked elsewhere for range" (Osgood, p. 182). Squatter sovereignty was sufficient for settling land ownership questions during the early periods of settlements, but increased population density changed the level

of property rights activity. Such activity ranged from the description of "accustomed range" in local newspaper advertisements to the filing of legal documents of ownership and the fencing of the open range with barbed wire in the 1870s. Between 1860 and 1900 changing land values and changing costs caused individuals and groups to devote more resources to definition and enforcement activity in order to capture potential rents to land. These efforts included not only control of land held privately but also control of grazing on the public domain. The result of these activities was a successive movement toward exclusive ownership of land on the Great Plains.

Property rights in cattle followed much the same evolutionary process. The most efficient size of operation on the Plains was vastly larger than that in the East, and the lack of fencing materials prior to the introduction of barbed wire made fencing out of the question. Hence, western ranchers were forced to turn to alternative methods of defining and enforcing property rights. In the absence of ownership conflicts, the return to establishing and enforcing property rights in cattle was low, but "the questions arising over the ownership of cattle and the rights of grazing, difficulties that have bothered the pastoral industry from the beginning of time, were intensified as the number and value of the herds increased" (Osgood, p. 114). With this came the increased use of branding and efforts to establish brand registration laws as a means of defining and enforcing private ownership rights over livestock. Again the western agriculturalist was forced to adapt the institutional framework to fit his needs.

Finally, in the case of water rights, the unique endowments of the Great Plains led the frontiersmen to invent and adopt an ownership system unique to their region. The initial adoption of the riparian system made sense for two reasons: the precedent in eastern law made the rules easy to implement in a legal system founded in the East, and the initial abundance of land adjacent to water made the riparian system adequate for the allocation of that resource. However, again as the settlement pressure increased, the returns to activities aimed at changing the rules of the game also increased. Spurred by such activity, a system of water law evolved that granted to the first appropriator an exclusive right to the water and to later appropriators rights conditioned upon the prior rights of those who have gone before, permitted the diversion of water from the stream so that it could be used on nonriparian lands, forced the appropriator of water to forfeit his right if the water was not used, and allowed for the transfer and exchange of water rights between individuals (Dewsnup and Jensen). That this system is strongest in the areas where water is not scarce, is combined with the riparian system in the states bordering the most arid portion of the Great Plains, and is not used to any significant extent in the more humid East suggests that benefits and costs do significantly influence the property rights system.

The Closing of the Frontier

Although much of the agricultural history of the United States can be described as a continuing process of defining and enforcing private rights in inputs, other concerns did come into play during the last half of the nineteenth century. Well-defined and enforced rights do minimize externalities and promote efficiency, but individuals will attempt to change the rules for reasons other than efficiency. The decision maker may use his resources in an effort to affect the transfer of existing property rights from another owner to himself. Such efforts were very much a part of farm organization activities during this period.

It was also recognized that the cost of establishing private rights in some areas was too costly and other solutions resulted. The granting of public lands to railroads can be viewed as a means of allowing those railroads to capture a greater portion of the social rate of return on their investment than otherwise would have been possible. Likewise, the passing of the Morrill Act in 1862 was occasioned by the belief that the advancement of agricultural knowledge was not being carried out rapidly enough by the private sector. Although it took several decades for agricultural research to bear much fruit, Griliches's estimates of the social rate of return on a single innovation, hybrid corn, indicates that there are significant externalities in such research.

During the last quarter of the nineteenth century the closing of the great American frontier changed the attitudes and opportunities of farmers. Cheap land, considered by some as a "safety valve" for many economic and social problems, was mostly spoken for by private individuals or by government agencies. Agriculture had expanded into the fron-

tier regions of the country where in many cases the soil was fertile and new technology readily adaptable. The results of this expansion were manifested in several ways. First, agricultural output increased at an unprecedented rate. Between 1869 and 1914, wheat output increased by 309%, corn by 322%, oats by 375%, cotton by 644%, and cattle by 250%. Total farm output increased "about 200% during this period, while the nation's population increased about 150%" (Higgs, p. 80). Second, as output was increasing, prices at the wholesale level were falling.

> The productivity improvements themselves, inasmuch as they meant expansions of output, meant lower farm prices and, in view of the price inelasticity of demand for farm products, would have meant lower total gross farm incomes if demand had not grown simultaneously. The competitive nature of the industry insured that improvement was rather readily passed on to consumers in the form of lower prices. . . . But, in fact, the demand for farm products, even with large accessions of export demand, did not grow as fast as total demand in the American economy (Davis et al., pp. 403–4).

Hence, absolute farm prices were declining as were absolute and relative incomes (Higgs, p. 100). Finally, the closing of the frontier and the continued growth of the demand for land meant that land values in many areas appreciated rapidly. While these increases most certainly augmented the income of land owners in the form of capital gains, they also appeared as higher input prices that were real opportunity costs to all. Coupled with the above problems was the market instability experienced by agriculture's entry into wider trade areas and the concern for concentration of economic power in the hands of a few.

During this period numerous agrarian protest movements entered the political arena in an effort to influence the perceived low and fluctuating farm incomes, the high nonfarm prices thought to be caused by monopoly power, and the wide margins between farm and market prices. "Farmers' faith in untrammeled individualism was modified by demands that 'something be done' by government or by voluntary association to stabilize farm incomes and to improve and maintain the relative standing of the family farmers in the economy" (Davis et al., p. 410). Groups such as the Grangers, the Farmers' Alliances, and Populists rose to the challenge of obtaining for the farmers their "fair share." While such efforts were nothing new to the American economy, the magnitude of these efforts marked a major turning point. As illustrated above, the agricultural sector played a major role in the evolution of private property rights in inputs such as land. The major concerns during the late nineteenth century, however, might be characterized as questions of property rights in outputs. The claims of "too low" agricultural prices, "too low" farm incomes, and "too high" freight rates can be interpreted as claims that farmers desired property rights in a larger share of the total market value of their output. The agrarian protest movements of this era can be viewed as efforts to muster resources to define and enforce these rights. However, acquiring these rights necessitated a transfer from other owners.

With the perceived concentration of power in some input markets such as railroad transportation and grain storage, the farmers saw increased benefits from group action that could be used to countervail these monopoly elements. The declining prices received at the farm also added impetus to the protest movements by giving the protestors more to gain if they were successful in their efforts. On the cost side of the ledger, falling farm incomes reduced the opportunity costs of resources devoted to changing the rules. Rather than spending extra hours in the field, it may have been much more productive to attend Grange meetings in the hope of increasing the return on crops produced. Moreover, during this era the effectiveness of group organization increased. The idea that power could only be resisted by power became commonplace in American attitudes as individuals joined their fellows to use the law to further their economic, social, or civic interests.

Nothing New—The Early Twentieth Century

During the last twenty-five years of the nineteenth century, farmers made great strides toward the organization of their efforts to increase farm income through collective action. This was not the first time members of the agricultural sector had engaged in such efforts; for example, farmers were involved in the formulation of the country's tariff policy during the early years of nationhood. But their primary focus up until the last quarter of the nineteenth century was with the definition and enforcement of property rights, especially in land. Even though by the end of the century

the organization effort was at a low ebb, there is little question that farmers had made their mark and that they would continue to do so. "They had demonstrated that organized farmers could exert a significant influence on national policies. Much had been learned about tactics in the attainment of given ends, and the dangers of direct political affilitation with specific parties" (Benedict, p. 114).

Because of this success of the agrarian movement, efforts to organize probably would be more productive, and more collective efforts might occur. In the context of the theory presented herein, with the groundwork laid, the marginal benefits from activity designed to define and enforce property rights in higher incomes should have increased. However, marginal costs reduced the amount of such activity during the first fifteen years of the new century. Good years for the farmer made his time in the field more valuable and increased the costs of devoting resources to collective action. Between 1900 and 1915 farm prices continued an upward march that left them more than 50% higher by the end of the period. Rising incomes that accompanied the rising prices earned the era the designation of "the golden age of agriculture." These good times reduced the relative net return from collective action and hence the amount of such activity.

The impetus for a revival of organized political activity came from the deterioration of the "golden age." By the middle of the second decade of the twentieth century, homesteading had slacked off and was no longer providing for agricultural expansion. The advent of World War I and the policies of the government during that conflict kept farm prices and incomes up until 1920. Expanding overseas demand accounted for part of this prosperity. But when wartime credits to allied countries were discontinued in 1919, this demand fell off, and economic conditions in the agricultural sector began to change. This, combined with the signing of the Armistice, caused a sharp decline in farm prices in 1920 and an even sharper one in 1921. With the decreasing demand and an inelastic supply, wheat prices fell by one-half and corn by one-third. "Thus, by the spring of 1921, American agriculture found itself in a more unfavorable position than it had experienced at any time in the memory of men then living, or possibly at any time since the nation's beginning" (Benedict, p. 172). The stage was set for another surge of activity that would attempt to secure higher farm incomes through the coercive power of government.

The major focus of the activity was not much different than that which had existed twenty-five years earlier. The farmer's share of national income was below what was considered to be "fair"; prices dictated by the markets were "too low" relative to farmer's expectations. In other words, in the eyes of the farmer, a portion of the true social value of his product was not accruing to the rightful owner; somewhere in the market system property rights had been tenuated, and the government was called upon to correct the situation by redefining and enforcing those property rights. The market had not necessarily broken down due to the existence of concentration of power or externalities, but farmers perceived that such a situation existed.

The success of the "new farm movement" was insured by the advent of the Great Depression. To the U.S. farmers of the third and fourth decades of the current century, the costs of devoting resources to the establishment of "new property rights" were low since the markets for their products were yielding poor returns. In addition to these cost considerations was the fact that the progressive era had shown the potential effectiveness of organizing to influence the rules of the game. The potential for higher incomes, coupled with the expectation that they could be obtained if the organization was strong, raised the benefits from institutional change activity. Resources employed by the various groups were aimed at increasing the incomes of members by giving them the right to control output in their sector, to receive parity prices, and to have a say in the establishment of prices charged by input suppliers such as the railroads and grain elevators.

The success of their efforts is evident in the farm policy of the federal government that has emerged during this century. Bills such as the cooperative marketing bill of 1922, which exempted co-ops from antitrust legislation, the McNary-Haugen bills, which would have enabled government purchases of surplus commodities in 1924, and the New Deal price-support programs are all examples of the success of organizations such as the Farm Bureau. "By the end of the 1930's the agricultural price-support program, the basic program desired by the farmer, had become institutionalized into the American political structure, and has continued so in one form or

another since that time (Davis and North, p. 100).

The Environmental Movement

While a majority of the property rights activity of farmers in this century have been of the type described above, recent years have seen a return to the concern for property rights in inputs such as land and water. The conservation movement that began late in the nineteenth century was revived during the Great Depression, revived again during the past two decades, and might be seen as an effort by various groups to define and enforce property rights in resources that have no such governing rules. In the case of air, for example, the increasing scarcity of clear air has induced many to secure behavioral rules governing the use of that scarce resource. Land and water use have come under similar scrutiny, and since these resources are valuable inputs to the farmer, he has been forced to engage in the battle for rights.

Land use planning, described by some as the "taking issue," is an excellent example of the current issue. As land in general and open space in particular has become more scarce, the rate of return on defining and enforcing property rights in such resources has increased. The response of individuals to this return has resulted in a proliferation of rules and regulations governing land use, many of which transfer rights the farmer considered to be exclusively his to other groups or individuals without compensation to the farmer. The ability of the farmer to alter the course of a stream provides an example. While this is not a right guaranteed by law in most cases, it is one that the farmer thought he owned. Legislation designed to regulate stream use has altered these thoughts.

Efforts to alter the rights to resource use have raised the benefits to farmers from better defining the rights that they considered secure. In many cases existing organizations have turned their efforts to this cause, while in others entirely new organizations have been formed.

Summary

From colonial times through the first three-quarters of the nineteenth century the main focus of agrarian property rights activity was on defining and enforcing property rights in inputs, and his focus was instrumental in directing the course of private property rights, especially in land. From the last quarter of the nineteenth century until the present, the primary concern of the farmer has been with the establishment of private property rights in a larger share of the national income, and again these efforts were influential in setting the direction of federal policy. Now with the rise of water and land use planning, the agricultural sector is again concerning itself with the definition and enforcement of rights in inputs.

Farmers are not the only productive group in society that affect the type and distribution of property rights, but it is clear that they have had a voice. Their commitment to private property manifested itself in the large-scale output increases that the nation has experienced. On the other hand, their more recent concerns for equity have helped force open the door for increased transfer activity accompanied by government regulation. Clearly, the rules of property rights significantly influence productivity, and these rules are endogenous to the system. Hence, in this bicentennial year it is important that we consider the extent to which the present system of property rights encourages efficiency and promotes transfers not only in the agricultural sector but in the economy as a whole.

Property and the Future of Agriculture

Gene Wunderlich

> Each recognition of a new thing as the object of legal rights has opened a new chapter in the law, often one of vast complexity. Philbrick (p. 692)

This paper is about complexity. I am going to examine complexity and property in two ways, a short way and a long way. The short way is a cowboy story, and the long way is the same principle explained in the words of an economist.

Consider the cowboy (this is an agricultural paper; apologies to the marine economists who are familiar with shipwrecked Crusoes). He rode alone into an open range with only his horse and saddle as property. He rounded up wild cattle of appropriate gender and confined them and their offspring until he had a herd. The herd grew by itself limited only by natural predation, cowboy consumption, and sales of beef to the folks back East.

Enter cowboy B who did likewise. Organizational opportunities consisted of a shoot-out (winner, if any, takes all) or a slightly more complicated property arrangement by which cattle were claimed and recorded by branding (if the cattle had any say, they would have preferred title registration in deference to their smoldering flanks). The cattle were comingled with cattle of other brands on the common prairie.

One year rain was short, as was the grass, and land for grazing became scarce. Organizational opportunities arose again. The options were another shoot-out or a slightly more complicated property arrangement by which the cowboys, then numbering three, agreed to limit the size of their herds by formula. The formula worked fine until the enterprising cowboys weighed the risks of cheating against getting caught. Organizational opportunities arose again, with the consequences of one or more shoot-outs or a still more complicated arrangement that conceded enforcement to a fourth party (they did not like the enforcer very much, so they called him government).

When the range became too crowded with cowboys, some of them took to growing clover for the cows and carrots for horses. But open range is a poor place to grow clover and carrots with cattle and horses around, so still more organization opportunities arose, leading to more shoot-outs or some rather complicated property arrangements involving surveys, fences, deeds, recording, *inter vivos* transfers, and *cavaet emptor*. Some of the cowboys could not speak Latin, so lawyers were invented. Cowboys no longer spoke or shot it out with other cowboys. Cowboys spoke to lawyers who spoke to other lawyers who spoke to cowboys.

Meanwhile, ranchland became scarce. The old free range became expensive, and cowboys discovered it was more profitable (and much easier) to sell land than to raise and sell cattle. Organizational opportunities abounded, but instead of shoot-outs there were contracts, litigation, and legislation. Leasing contracts, for example, allowed buying for just a short time. Land became so valuable that people could only buy or rent the separate services of land one at a time. Each of these separate services became a right. Computers were enlisted to maintain a continuous record of all the property rights. In time the land itself was forgotten, and major industry was built on the trade of real property rights. Organizational opportunities flourished even when the land did not. The story fades out in the year 2027 when a third generation cowboy and a battery of lawyers invented a transferable viewing right for the sunset over Rattlesnake Butte. [end of parable]

> The problem of the ownership of property is in my view, one of great importance and of common concern throughout the free world. Meade (p. 177)

We have been asked to consider, as part of the AAEA proceedings, the future of property and agriculture. The reason is plain. The rules comprising the institution of property affect

Gene Wunderlich is with the Economic Research Service, U.S. Department of Agriculture.

The author appreciates the review of an earlier draft by Robert Boxley, James Lewis, Carmen Sandretto, and Roger Strohbehn.

the way wealth and income are distributed and resources are used. It is as important for us to understand future property rules as it is to understand future demands and supplies of petroleum, fertilizer, labor, or seed.

The task of translating the past into the future should not be difficult; it is a process used from early childhood. Each of us have learned, with varying successes, to identify important events and activities. So it is with the future of property. The future of property should be no more difficult to predict than the future of technology, society, and mankind. Nor is it, I fear, any less difficult.

The Approach

This is not the place for a discourse on methodology, but it is perhaps useful to distinguish between predictive models and reasoned speculation. The approach to the future of property used here is best described as speculation. It is doubtful if any treatment of the future can be much more. A model for prediction implies facts for testing that, by the very nature of the future, are not available. In Lachman's words, "the impossibility of prediction in economics follows from the facts that economic change is linked to change in knowledge, and future knowledge cannot be gained before its time" (p. 71).[1] Our speculation is about those human interdependencies and organizations of the future that pertain to property, especially land in agriculture.

Property Semantics

What is property? Ely remarked that "the essence of property is in the relations among men arising out of their relations to things" (p. 96). Others variously define property as a system of authoritatively sanctioned rights, duties, privileges, and liabilities among persons with respect to property objects (Wunderlich).[2] The objects might be goods, services, territory, ideas, or enterprises. The persons can be natural persons or legal entities such as corporations or trusts. The sanctioning authority is government or its substitute. The rights and duties are relations between the holder and others.[3]

The critical element to be distilled from the definitions and descriptions is "distribution." Property distributes opportunities and obligations among persons. Only indirectly, by personifying benefits and costs, does property prescribe use of things. The effect of property on decisions about the levels and combinations of resources is inferred from incentives presumed to exist from the distributive qualities of property.

The rights and privileges attending property are assumed to create incentives, which are assumed to create behavior with respect to resource use. These assumptions are so plausible that they seem not to have been seriously questioned, and the linkage between distribution of rights among persons, benefits and costs, incentives, decisions, and behavior have been fused into a doctrine of appropriability and liability. This doctrine provided conceptual underpinnings for the literature of externalities that bloomed in the environmentalist era.

Thus, some rather elementary ideas about property added immensely to economic understanding (Demsetz, McKean, Furubotn and Pejovich).[4] Unfortunately there has been little *quid pro quo*. Economics has not been equally generous to the concept of property. The "bundle of rights" remains more or less as stated by Noyes in 1936:

> this rather will-o'-wisp thing called dominion or ownership . . . is said to represent a bundle of rights of a certain nature with reference to a certain object. Other kinds of bundles may exist with reference to the same object. . . . All the aggregates combined, which have reference to a single object, constitute complete property in that object (pp. 309–10).

Describing property as a distributive instrument does not diminish its role in resource use. It merely affirms property as primarily an

[1] Shackle states further, "The analyst can reason only about what is in effect complete; and in a world where there is time, nothing is ever complete" (p. 27).

[2] The concept of property here draws from Ely, Hohfeld, the American Law Institute, Noyes, and from suggestions and ideas from Quintin Johnstone, Myres McDougal and Harold Lasswell; it is described in greater detail in Wunderlich.

[3] Hohfeld claimed that "one of the greatest hindrances to the clear understanding . . . arises from the express or tacit assumption that all legal relations may be reduced to 'rights' and 'duties' . . . ." (p. 35). He thereupon classified all legal relations into jural opposites (right, no right; privilege, duty; power, disability, and immunity liability) and jural correlatives (right, duty; privilege, no right; power, liability; immunity disability). Hohfeld's scheme was useful largely because it showed the implications of rights—privileges held by one party on the duties and on rights of others.

[4] Following Coase's concepts of social cost, Demsetz and others (e.g., McKean) explained externalities in terms of failures to assign property. The doctrine of appropriability, referred to as the "property approach" to economic efficiency issues, was reviewed in Furubotn and Pejovich.

aspect of the distribution of wealth, power, and status, which may in turn affect the way property objects (resources) are used. Looking at the future of property, one should give first priority to distribution of property rights and then examine the implications for resource use in, say, agriculture.

Complex Systems and Property as Information

Property is a system through which owners communicate to others their interests in property objects. Essentially, property is an information system. As the number of property objects, interests, and owners increases, the system becomes more complex. Simple one-to-one contracts give way to generalized rules. Then the general rules become numerous, requiring codifications with increasingly formal and elaborate procedures for enforcement, adjudication, and modification.

An expansion of property objects and persons would cause one to expect the property system to rely more on groups, voluntary organizations, and government to become the decision makers. These organizations have increasing needs for information. Systems capable of handling large volumes of information tend to become specialized. Davis and North explain the tendency:

> In general, not only is information costly, but it is subject to increasing returns. That is, one must frequently pay for information, but the cost does not change much whether that information is used to effect one, one hundred, or one thousand transactions. If information costs are substantial and if they are subject to decreasing costs, it is likely that substantial profits are to be earned from increasing information flows that decrease uncertainty (p. 21).

The market for land has traditionally been local and specific to a particular unit; each transaction has been, to a large extent, tailor-made. However, conditions surrounding the exchange of land are changing. Already a specification market is developing in urban residential real estate. Thus, according to Davis and North criteria, the conditions for institutional innovation exist in real property rights.

The increasing complexity of the real property system is an inevitable consequence of more parcels of land, more separable rights, and more rights holders. There are currently between 85 and 100 million parcels of land counted for tax purposes (U.S. Dep. Commerce 1974, Behrens). From these units of ownership, at least a third have separated a lease-hold interest (U.S. Dep. Commerce 1975). Most parcels are subject to some separations of interest such as easement, reservation, and covenant, or security, regulation, and tax.

What does this complexity mean in terms of the distribution of land ownership? It means that the bundle of rights is divided in many parts, and the parts are held by many people. What is called complexity in the property system may result in a wider distribution of real property than is indicated by available measures such as a Gini ratio of land ownership (Johnson). A small portion of a population holding fee ownership, for example, does not necessarily mean that the distribution of all interests in land is concentrated. The degree of concentration of land ownership may be an illusion resulting from narrowness of concept of ownership and the inadequacy of information about ownership.

The many interests in a parcel of land are much more difficult to identify and comprehend than the parcel itself. One tends to be object- (say, parcel of land) rather than concept-oriented, and the tendency is to assign to an owner a single interest to an object. This is revealed in the choice of the word "attenuation" in the property rights literature, for example: "By considering how the attenuation of basic property rights affects the actions of decision makers, it becomes possible to secure new insight in the behavior of various types of firms" (Furubotn and Pejovich, p. 1148). Attenuation connotes a diminution or disappearance rather than separation or relocation. Is it correct to say that a lease—the right to use a parcel of land for a given period of time—is an attenuation, or is it a separation of a use right from the fee ownership? Likewise, does an easement or regulation reduce or attenuate a right to use; or does an easement simply relocate a particular right, and a regulation represent the exercise of a right a government had all along?

The idea of attenuation results in part because the inadequate information quality of the present property system allows all the separable property interests, except the original fee, to disappear into oblivion. Presumably a more sophisticated information system could identify, record, publicize, trade, and tax each

of the separable property interests.[5] To do so would result in a more accurate valuation and marketing of separable rights. One of the interesting consequences of the recent attraction of transferable development rights is that separable rights for particular uses are distinguished and traded.

In the long run, the benefits to someone of developing the more sophisticated property information system will probably exceed the cost. The precondition for organization innovation, in terms of the Davis and North criteria, will exist, and enterprising individuals, groups, and governments will refine the market for property rights.[6] Interests in property will become more widely distributed, not merely attenuated.

The anomaly of power will be that, as the distribution of property interests become more widespread and as information systems become more specialized (high initial costs, low unit costs), new forms of concentration of property may arise. Particular types of interests may become the focus of information specialists who control access to information sources. To some extent the present limits on access to multiple listing in real estate is a step in that direction. As the information system becomes organized and regulated, access to the system may be restricted and its value expressed as franchise—a seat on the New York Stock Exchange, for example.

The concentration of economic or political power associated with the ownership of large amounts of land could be submerged by control of information about land. What the stock market has done for capital, the land information market will do for land.

The Future of Property

In general, what can be said about the future of the real property system in the United States? The following speculations and their consequences are offered as a step toward a better understanding of that future. The speculations are presented more or less in descending order of certainty and directed toward land.

(*a*) There will be more holders of property. Demographers project more people, and there is no reason for assuming that organizations, trusts, and other potential holders of rights will not increase with the number of people. There will be more property objects. Unless the human tendency to make and collect things change, there will be more ideas, goods, services, and continued vertical and horizontal divisions of territory. There will be more separation of interests (rights) in property. Wants will become more specialized and less enduring, so the rights, duties, privileges, and obligations will become more narrowly defined and will turnover more rapidly. Thus, the quantity of property interests will increase. The rules pertaining to the property interests will increase in number or include larger numbers of interests within each rule.

More legislative, administrative, and judicial resources will be required for the organizational overhead to manage larger systems. Success of future property systems will depend on highly sophisticated mechanisms for separating, identifying, transferring, collecting, and managing property interests. Information handling will determine the character of the institutional future.

(*b*) Property rights in land will become increasingly separated, permitting the retention of the fee in fewer hands, especially by groups and organizations. More of the interests in land held by individuals will be second-order interests, such as negotiable stock in a land-holding corporation. Land for investment will be held by incorporated and syndicated holders with security interests in large financial organizations. Property interests will be concentrated along classes of property, e.g., a single group may own all the development rights in an area. A power company may specialize in owning rights of way for the operation of an electric power grid. Some of the concentration will include government; for example, county government may hold scenic easements on all agricultural land to insure an overall visual quality in the county.

(*c*) New systems of classification, brokerage, marketing, and finance will permit more rapid purchase and sale of fee interests, leases, options, easements, and other separated interests. The real estate market will be increasingly national and international.

(*d*) Title assurance, recording, and registra-

[5] Conceivably each separate interest could be assigned a value and taxed. Such a system would be intricate but would have the advantage of precluding some current tax aberrations such as preferential use value assessment.

[6] Davis and North's model for institutional innovation, reduced from its refinements, is simply that an innovation will come into being when "there are potential profits that can be harvested by anyone (or any group) who can innovate new institutional arrangements that will overcome . . . barriers [of economy of scale, externality, risk aversion, political pressure, etc.]" (p. 61).

tion will be automated and simplified. Uniform standards will reduce costs and ease interstate and international transactions.

(*e*) Government will acquire, hold, and manage more interests in real property. Common property will become more common. The share of interests in land held by government will increase proportionally with the number of people, parcels, and interest separation. This speculation is based on the theory that as an organization, such as a nation, becomes larger and more complex, a larger share of total resources is devoted to management and coordination. At least some of the centralizing tendency will take the form of government.

(*f*) Against the centralizing tendencies of management in large-scale organization and the waste of coordination is the decentralizing tendency to form small-scale autonomous decision units. Polycentrism is the term given to systems whose elements make mutual adjustments within a general set of rules (Ostrom). Polycentric organization may permit refinement in property information without elaborate machinery for policing and adjudicating rights.

The Future of Agriculture and Property

> The condition most favorable to the prosperity of agriculture exists when there are no entails, no unalienable endowments, no common lands, no right of redempton, no titles. Polanyi (p. 180).

The future of agriculture will be determined by a large number of factors, including but not limited to property. Biological sciences will be the most important influence on the future direction of what is now called agriculture, but the property system will affect the distribution of benefits and costs and may have some effect on the direction and pace of change (Boxley).

The biotechnical features of world food and fiber in relation to population has been stated in the optimistic terms of Kahn and Brown:

> For the balance of this century, the prognosis is quite favorable for two-thirds of humanity . . . but quite ambiguous for the poorest third of the world. . . . Our assertion, however, is that these can be greatly mitigated and possibly solved by creating sensible programs within and outside the trouble areas. . . . Would there be enough food, we may still ask, if, after 200 years, the world population reached, say, 20 billion, about five times the current population? The answer to that question, we assert, is a simple yes!" (p. 332).

Paarlberg is less sanguine than Kahn and Brown (see Paarlberg 1976, Rasmussen):

> Agricultural production, even in the less developed countries, will probably increase at a rate somewhat greater than population over the next 10 years, so that per capital supplies of food are likely to increase moderately. The improvement will not be great, however, and it will not be sufficient to satisfy either the nutritional needs or the expectations of the people. . . . Let us now direct our attention to the long-term food problem, which will extend well into the 21st century. Unless there is a check in the rate of population growth, I see no solution to the food problem" (1975, pp. 300–301).

For those even less optimistic than Paarlberg, the biological image presented by Borgstrom is even more formidable:

> "Demographers expect the world population to double between 1975 and 2000. That means that even if we somehow manage to double world production of food, minerals, housing and everything else, more people than ever would still be starving and malnourished. The hunger gap can be removed only by trebling food production during the next 25 years.
>
> In biological terms, the true feeding burden of the planet is not 4 billion people, but rather 20 billion population equivalents (PEs): We must include livestock as well. A PE is a unit of protein intake; that of a human is one. The feeding population of the United States is 1.7 billion PEs, a number that includes 215 million human beings, 150 million pets, and livestock. The one billion more people the demographers expect in the next 13 years are really—in biological terms—five billion" (pp. 71–72).

In the long run there is little basis for optimism unless mankind can bring itself under biological control. In the short run, food and fiber production can be greatly expanded by mere extension of present knowledge. Control of insects and diseases, improved fertility and water management, soil conservation, and refined materials processing all will increase the capacity of the nation to produce food and fiber (Quance, National Academy of Sciences 1975a).[7]

---

[7] For a more systematic examination of current food systems and near futures, see U.S. Department of Agriculture and some 1985 projections in Quance. The National Academy of Sciences report (1975b) is consistent with Paarlberg. The report is summarized with "For the next decade or so, we think we perceive that the supply of food, feed and fiber will be adequate . . ." (p. 102). But the report adds, "This period of adequacy, which we believe we can foresee, is somewhat irrelevant in view of the concerns raised in this report" (p. 102).

In the longer run at least two technological advancements—energy management (Steinhart) and genetic engineering—will greatly enhance the potential for food and fiber production and will also affect the organization of agriculture.[8] Solar energy is presently used at a small fraction of what might be available. There is great potential in methods to tap the power of the sun (Calvin). Plants may be used to store energy for fuel, particularly in humid areas. In arid areas solar power generation is possible through heat and steam or chemical generation of electricity. Solar energy, however, awaits major scientific and technological development before it becomes the main source of power.

The remarkable advancements in the science of genetic information clearly portends major development in food and fiber production. Plants and animals will be designed with a combination of selective breeding and DNA modification. Insects can be bred for toxic vulnerability to cheap nonpolluting poisons. Nitrogen-fixing qualities can be built into plants. Animals can be designed for market preferences. Many opportunities exist, but genetic engineering is in its infancy, and the scientific community is proceeding conservatively. The redesign of humans to expand economic capability of resources—smaller people, for example—is an intriguing possibility but unlikely in the near future.

With more energy and more efficient plants and animals to use the energy, the likelihood of the omnivorous, flexible homo sapiens to survive and prosper is great if not assured. The quality of life, satisfaction of demands, and specific adjustments of the supplies of goods and services will depend on population levels, structure, and tastes such as nutritional values.

The effectiveness with which scientific effort is encouraged and used will depend to a great extent on organization. It is almost certain that the agriculture of the future will look no more like today's agriculture than today's agriculture resembles neolithic food gathering. The organizational change from today's agriculture probably will be toward two general forms: the food and fiber factories, concentrated physically and financially to serve national and global transportation facilities, and the natural farms based on occupational (today's subsistence, part-time, and retirement farms), recreational (today's hobby farms but in greater number), and cultural (tomorrow's art form) objectives. The two organizational forms will coexist and to some extent support one another. Financial requirements will tend to centralize and concentrate the food factories. The hobby, art, recreational, subsistence, and other natural farms are to a large extent consumption activities. They will not influence the bulk of the food and fiber production.

Speculation about the likelihood of future of farm factories does not mean that they are particularly desirable or inevitable (Clark, Schumacher). The potential for monopolization of food availability and the potential for a calamitous interruption of supply are two strong arguments against food factories or other forms of concentration. With a direction of research and development of more intensive, safe, imaginative, and pleasant use of labor; small-scale technology; production techniques for small-scale enterprises; small-scale marketing and financial institutions, a widely dispersed production-oriented agriculture could persist for a long time.

If there is continued unionization of the labor force, concentration of financial resources, and emphasis on mass production techniques in agriculture, then the food factory is likely. Resource markets will correspond to the concentrated production organization.

Two markets for land will appear: industrial, where high prices for land will encourage capital intensity, which in turn will increase the price of land, and consumptive or subsistence. Capital-intensive, financially sophisticated food and fiber factories will tend toward a separation of property interests in land and a development toward second-order interests in land (negotiable, transferable interest in a land-holding entity such as a corporation or syndicate). The consumption or subsistence farms will involve less separation of interests in land than the food factories but greater parcellation; an appropriate analogy might be today's single-family detached home, compared to an apartment condominium.

Much of the future of property and agriculture would appear to depend on effective information management. Both biological and organizational processes, almost by necessity,

[8] The use of machinery in the United States has resulted in a net loss of energy, i.e., agricultural consumes through oil more energy in British thermal units than it produces in food. Moreover, the energy "subsidy" (calories of input in relation to calories of output) has risen from one in 1910 to eight in 1970 (Clark, p. 44).

will become more complex. In research, management, and legislation, information requirements will increase. Issues of privacy, independence, freedom, responsibility, interdependency, control, and equity will surface in many ways in many places. Better information, obtained faster and less expensively, will be needed to resolve these issues. The property system will be no exception.

The problem of organizational complexity and information as it pertains to property and agriculture in the past and in the future suggests two areas of social science research: historical theory of complexity, equilibrium, and growth of institutions and a theory of the conservation of information on which research and design of organizations could be based.[9]

The Demographic Shift Toward Rural Areas
(Lynn Daft, Congressional Budget Office, Chairman)

A Further Look at Nonmetropolitan Population Growth Since 1970

Calvin L. Beale

The fact that the trend of population growth in the United States had turned toward rural and small town areas began to become public knowledge late in 1973. It took a while for the information to be widely distributed and to be accepted, for it went against the grain of much that economists and others in research or policy positions believed probable. By now it has been widely reported in the news media and seems to be part of the public's general stock of information. The purpose of this presentation is to give an updated assessment of the trend and of the circumstances that are associated with it. (For an earlier and fuller discussion of the subject, see Beale 1975.)

The simplest way to show the trend is to compare growth and migration rates for metropolitan and nonmetropolitan areas. From April 1970 to July 1974, the nonmetropolitan counties of the United States increased in population by 5.6%, while metropolitan counties grew by 3.4% (table 1). Neither of these rates is especially high, for the birth rate has been low almost everywhere. But with the possible exception of a brief period during the heart of the Great Depression, we do not appear in the modern history of our country ever to have had a previous time when nonmetropolitan population growth rates exceeded metropolitan rates. From 1970 to 1974, a net of 1.6 million people moved into nonmetropolitan counties. By contrast, 3.0 million net outmigration took place from these counties in the 1960s, and an even larger number in the 1950s. County population estimates for 1975 are available for thirty-two states at the time of writing and show a continuation of the 1970–74 pattern (U.S. Dep. Commerce 1975a). I expect the net movement nationally into nonmetropolitan areas to be about 1.9 million for 1970–75.

It is my experience that people who are cautious or skeptical about the trend want to know at least three things. Are the data reliable? How widespread is the phenomenon? Couldn't it just be an increased rate of sprawl out of metropolitan areas into adjacent nonmetropolitan territory?

The principal source of current population data is the annual series of estimates for all counties that the Bureau of the Census now makes in cooperation with state agencies (U.S. Dep. Commerce 1975a). There is simply no foolproof method of estimating population change for counties in intercensal years, and some of the estimates will undoubtedly be proven incorrect by the next census, even as to direction of change. But the average quality of the county estimates is good (as can be judged by their degree of correspondence with special censuses that are taken) and has improved with the addition of residential data from the Internal Revenue Service since 1973. (These data are made available to the Bureau of the Census in the form of computerized records of individual income tax returns.) Current estimates may overstate metropolitan populations to some extent, but it is not conceivable that the figures are yielding a wrong signal at the national level. Interview data from the Current Population Reports show the same pattern of growth, although at more modest levels (U.S. Dep. Commerce 1975b). Furthermore, available causal data, such as the Social Security Administration's statistics on covered employment and on location of retired worker beneficiaries, confirm the population data and are based on records

---

The discussant for this session was Lee M. Day of the Northeast Regional Center for Rural Development.

Calvin L. Beale is the leader of the Population Studies Program, Economic Research Service, U.S. Department of Agriculture.

Table 1. Population Change by Metropolitan Status and Selected County Characteristics

		Population					Net Migration			
		Number (1,000)			Percentage Change (%)		1970–74		1960–70	
Item	Number of Counties	1974	1970	1960	1970–74	1960–70	Number (1,000)	Rate[a] (%)	Number (1,000)	Rate[a] (%)
Total United States	3,097	211,392	203,212	179,323	4.0	13.3	2,076	1.0	3,001	1.7
Metropolitan status[b]										
Metropolitan counties	628	153,930	148,809	127,191	3.4	17.0	461	0.3	5,959	4.7
Nonmetropolitan counties	2,469	57,463	54,404	52,132	5.6	4.4	1,614	3.0	−2,958	−5.7
Adjacent counties[c]	969	29,780	28,022	26,116	6.3	7.3	1,010	3.6	−705	−2.7
Nonadjacent counties	1,500	27,683	26,382	26,016	4.9	1.4	604	2.3	−2,253	−8.7
Entirely rural counties	623	4,618	4,353	4,548	6.1	−4.3	190	4.4	−553	−12.2
Characteristics of nonmetropolitan counties in 1970										
Counties with 10% or more net inmigration at retirement ages[d]	360	8,653	7,554	6,340	14.5	19.2	932	12.3	624	9.8
Counties with senior state college	187	9,031	8,434	7,463	7.1	13.0	323	3.8	91	1.2
Counties with 30% or more employed in manufacturing	638	20,143	19,257	18,193	4.6	5.9	356	1.8	−746	−4.1
Counties with 30% or more employed in agriculture	331	2,062	2,057	2,305	0.2	−10.7	−17	−0.8	−412	−17.9
Population density per square mile in nonadjacent counties										
150+	15	1,176	1,124	1,020	4.6	10.2	17	1.5	−10	−1.0
100–149	35	1,929	1,842	1,699	4.8	8.4	18	1.0	−73	−4.3
75–99	61	2,781	2,674	2,568	4.0	4.1	20	0.7	−170	−6.6
50–74	127	4,298	4,099	3,990	4.9	2.7	84	2.1	−313	−7.8
25–49	351	7,764	7,412	7,270	4.8	1.9	176	2.4	−541	−7.4
10–24	405	5,681	5,412	5,562	5.0	−2.7	177	3.3	−584	−10.5
Less than 10	506	4,054	3,820	3,907	6.1	−2.2	111	2.9	−561	−14.4

rather than estimates (U.S. Dep. Commerce 1974; U.S. Dep. Health, Education, and Welfare). Beyond this, one can always go and see for oneself. Many local journalistic accounts document the change, and in my travels I have yet to visit an indicated turnaround county where the local officials were not aware of the trend occurring.

As measured by the rate of net migration, all but two states show increased net retention or greater acquisition of population in their nonmetropolitan areas in the 1970s as compared with the 1960s. The two exceptions are Rhode Island, where the only nonmetropolitan county had a military base closing, and Connecticut, where the state's two nonmetropolitan counties continued to attract population but at a reduced rate. In the 1960s, thirty-six states experienced nonmetropolitan outmigration. This number is down to eight in the 1970s. Thus, the new trend of population change in nonmetropolitan areas is widespread, affecting every region and subregion of the country.

The third question, concerning metropolitan sprawl, is best answered by looking separately at those nonmetropolitan counties that are adjacent to metropolitan areas and those that are not. The adjacent counties contain slightly more than half of the total nonmetropolitan population, and their population increased by 6.2% from 1970 to 1974. This rate of growth is somewhat higher than that of the nonadjacent counties (which was 4.9%) and has increased since the 1960s. So there is an adjacency effect, as one might logically expect. But it is not an either/or situation. Both adjacent and nonadjacent classes of nonmetropolitan counties have had a migration reversal. The force of the reversal has actually been stronger in the more remote nonadjacent class than it has in the adjacent group. Numerically, the reversal amounts to an average of 369,000 persons annually in the nonadjacent counties compared with 307,000 annually in the adjacent counties.[1] As a result, there is less difference in the migration pattern of the two classes of counties today than there was earlier, although the adjacent group still has the higher rate of growth.

My basic approach to drawing inferences from the data about the nature of the new

[1] These numbers represent the difference between the average annual net migration for each adjacency group in 1970–74 compared with the annual average of the 1960s.

trend has been to classify counties by certain basic functional characteristics and examine the trend in those that are dominated by some feature or function. In this approach, the nonmetropolitan counties that show the most rapid growth are those that can be termed retirement counties. The designation is made on the basis of 1960–70 trends and excludes the additional retirement counties that are now developing, but the results are impressive. In the 360 nonmetropolitan retirement counties total population grew by 14.5% from 1970 to 1974, with a net inmigration of 932,000 people. This is a rate of growth of more than 3% per year. The inmigration to these counties was more than half of total net inmigration into all nonmetropolitan counties. But essentially all retirement counties gained in total population. Thus, the rest of the country contains nearly all of the 600 nonmetropolitan counties that have lost population, as well as others that have grown. Many of the retirement counties have other sources of growth than retirees, such as recreation businesses or manufacturing. Although we all nominally understand that there are more older people than there used to be and that retirement plans have become more generous in both money and age of eligibility, we have not fully anticipated the potential implications of these developments on population distribution. Most retired people do not move, but those who do go disproportionately to nonmetropolitan locations, especially areas accessible to water (whether lake, reservoir, or ocean), scenery, or a favorable climate. They create business and employment, yet are not constrained by the need for employment themselves.

The second most rapidly growing class of nonmetropolitan counties is that where a senior state college is located. These counties include 9 million people, are basically exclusive of the retirement counties, and grew by 7.1% from 1970 to 1974. Like the retirement counties, they were already having population gain in the 1960s. The pace has increased in the 1970s, but there is suggestive evidence that it may have slowed since 1973 with the end of the military draft and the general peaking out of college enrollment rates.

In the 1960s, one of the main economic trends was the decentralization of manufacturing. In that decade, there was little manufacturing growth nationally, but a substantial shift of plants to small city or rural locations took place. The most cited reasons for the shift seem to be utilization of underemployed nonmetropolitan female labor force, lower wage rates, better worker attitudes, less unionization, availability of cheap land, improved transportation, and flight from urban ills in general. In some parts of the country the increase in manufacturing jobs was truly dramatic. For example, in the twenty-three counties of Tennessee that lie on or west of the Tennessee River (exclusive of those that adjoin Memphis) manufacturing employment rose by 98% in the 1960s on a base of 32,000. In twenty-six counties of northern Arkansas—both Ozarks and northern Delta—the growth was 70% on a base of 24,000.

Often this growth took place in areas that had a comparatively small initial proportion of workers in manufacturing and were simultaneously losing farm employment heavily. Thus, the impact of the manufacturing growth on population retention in the 1960s is somewhat masked, for a majority of it did not occur in counties already having a large industrial base where additional nonfarm jobs would automatically be reflected in net employment and population gains.

If one looks at the record of counties that now have a high dependence on manufacturing, such counties (defined as those where manufacturing comprised 30% or more of all jobs in 1970) had a 4.6% population increase from 1970 to 1974. This is higher than their growth of the 1960s and represents a turnaround from outmigration to inmigration. But it is distinctly below the rate of growth being observed in counties with less than 30% dependence on manufacturing. Manufacturing comprised 50% of all growth in nonmetropolitan employment in the 1960s. The subsequent slackening of manufacturing and the surge in trade, services, and other sectors (except government) has seen manufacturing jobs amount only to 3% of nonmetropolitan job growth from 1970 to 1976 (USDA).

As might be expected, counties with high dependence on farming are still having net outmigration. Those with 30% or more dependence as measured by a 1970 industry group of workers had only 0.2% growth from 1970 to 1974 and 17,000 net outmigration. Even so, this is a far lower pace of outmovement than in the 1960s, and counties that continued to have this degree of involvement in the production phases of farming contained just 1 million people in 1970, less than 0.5% of the total U.S. population. The agricultural employment base

is now so small that its trend can have relatively little further effect on the total trend of nonmetropolitan change.

One of the most interesting and significant aspects of the recent trend is the complete shambles that it has made of the former strongly positive association between density of population and growth. If one classifies nonmetropolitan counties by persons per square mile, as in table 1, it is immediately apparent that in the 1960s preexisting high density was almost a guarantee of population growth, and very low density was associated with population decline and heavy outmigration. In the 1970s, the highest rate of growth occurred in the counties with the lowest density, rather than the highest, and there is little difference among other classes. This finding is also consistent with the fact that if counties are grouped by size of largest town, the completely rural group (with no place of 2,500 people) shows the highest recent growth.

Here is convincing, even startling, evidence of a rapid shift down the scale of residence that involves the most remote, least settled, and least urbanized parts of the country. Nothing in the literature of the 1960s foresaw such a change in the association of scale and density with growth.

This feature leads me to note a distinction among the metropolitan areas that is sometimes overlooked in the metropolitan-nonmetropolitan dichotomy that characterizes so much of the public discussion of the trend. If one groups metropolitan areas by size class, those of less than 750,000 population are found to have had increased net inmigration during the 1970s. Only above this size is the movement into the metropolitan areas typically reduced or negative. The small and small-to-medium-sized metropolitan areas are showing the same increased attractiveness to population growth that the nonmetropolitan areas are showing. The major point of inflection from the trend of the past is up within the ranks of the metropolitan areas. The nonmetropolitan reversal is the most extreme aspect of a larger trend.

Press reports on the new trend have occasionally carried back-to-the-farm headlines that had no basis in the content of the story. But there are a couple of agricultural aspects that need mentioning. First is the not-well-enough-known fact that since 1970 the decline in younger farmers has stopped and the median age of farmers is dropping. Persons under age thirty-five solely or primarily self-employed in agriculture rose by 35% from 1970 to 1975 as measured by the Current Population Survey (Beale 1976). The departure of farmers over sixty increased, and median age fell from 53.1 years to 50.4 years.

I have visited agricultural officials in about twenty counties in several states in 1976 and in almost every case have gotten field confirmations of the trend, usually emphatic confirmations. Noneconomic considerations related to attitudes and values are given almost as often as are economic factors as motivating factors in the increased number of young farmers. The result is to introduce more young farm families into the countryside despite some continuation of the trend of farm consolidation. Second, in less commercial farming areas, there is an undeniable trend of entry into farming of people with nonfarm backgrounds. This back-to-the-land phenomenon is difficult to quantify but is commonly reported in news stories and is very much in evidence in areas such as the Ozarks, northern New England, the Upper Great Lakes country, the Blue Ridge Mountains, and parts of the far West. Failure rates are almost certainly high, but some net accrual to the rural population occurs.

Allied to this aspect of the overall trend is the reported trend of occupancy of former farm homes. In the same field visits referred to above, it was consistently reported that the practice of demolishing former farm homes that was so common a few years ago has changed. Such homes are now commonly rented or bought with five or ten acres by people who work in towns (whether metropolitan or not).

Trend data on towns per se are available only through 1973 and are not as reliable as for counties, at least among smaller-size places. But a tabulation of the Census Bureau's estimates for 1973 (not shown here) shows nonmetropolitan towns of 10,000 or more people increasing in population by little more than half the rate of the rest of the nonmetropolitan population since 1970 (Fuguitt and Beale). This is consistent with the growth pattern for counties classed by size of largest place or by density and with the diminished rate of growth in nonmetropolitan urban towns that was found in the 1960s. In many respects the nonmetropolitan towns are experiencing in a micro way the same trends as metropolitan central cities; that is, there is a decay of the central

business district, growth of suburban shopping malls, and a dispersal of people out into the surrounding countryside or villages. The towns continue to annex land and people in states where the laws are permissive, but they find it increasingly difficult to reacquire in annexable areas as many people as they lose to areas too distant to annex. In a very real sense the current trend of population distribution is one of renewed rural residential growth—open country and village. A majority of it occurs in counties that have no places of 10,000 people, and it is especially pronounced in counties that lack any town of even 2,500 people.

As a result, there is a strong likelihood that the total rural population may increase when the next census is taken. In the past two generations, so much growth in rural areas has become urban in character and reclassified as such that there has been essentially no net increase of the rural population. I am rather dubious that the rural population could ever go above 60 million people, but it now appears to be advancing toward such a level.

Presentation of these trend data leads logically to questions about the future. The older I get the more skeptical I become about demographic projections. The record as to fertility, total population, and distribution ranges from poor to terrible. Yet the demand for projections and the comparative painlessness of making them in the age of computers combines—like Shaw's view of marriage—the maximum of temptation with the maximum of opportunity. I simply do not believe that we can foresee societal behavior well enough to say with any confidence how long the current shift of growth patterns to smaller-scale communities will last or how far it will go. Beyond stating that I do not envision the end of great cities or urban dominance, I am content with saying that the current distributional trend is real and substantial (not just a transient and negligible aberration) and has substantial momentum that seems likely to continue at least into the next decade.

All of the current complex of forces that produce the trend essentially favor a continuance over the middle term. Some are the comparatively favorable economic condition of nonmetropolitan areas as reflected by growth of jobs and reduction of the metropolitan-nonmetropolitan income gap; the absence of much further displacement from farming; the revival of mining; continued growth of a retired population oriented toward recreational or climatically favored areas; the downscaling residential aspects of the environmental-ecological movement, butressed by certain nature-oriented and antimaterialistic elements of the youth revolution; the unfavorable image of the great cities in such areas as crime, drugs, pollution, race conflict, school troubles, and fiscal matters; the near elimination of many former rural-urban gaps in material conveniences of living, such as water supply, plumbing, heating, electricity, roads, and communication; the high cost of metropolitan housing; and the emergence of an adequate system of post-high school education in nonmetropolitan areas.

The major potential problem that I foresee is the matter of gasoline costs and supply. The new trend of population is not energy conserving. Rural people use considerably more gasoline per capita and have less in the way of public transportation alternatives during an emergency (Rupprecht). What would happen if there were another oil embargo of greater length? What would happen if the price of gasoline assumed European levels?

A second potential lessening of the nonmetropolitan migration could stem from the low birth rate of the last decade. Fewer families in the coming years will have an incentive to seek smaller communities out of concern for the welfare of their school-aged children, a motivation fairly commonly encountered today.

A final consideration in viewing the overall trend is that it has to be put in world context. Demographic turnarounds of this magnitude rarely occur in national isolation. The present trend is international in character. It may be further advanced here than elsewhere, but slowdowns in urbanization can be measured in a number of the most advanced nations (Wardwell). I had no sooner published on the subject than I received an article by investigators in Sweden on the return to small towns in that country. Social scientists have given little thought to the probable settlement pattern in modern nations beyond the urbanizing period. Once modernization proceeds to the point that rural-urban disparities are relatively eliminated, and urbanization rushes to the point that the urban environment is impaired, is there any further need for or likelihood of additional massing of people? The answer may be "no."

Some would say that the present trend is nothing but an urbanization of life in rural

areas, whatever the location. To some degree this is undoubtedly true. Indeed, the AAEA once heard a presidential address on "The Urbanization of Rural America" (Bishop). But the new trend cannot be simply explained away semantically. It represents a major departure from what was publicly anticipated and will have a variety of consequences. Whatever the style or content of life of former urbanites in the rural and small city environment, the setting is no longer metropolitan urban for them, and the difference is consciously meaningful to them.

The advantages of urbanization are erodible and not without limits in societies where rural areas are no longer isolated and backward or retarded by an urban-oriented value system. Subtly but surely, we have entered a transition in population distribution that does not make this country a rural nation again but that greatly modifies the vision of unbridled megascale urbanism that seemed to dominate our perceptions a few years ago.

Forces Influencing Rural Community Growth

Kenneth D. Rainey

This paper focuses on three questions. What is happening demographically in the rural areas of the United States? Can the recent growth trend be expected to continue into the future? What does this imply as far as public policy and programs are concerned? The first question has been dealt with very capably by Beale (1975, 1976). There is little room to doubt his statistical evidence. As the latter two questions lend themselves more to nonstatistical arguments and as I have little data, I will concentrate on them.

That this country is at or nearing the end of an era seems certain, but what lies ahead is by no means certain. Several years ago the Virginia Rural Affairs Study Commission published its first report with these words and nothing else on the cover: "Since the industrial revolution, cities have been growing and rural people have supplied the growth." Today that quote would not be accurate. Cities, at least the largest ones, do not seem to be growing any longer, and taken as a whole the nonmetropolitan areas are growing faster than the metropolitan areas.

Twenty years from now will another rural affairs report state: "The decade of the seventies marked the end of metropolitan growth and the beginning of a rural renaissance. A new settlement pattern developed in the United States, one that was unique for a high technology economy"?

The statistics on growth in the seventies suggest three possibilities: (*a*) a change in the functions of metropolitan and nonmetropolitan areas; (*b*) the decline of the city as the major cultural and economic focus (it has happened before; at the end of the Roman era in the fifth century cities could not be sustained by the culture and were thus abandoned); and (*c*) a decline in the utility of our statistical definitions and the continuing homogenization of America. This latter is much less dramatic. If it is merely the definitions, we ought to be able to handle that among ourselves. The homogenization of America, however, might be just as much a cause for concern as the beginning of a new Dark Ages.

What is probably happening is a mixture of all three of the above possibilities. What is happening and what it means will not leap out of the statistics on metropolitan and nonmetropolitan change. Instead, one must step back to look at some of the major forces that will influence the American economy and demography for the next few decades. It is these major national forces that will shape not only how many people will live in the rural areas but also their relative well-being.

First among these forces is the aging of the baby boom. The children born in the post-World War II years have had already a tremendous impact on this nation. Grade schools had to be built to accommodate them, then high schools, and then colleges and universities. Some analysts warn that the biggest challenge lies ahead—having an economy that will not only generate jobs for these young adults as they enter the labor force but also will contain adequate opportunities for upward mobility as this group advances into middle age (Johnston). Moving an inverted population pyramid through hierarchical organizational structures seems quite a challenge. How this can be met is one of the great unknowns of the future. Johnston points out that the annual growth in the labor force in the years preceeding the coming of age of the war baby boom cohorts was about 880,000, of which less than 150,000 were teenage workers. More recently the annual growth has been over 1,700,000, with over 300,000 teenage entrants. The peak lies ahead. To the growing number of new teenage entrants into the labor force one must add the rising expectations of women. This combination is difficult to por-

Kenneth D. Rainey is vice-president for program management at the Academy for Contemporary Problems, Columbus, Ohio.

tray adequately in statistical terms. There has been a tremendous growth in the measured labor force, an even greater growth in the potential labor force, and a still greater growth in the demand for jobs and careers that offer some upward mobility.

The movement of the war baby boom cohort into the labor force is one of the most important, if not the most important, factors that will shape the future distribution of population in the United States. Where the war babies go will be where the growth will occur. As has been true of past generations, they will doubtless go where the jobs are. Where will the jobs be in such vastly expanded numbers? More important, will economic and political institutions be able to generate them anywhere? Let us not be choosy about rural or urban locations. If they cannot be generated, we may face a social time bomb far more important than the metropolitan-nonmetropolitan distribution of population.

A second trend to be recognized is the continued decline in the birth rate and aging of the population. It seems the birth rate will continue to decline in both rural and urban areas (U.S. Dep. Commerce 1974). Rural areas will not serve one of their traditional functions as supplier of immigrants to the cities. As the population rapidly ages, there will be a substantial shift in the demand for public services. Fewer schools will be needed, but health care needs and facilities for the aged will increase.

Third, the problems of the war babies will be made much more acute if the predictions regarding lower rates of job formation and economic growth in the United States do come to pass. One current debate is whether the U.S. rate of economic growth over the next few decades will be substantially less than it has been in the post-World War II period (U.S. Dep. Housing and Urban Development). An election year may not provide a dispassionate assessment, but some implications of slower growth are troublesome. The United States has done its problem solving out of its growth. It has not gone in for absolute redistribution of wealth, only for changing who gets what shares of the increment in national wealth. Furthermore, the most serious consequence of slower growth is that it will doubtless reflect a lower rate of job formation.

Energy supply and cost constitute a fourth factor. The cost of energy relative to other costs almost certainly will increase. Some supply difficulties and shifts in the various fuel shares of overall energy needs also seem likely. This will have many confusing impacts on rural areas and their development. First, rural areas as suppliers of raw materials for energy will see tremendous activity (a carefully vague word). Appalachia is now having another of its boom periods—lots of jobs, lots of activity. But whether it will have a lasting, favorable impact on the well-being of the Appalachian people is not clear. Second, rural industry has become dependent on relatively cheap oil. Agriculture is now dependent upon both energy uses of oil and petrochemicals for insecticide and fertilizer (Wilson). Availability problems and increased cost not only will require adaptation to new sources and equipment changes but also may severely decrease the profitability of some kinds of production. Increases in the price of gasoline for automobiles will make the rural pattern of long distance commuting very expensive. Increased transportation costs for industry may again tip the production cost balance in favor of more central locations.

The final factor to consider in looking at the future of nonmetropolitan areas is the role of American agriculture in maintaining the world food supply. The huge decrease in rural population due to the mechanization of agriculture is doubtless over. We have more than enough productive capacity to meet our own needs and traditional markets. If the United States was to become a major supplier of antistarvation food reserves to the world, it would mean a substantial increase in production and in the relative wealth of U.S. agriculture, but probably only a modest increase in rural population.

Each of these major forces has more than one possible outcome, of course. It would be mere fortune telling to say which outcome will occur. We have been surprised in the past by shifts in such factors as birth rate and lifestyle preferences. Furthermore, the factors can be combined in a number of ways, offering a sort of do-it-yourself futures kit.

What may be happening is an extension and blurring of the metropolitan outer ring (U.S. Dep. Commerce 1975). The settlement pattern of the United States is developing into a huge Swiss cheese, with two kinds of holes. The first kind of hole is the central cities of the older and larger metropolitan areas, which are emptying like the dust bowl of the 1930s. The other kind of hole in the demographic Swiss cheese is the large and still remote areas in the mountains—the Great Plains and the West. Both of these kinds of holes seem likely to lose population, at least relatively, to the cheese

itself. We have no present statistical term to describe the cheese. It is the fringe of the major urban conglomerations, the smaller and medium-sized metropolitan areas, and the less remote nonmetropolitan regions. Beale is quite correct in saying that much of the 1970–74 growth cannot be explained adequately by saying it is merely nonmetropolitan areas becoming metropolitan (1976). However, an important factor is that all of this fringe area, whether metropolitan or not, is tied to the metropolitan economy for many kinds of services and trade. The growing counties are hooked into the metropolitan areas for most of their supplies, services, and markets.

For future public policy the meaning of all of this can be summed up in three inequalities.

First, agriculture does not equal rural America. For a long time, we have known it is improper to equate the needs of agriculture with those of rural areas, but we continue to do it anyway. Agriculture is an increasingly urban business even when it is done far away from the city. Thirty-six percent of the agricultural employment is in metropolitan areas, and only 12% of the nonmetropolitan employment is in agriculture. From a public policy standpoint, one should be careful about arguments concerning the likely benefits to be achieved through certain public programs for either agriculture or the rural community. The welfare of the two have less and less to do with each other.

Second, industrial development does not equal increased community well-being. Summers's recent work is a very important research finding in the field of economic development. It gets at the mythology of industrial development and shows new manufacturing plants often cost the rural community far more than it gains. The multiplier is much lower than once anticipated. We lack good ways to calculate in advance costs and benefits to different parties. The community sometimes gives away its taxing potential to attract the industry and then must provide facilities to serve it. The labor force commutes in from a nearby metropolitan fringe with a lunch box. A wholesale revamping of both national and state economic development programs is needed. We are paying a tremendous public price to take money out of one pocket and put into another. An even more serious concern is that we have not known what pocket we were putting it into.

Third, growth or increased well-being for rural America does not equal growth or increased well-being for the rural community. Because much of the rural population and rural industry is directly linked to nearby metropolitan regions for supplies, services, and markets, the growth in rural population and even rural employment does not reflect a corresponding increase in the health of rural small communities. This is the final area that public policy should address. These communities are called upon to supply public services but frequently are losing ground economically. Small town business is losing out to metropolitan areas. Rather than filtering its needs for equipment, supplies, or repairs through small town business, primary industries, whether agriculture or manufacturing, increasingly go direct to metropolitan outlets. The retail consumer does the same thing, bypassing the small town store for the shopping centers. Economists do not worry about this sort of thing, because in their view it represents a triumph of the market economy, and they have little enough of that to point to. But this "triumph" represents discontinuity, a growing gap between those communities expected to provide public services and their ability to pay for them. It also represents the increasing ability to some people and organizations to externalize their costs on others.

As Beale pointed out, people are slow to accept the notion that the growth patterns have changed (1976). We knew and loved the notion that people were moving from the country to the city, and it has been very hard to cast off the mental image of that development pattern. If people are slow to accept these changes, they are slower still to change public policy to adapt to them. Agriculture and community development policies are still based largely upon the images of the past—the need to keep people on the farm, even the small and relatively inefficient producer and the need to help depressed areas, which were largely rural. Congress and the state legislatures will have to be busy and effective in the next few years if we are to stop giving out the medicine to cure a sickness the patient no longer has, while ignoring those that now afflict him.

Economic Implications of the Recent Population Shift Toward Rural Areas

Marion Clawson

Beale has presented clear evidence that a shift in the direction of migration has taken place in the United States in the past few years (1976), and he has given the best available indications of who these people are, in terms of their age, income, occupation, family status, and the like. My task is to speculate on the economic, social, and political significance of these population changes. In the nature of the situation, any remarks must be more speculative and less firmly based on facts than is his statement.

It is well to start by recalling that Americans have always been a mobile people, quite possibly the most mobile large population the world has ever known. The first century of our national existence was dominated by the vast westward tide of migration; the Bureau of the Census has calculated that the center of population in 1790 (when the first Census was taken), was 23 miles east of Baltimore (U.S. Dep. Commerce); by 1890, Turner in his famous essay, using census definitions, concluded that the frontier had vanished. The second century of national history was dominated by the vast rural-urban migration, which built the cities and transformed the nation. Each of these two major migration tides extended to some extent to earlier and later periods. Overlaying and supplementing these two major streams of population movement have been numerous others, smaller in numbers, more localized geographically, more specialized in population characteristics, or with some combination of these factors.

Extensive areas of the United States have lost population persistently. More than a third of all counties have lost population in each decade since 1910, with half losing in the 1940s and 1950s, and a substantial proportion of these counties have lost in most or all these decades. There are extensive areas of the Corn Belt, as well as hill country, mining areas, and other less economically soundly based areas, where the maximum population was reached as early as 1900. Our economic literature is full of theorizing and of empirical studies of growth; decline, at least in population numbers, has been common, yet has had but a small fraction of the professional attention (Clawson).

Still less professional attention has been directed at areas that declined in population for a considerable period of time, then reversed their own trend and grew. The 1930s were generally a period of population growth in many counties that had previously declined, but this was a measure of the greater unemployment and depression in the city than in the home county. There are more than fifteen counties in southern and central Indiana that have lost population in every decade from 1900 to 1930 (and some in earlier decades as well), only to reverse themselves in the 1930s and to grow in population in every decade since then. It is interesting that in central and southern Illinois also about twenty-five counties declined in the same period of decline (1900–30) but have continued to lose in at least two out of three decades since 1940. There appears to be no explanation for these divergent trends within roughly comparable states. The 1960s was a period of population growth in roughly 100 counties in the South, mostly in the Ozarks and other hill country, and some in other parts of the country, which had previously lost population for several decades. Hansen has tried to explain the recent population trends for groups of "turnaround-reversal" and "turnaround-acceleration" counties of the 1960s, but, by and large, the "reversal areas" have had little professional analysis.

Beale (1976) and others are now calling our attention to the recent and general reversal of population growth in relatively rural, or nonmetropolitan, counties as compared with metropolitan ones. He has pointed out that some

Marion Clawson is with Resources for the Future, Washington.

of the increased population is due to greater retention of the natural increase, but some is due to net immigration. While the counties nearer the metropolitan areas have grown somewhat faster, the more remote nonmetropolitan areas have also grown, and faster than the metropolitan areas.

Any analysis of migration or of population changes generally is dependent upon the disaggregation of time and space in the available data. Until fairly recently, analysts were dependent upon the ten-year population census for relatively finer-grained analyses. It is only in comparatively recent times that the kind of relatively fine-grained analysis based on annual data, which Beale has presented (1976), was possible. But the geographic unit of analysis may affect results also, whatever the time intervals used. For convenience in analysis, many have used county data; this seems the best compromise between geographical specificity and manageable amounts of data. Nevertheless, county data may conceal many intracounty shifts in population. For instance, a county may show a relatively constant population over a series of decades, yet the largest town has been growing steadily, obviously at the cost of population loss elsewhere in the county.

Are the recent shifts in population, away from metropolitan areas and toward nonmetropolitan areas, the beginning of a major persistent trend, or will they prove to be a relatively limited episode in national population history? Are they the beginning of a new wave of major population movement, in some degree comparable to the westward and cityward tides of the past, or do they represent primarily a backlash from the rapid—perhaps overly rapid—metropolitan growth of the past twenty-five years? Only time will tell. The changes described by Beale (1976) are too recent and too small for us to draw any firm conclusions.

In some of his writings, Beale has suggested that the recent shift to nonmetropolitan areas has been in a sense "against the current" of income; that is, instead of moving toward higher incomes per person, as migration historically has, people are now choosing somewhat lower incomes and better living conditions (1975). Does this in some degree represent a new attitude toward income and the material aspects of living that income can buy? If so, how far is it a function of the higher average income levels of today; i.e., when one enjoys a good level of living, perhaps he can be more cavalier about further increases in income than he was when he was poorer. It is true, as Beale (1976) and others have pointed out, that opinion surveys have long reported that many people expressed a preference for small town living. Some of us have been unimpressed by these verbal expressions of choice, noting that in practice more people moved cityward than moved in the opposite direction. But maybe the time has now come when a significant number of people are acting as they have long said they preferred to act.

The recent migrations from metropolitan to nonmetropolitan areas involve substantial transfers of income. All migrations involve income and wealth transfers to some extent; migrants bring not only material possessions but also education, skills, and other personal qualities that often enrich the receiving area. But a significant proportion of the recently added population in the nonmetropolitan counties receive pensions or other payments, which were either earned elsewhere in younger years or are a transfer of public funds from taxes paid elsewhere, in either case, to recipients in the receiving area. The nonmetropolitan counties may indeed be the "best" place for such income receivers to live in terms of cost of living and of satisfactions attainable.

The flow of income to the recipient area can be a powerful economic force. Even where the recipients of such transfer payments are numerically only a small minority of the total population of the nonmetropolitan county, this income stream surely spreads throughout the whole community. Its direct recipients buy goods and services, and the provision of such goods and services in turn provides employment and income to many other persons in the community. There is no reason why an income stream based on transfer payments would have a smaller multiplier effect than an equal income stream based on commodity export. As the number and proportion of the total population living on income derived from sources other than current employment (i.e., pensions based on previous employment, public funds under any one of several public programs for the assistance of particular groups in the population) rises, then this sort of income potential for some kinds of areas also rises. If, at the extreme, all persons in the nation whose income did not depend on current employment chose to live in nonmetropolitan areas, non-

metropolitan counties (if one includes the necessary service population) would indeed experience large population increases.

As Beale has pointed out (1975), there has been some tendency for jobs to move away from metropolitan areas also in recent years. How far will the existence of a labor force, or of a potential labor force, in nonmetropolitan areas attract footloose employment there? Some part, perhaps a large one, of the postwar migration of jobs in Florida, California, and the Southwest was the pursuit of a labor force—people had moved to these areas because they wanted to live there and were available for jobs in those locations. It is by no means clear what kinds of employment, if any, would be likely to follow a potential labor force to nonmetropolitan areas. Employment in recreation enterprises, or in some kinds of manufacture such as furniture making, or various kinds of extractive employment (mining, forestry, and agriculture) may well be located in nonmetropolitan areas. Such employment will in turn generate service employment. But, over and beyond these, what kinds of employment would likely follow workers into metropolitan areas? For those who have observed the difficulties and general lack of success of rural areas in attracting manufacturing and other employment in the past, it is hard to visualize what may happen in the future. The level of national employment is obviously a factor here; if jobs seek workers, then migration of employment to areas of surplus workers becomes more likely.

It is hard to estimate what effect this migration from metropolitan to nonmetropolitan areas will have upon the average income per capita and upon content of living per average person in the nonmetropolitan areas. In the past, population loss from nonmetropolitan areas produced older populations, less well educated, with lower average incomes and poorer housing than in nearby counties gaining from immigration (Clawson). But this by no means proves that population increases will have the opposite effect. For the most part, those receiving transfer payments will not have high incomes, yet it is possible that fairly modest incomes on their part might actually lead to increased incomes per capita in the population-recipient areas. This would be true if the average income of the immigrants was above that of the former residents of the area, but it could also be true if the service and other employment created by the flow of immigration was at higher average annual incomes than had previously prevailed in the area. To the extent that the immigrants are a superior labor force, which induces a movement of jobs into a metropolitan area, then one would expect average incomes in the recipient area to rise. The net effect of these various forces is hard to estimate.

It is possible that living costs in the nonmetropolitan areas will be lower and/or living levels higher for a given level of costs. Land rents should be lower and hence the cost of new housing lower, building codes and other restrictions on building may be less costly, and there may be some relative surplus of existent moderate-cost tolerably livable housing in some areas. The opportunity to grow a garden will surely be greater, but the effect of this on net income may be modest indeed. Beale has suggested that transportation costs may be higher in nonmetropolitan areas, since workers will, on the average, have to travel further from home to jobs and will in almost all cases have to rely on personal auto transportation (1976). For some of the older people, the general lack and impracticability of public transportation in many nonmetropolitan areas may become a serious problem, irrespective of costs.

If the people who move to nonmetropolitan areas do indeed enjoy life more there, as they evidently hope to do, then of course important economic values have been created by their move even if we are hard pressed to give such values a quantification.

Increased population in nonmetropolitan areas will create a need for greater public services in such areas. To the extent that such an area has lost population during the past two or three decades, it may have some unused capacity in some forms of public services—schools, for instance. Many, if not most, nonmetropolitan areas have some excess capacity in their transportation networks; that is, somewhat more traffic can be accommodated on present roads, although more people may well lead to a demand for road improvements. Much will depend upon the age composition of the immigrants. Younger couples will create a demand for more schools; older persons will create a demand for more health services. The latter are the more likely to create serious problems for the local governments of nonmetropolitan areas. Persons fifty-five to sixty-five years of age who migrate to such areas may have few health problems now, but

in a decade or more they may create a severe local health problem. Many nonmetropolitan areas have had deficient health services in the past—too few doctors and dentists, hospitals too few and remote from much of the population, etc. One can reasonably question whether typical nonmetropolitan areas are the best places for good or economic health care for older people.

A significant immigration to a nonmetropolitan community, or a significantly larger retention of the community's natural increase in population, will change to some degree the social structure of the area. Outmigration in the past has left many nonmetropolitan areas with fewer young people. It has also probably left the community with a socially more conservative population, one more content with things as they are and less inclined to seek adventure and change. It is conceivable that newcomers (or retained young people) will fit into such a community (in the sociological sense of the term); indeed, it seems likely that many immigrants hope to do just that. But it is also conceivable that social tensions may arise between newcomers and old residents and between older and younger residents. To the extent that many of the immigrants are older and/or that a large proportion of the resident population is relatively older, there may arise sharp differences within the community, on age lines, on such matters as public expenditures for schools versus public expenditures for health services. It is hard to generalize about the social effects of the new population growth in nonmetropolitan areas, but one would expect there to be some effects, even if one is not sure in advance what they will be. Population change, especially population change arising out of migration, always produces social effects.

It is even harder to estimate the probable political effects of population growth in nonmetropolitan areas. Such areas have in many cases lost political power in recent decades, although often they have retained more power than their number of people alone would suggest. Will the newcomers, or the young people who now stay in the nonmetropolitan areas, be more active politically than if they lived elsewhere? Are they likely to be politically more conservative? Their search for what they seem to think are basic values of country and small city life might suggest political conservatism.

One may close by repeating an earlier point: it is too soon yet to have a clear indication of how profound these recent population shifts will prove to be, in terms of future numbers of people, future economic effects, and future social and political effects. The population trend of nonmetropolitan America should be an interesting phenomena to watch during the next decade or more.

A Migration from Chicago to Bull Shoals—Some Demographic Observations

A. C. Hoffman

I do not know how the demographers do it, but I classify migration in American into three major eras.

The first coincided roughly with the nineteenth century when, for whatever the reasons—to get cheap land, for adventure, or maybe just to get away from a nagging wife or the in-laws back home—many people migrated westward and settled the continent.

The second began approximately with the end of World War I, when farmers were just beginning to get "tractored" off the land, jobs in the cities were opening up as industrialization got well under way, and, after sampling the highjinks of the cities, the returning soldiers did not want to go back to the farm.

The third, as Beale has documented, is just getting under way, but this time the oldsters are in the vanguard. Armed with pension checks and plenty of time on their hands, they are setting out for distant places for a variety of reasons—to find the sun, for fun, or maybe just to try to make a new life for themselves and avoid having to babysit with the grandchildren. I am one of these, and what follows is by way of a report from the new frontier.

Bull Shoals is a little town of about 1,000 people in northern Arkansas, located near the dam on the White River that forms Bull Shoals Lake. It is nationally famous for its bass and trout fishing, but if you knew this already, it means you are neglecting your work and fishing too much.

Most of the people migrating to Bull Shoals are oldsters from up North. But quite a number of younger people are also coming and bringing their needed skills—plumbers, shop keepers, even professional people. Almost without exception, the immigrants in both these age groups are glad they came, and so are most of the natives who were already here.

There is also a discernible third group, much smaller, and comprised mainly of younger people who are seeking a simpler life-style. They do farming of a sort, grow and eat organic foods, do art and handicrafts, worry about the ecology, and sometimes let their hair grow long and tie it up with ribbons. Needless to say, they are regarded with some suspicion by the natives and their status in the community is not unlike that of the hillbillies in Chicago when they started migrating there a generation or so ago.

Development theory teaches that one should begin with the infrastructure. The infrastructure of Bull Shoals consists of the mayor and his council, a post office, one-and-a-half policemen, a volunteer fire department, and a hospital. The next thing to add to the infrastructure is a sewer system, so we can stop polluting ourselves and our beautiful lake. Across the dam and up the road a quarter mile is another little town, Lakeview. It is an exact replica of Bull Shoals, with an identical infrastructure; it is also trying to get a sewer.

To a casual observer, it would make sense to merge these two little towns and combine their infrastructures, thereby saving the taxpayers a little money and giving them better service. But woe to the local politician—or the rural development expert from Arkansas State University—who would come into either town and propose that! Bull Shoals and Lakeview are not unique in this; there are literally hundreds and probably thousands of local county and town infrastructures in rural America that, if efficiency were the only criterion, ought to be consolidated but almost surely will not be.

Community planning in Bull Shoals is, of course, in the hands of the local tradesmen and real estate brokers, who in turn are guided by the "unseen hand of Adam Smith." Since more people mean more business, the community is highly growth oriented. Some oldsters would like to see less growth or even no growth at all, but we have not had much to say about it.

Brave words are being spoken these days

A. C. Hoffman is a former vice-president of the Krafts Food Company, Chicago.

about rural planning, guided growth, etc., and I wish Godspeed to all planners everywhere. But in Bull Shoals, as in many other rural towns, planning continues to be done mainly by the marketplace. This is not meant to deprecate what the planners are trying to do. They must keep trying if there is ever to be hope for anything more rational from a public standpoint, but it is a long, hard road and involves changing some fundamental values and beliefs in rural America.

The economy of Bull Shoals and its environs is a mixed bag. When I started going there twenty-five years ago to fish, it was mainly agricultural. By Corn Belt standards, most of the farms were small, scraggly, and unkempt, many of them still are, but new things are happening.

As people and capital started coming in from the outside, and some of the natives prospered in their business and professional ventures, land ownership began drifting more and more into the hands of the well-to-do. Now one can drive about the countryside and, after a run of typical Ozark farms, come upon some pretty fancy farm setups by any standard—white fences, good buildings, fertilized pastures, and good beef cattle, often purebreds or the new exotics. As recently as fifteen years ago, farm land in the area was selling for \$30 to \$40 an acre; now it sells for five or ten times that and is still rising. Unfortunately I did not have the foresight to buy any.

Bull Shoals cannot yet be classified as an industrial complex, but it is on the way. A few years ago one of the national pharmaceutical companies (Baxter Laboratories) came into the community with a plant employing 4,000 people. Down the road a few miles is a shirt factory and also a company that manufactures bass boats, which it sells from coast to coast. One can get into quite an argument locally over whether the coming of industry is good or bad. Some call it "The Rape of the Ozarks," but most think it is the greatest thing that ever happened. Certainly from a material standpoint, it has improved the well-being of the community.

If one asks people why they migrated to Bull Shoals, most of them will say that one of the main reasons was to escape the crime and venality of the cities. In this respect, their hopes have not been fully realized.

On a per capita basis, crime in the Ozarks is probably not far behind what it is in Chicago. There are usually a couple of murders a year in the community; recently the Bank of Bull Shoals was successfully robbed by a couple of escaped convicts, and not long ago a shopkeeper in a neighboring town was shot dead in a holdup. The local weekly paper frequently reports up to a half dozen break-ins, and there is a usual spate of brawls and bloodlettings sufficiently serious to call in the police.

In several important respects, however, Bull Shoals is considerably better than Chicago in the matter of law and order. Not that it makes much difference to the victim, but most of the crime (not all of it) is personally motivated in the sense that it results from human passions or drinking too much pop of a Saturday night rather than being perpetrated by organized syndicates or street gangs. So far at least, one can go out during the evening without much fear of being mugged, though one might return home to find that the house had been broken into and the shot gun and fishing gear stolen.

There are no race problems for the simple reason there is not a single black person in Bull Shoals and very few within a radius of 100 miles. If we had the same racial mix as Boston or Birmingham, we would probably do no better than they with the race problem. A year or so ago there was a large offering of Vietnamese refugees from nearby Fort Chaffee. No one in Bull Shoals took any.

Harold Breimyer has reported that, although he was not fully aware of it at the time, the rural community in which he grew up had a social aristocracy with lines as rigidly drawn and impenetrable as the snootiest suburb.

So far Bull Shoals is more democratic than that. Social activities in the town revolve mainly around the Veterans for War, clubs for card playing and bass fishing, the church groups, and Friday night bingo. But this may not last. Several local enterprisers recently built a nine-hole golf course, so we are now in the first stages of developing that sine quo non of American middle-class aristocracy, the "Country Club Set"!

Bull Shoals cannot match Chicago in offering the carnal pleasures, but we do have some local action. There is, of course, pot smoking, and last week's paper reported the arrest of twelve persons for selling narcotics, ranging from marijuana to cocaine. As the prosecuting attorney said at the arraignment, "I would say we have a drug problem comparable with that

of much larger cities." I am not sure whether this will be good or bad for the tourist trade.

We have no expensive night clubs, no topless waitresses, and no porno movies. I have been told, however, that pleasures of the flesh are available on a commercial basis in a nearby town.

Many agricultural economists do a lot of tub thumping about what they regard as the relative inadequacy of rural health care, and for this they frequently put a large share of the blame on the medical profession. This may not be an altogether accurate or complete view of the matter.

It was mentioned at the outset that Bull Shoals had a hospital and a team of doctors, and within a radius of 15 miles are two more hospitals with their medical teams. Not all rural areas are as fortunate in this respect, but I (having been in most of them) know of no county seat in Arkansas that does not have a hospital and doctors who can do the ordinary medical procedures. If there is need for more than this, there is almost sure to be the proper specialist in the nearest sizable town, probably closer in terms of time than I was to my doctor in the Chicago Loop. Local doctors do not do heart transplants, but most of them are fully up to the average standards of the profession.

No one denies that many people in rural areas are not receiving adequate health care, just as many people in the cities do not, and for the same reason—they cannot afford it. Until poverty is abolished, or some form of national health program is established for everybody instead of just the war veterans and the oldsters, there is little that can or will be done about inadequate health care in a basic sense.

Oldsters do not procreate much, so I have had no first-hand experience with the local schools. The children in Bull Shoals, from kindergarten through high school, are bused down the road 7 miles to Flippin. Flippin schools do not have all the frills of a north-side Chicago suburb, and they do not have a football team, but if I had the choice of Flippin schools versus most of those in the inner city of Chicago, it would be Flippin hands down.

For those who equate educational progress with the abolishment of the one-room school house, Arkansas no longer has any. Among the last to go was one about 30 miles from Bull Shoals, a delightful place where the second graders, if so minded, could learn faster by listening to the third graders recite.

No report on life in America in these times is complete without reference to the welfare state. So I drove down to our country seat of Yellville, where people go to get welfare and food stamps, to see how the local chapter was coming along.

Marion is a typical rural county, with a population of about 7,000, a mixed economy, and no town with over 1,000 people. About 12% of the people in the county are receiving the food stamps and 3% Aid-to-Dependent Children. On this particular day, 164 people (about 5% of the total work force) were listed as unemployed, looking for work, and receiving one or more kinds of welfare. To place these efforts into perspective, it would be helpful to compare the money spent annually in the county for welfare with the amounts spent for schools, roads, police protection, etc. Unfortunately, because each welfare program is administered separately, total expenditures were not readily available; most records are in terms of numbers of cases rather than money spent. Anyway, there are perhaps some kinds of statistics the people are better off not knowing.

That sewer for Bull Shoals mentioned at the outset is another important component of the community government spending. The estimated cost of the sewer is about $4 million, 75% to be paid by a federal grant and the remainder by the local people. There are many who say that Bull Shoals cannot afford the sewer, and anyway the federal government should not be running up a big deficit by spending money on sewers. They may be right, but this is a matter of spending priorities. Many of these same people will not bat an eye when they read that Congress is about to authorize construction of a new wing of Air Force bombers, which may eventually cost $90 billion, and I will defend the people of Bull Shoals as being no more hawkish than people anywhere else in America, probably less so.

If only Congress would provide the necessary legislation, all the skills and human resources needed to get our sewer are potentially available in the local area and at far less cost to the taxpayers than under present arrangements. Down the road 15 miles the Army Corps of Engineers maintains a staff with more than the necessary skills to engineer and supervise the construction of a sewer. Having about run out of dams to build, they would probably be glad to get the work. What could be simpler in terms of ordinary common

sense than to use, at least for a major part of the labor, some of those listed locally as unemployed, looking for work, and receiving welfare!

I have mentioned this little matter of Bull Shoals' sewer because it illustrates perfectly the sheer waste and degradation of human beings that goes on everywhere in the nation because we persist under the welfare state in giving the unemployed a dole instead of useful work to do. If something more rational is not forthcoming soon, it will bankrupt us, both morally and financially. For whatever the reasons, professional economists have not been in the forefront of those who have proposed public service employment; agricultural economists, to the extent they have bothered at all to look at the problem of rural poverty and unemployment, have usually ended up wringing their hands and urging the need for more food stamps!

In 1972 Congress passed the Rural Development Act, which provided rather generous funding for research into the problems of rural well-being and development. If in all the research planned or under way with these funds, there is a single project relating to some type of public service employment for rural areas, then I will be surprised and simply delighted to hear about it and to stand corrected.

In conclusion, I love Bull Shoals and am glad I migrated there; but I do not think America can solve all her social and economic problems, or even very many of them, by closing down places like Chicago and everybody going out to the countryside.

Implications of Rising Energy Costs for Irrigated Farms in the Oklahoma Panhandle

Harry P. Mapp, Jr., and Craig L. Dobbins

As recently as five years ago, research on irrigated crop production in the Oklahoma Panhandle and surrounding area overlying the central basin of the Ogallala Formation focused on irrigable acres and regional share of national production as limits to irrigation development. An aggregate analysis was conducted to determine the economic life of the underground water supply for alternative scenarios regarding the rate of development in irrigated crop production (Bekure, Bekure and Eidman). In addition, bioeconomic modeling was used to determine the effects of alternative means of regulating water use at the firm level (Mapp, Mapp and Eidman). In these analyses, input and output prices, intensity of production practices, and the institutional structure were assumed constant through time.

Several recent economic analyses have focused on aggregate or regional effects of alternative product and input prices in areas to the south of the central Ogallala (Condra and Lacewell; Lacewell, Condra, and Fish). Within the central Ogallala, analysis at the firm level has focused on developing costs and returns for reduced tillage production practices and evaluating the effects of changes in overall energy costs on kilocalories of output (Schwartz; Eidman, Dobbins, and Schwartz). This paper examines the impact of rising natural gas prices on the pattern of irrigated crop production, net farm income, and the quantity of water pumped through time for representative farms under various sets of assumptions regarding water resource situations, crop prices, and tillage practices.

The geographic setting for this analysis is the Oklahoma Panhandle. The area is semiarid, receiving from 15 to 18 inches of rainfall annually. The existence of large quantities of underground water suitable for irrigation, favorable input and output price relationships, and the profitability of irrigated production have resulted in rapid irrigation development over the past decade. The larger profits from irrigated production are obtained at the expense of greatly increased energy inputs, particularly natural gas. In the three Oklahoma Panhandle counties, 91% of the irrigation wells are powered by natural gas (Schwab). Natural gas accounts for about 60% ot total energy inputs for irrigated production (table 1). This analysis focuses on the effects of a change in natural gas price rather than an overall rise in the price of energy-related inputs.

Recharge of the Ogallala aquifer is small relative to rates of water withdrawal and the static water level is declining steadily (Hart, Hoffman, and Goemaat). This analysis accounts for the interaction among rates of water use, water depth, well yield, and pumping costs in determining the optimum organization of production through time.

Discussants for this session were Otto C. Doering III of Purdue University, Ronald D. Lacewell of Texas A&M University, and Duane Harris of Iowa State University.

Harry P. Mapp, Jr. is an associate professor and Craig L. Dobbins is a graduate research assistant in agricultural economics, Oklahoma State University.

Journal Article No. J-3188 of the Oklahoma Agricultural Experiment Station. This research was conducted under Grant 14-34-0001-6037 of the Office of Water Research and Technology. The authors are indebted to Vernon R. Eidman and Harold J. Schwartz for their contributions on earlier phases of this research and to Odell L. Walker, Loren L. Parks, and James E. Casey for valuable comments and suggestions on initial drafts of this manuscript. Remaining errors or omissions are, of course, the authors' responsibility.

[d] HI, MI, and LI represent high level, moderate level, and low level of irrigation.
[e] The two-year wheat rotation alternates conventional and reduced tillage production practices.

Alternative Production Activities

Resource requirements, costs, and returns are estimated per acre for both conventional and reduced tillage methods of production. Each of the conventional tillage crops, except corn for grain, includes three levels of irrigation.[1] The reduced tillage methods of production are based on data compiled by Schwartz and are being used on a limited basis by farmers in the area. All production methods identified can be utilized with minor adaptations in the machinery available on the farm. Thus, the purchase of additional specialized machinery is not necessary. Input requirements, production, and net returns for each production activity are presented in table 1.

Prices and Net Returns

Two sets of crop prices (low and high) are used in the analysis. The low prices are based on 1976 target prices.[2] Crop prices are not expected to return to these absolute levels. However, the price relatives implied by target prices are based on historic series and provide a lower bound to solutions of the programming model. The high set of prices is based on seasonal average price relationships for 1969–73 and provides an upper bound on the programming solutions.[3] Input prices used in the analysis are those prevalent in the study area during early 1976.

The net returns presented in table 1 represent the residual returns to land, labor, machinery, overhead, risk, and management. Residual returns is gross receipts minus variable production costs, interest on operating capital and irrigation investment, and depreciation, taxes, and insurance on the irrigation system. With the exception of labor costs, this represents the net return to be maximized in the short run.

[1] Input-output data for the conventional tillage cropping activities are based on practices of the more efficient producers in the area. Thus, conventional tillage represents somewhat fewer tillage operations than the average for the area.

[2] The low set of output prices based on 1976 target prices are wheat, \$2.29 per bushel; corn, \$1.57 per bushel; grain sorghum, \$2.66 per hundredweight; soybeans, \$3.28 per bushel; sudan hay, \$22.00 per ton, and corn silage, \$6.34 per ton.

[3] The high set of crop prices is based on an assumed wheat price of \$3.50 per bushel. Other prices are calculated based on their average levels relative to average wheat prices during 1969–73. Other prices are corn, \$2.89 per bushel; grain sorghum, \$4.68 per hundredweight; soybeans, \$6.46 per bushel; sudan hay, \$33.60 per ton; and corn silage, \$11.20 per ton.

Representative Farm Situations

Previous studies suggest the economic life of the water supply in the Ogallala Formation differs for different water resource situations (Bekure, Mapp). Thus, representative farm situations are defined for three water resource situations. The first, a poor water situation, assumes 100 feet of saturated thickness and an irrigation well yield of 400 gallons per minute. The second, a moderate water situation, assumes a saturated thickness of 250 feet and an irrigation well yield of 750 gallons per minute. The third, a good water situation, assumes a saturated thickness of 412 feet, sufficient to produce an irrigation yield of 950 gallons per minute. For each water situation, the representative farm is assumed to contain 1,600 acres of land of which 1,440 acres are cropland and three irrigation wells equipped with surface distribution systems suitable for clay loam soils of the study area.

The interaction of rate of water use, decline in the water table, and reduction in well yield is accounted for by equations (1) and (2). The decline in static water level during any specified period is given in equation (1):

$$D_t = V_t/0.2A, \tag{1}$$

where D is the decline of static water level in feet, A is the total number of acres in the farm, V is the number of acre feet of water withdrawn, 0.2 is aerial drawdown coefficient, and t is the period.

Associated with the decline in static water level is a decline in irrigation well yield. This relationship may be expressed as

$$Q_t = \left[\frac{H_t}{H_o}\right]^2 Q_o, \tag{2}$$

where Q_t is the well capacity, H_o is the original saturated thickness in feet, H_t is the remaining saturated thickness, and Q_o is the original well capacity in gallons per minute.

The cost of pumping water during any time period depends upon the initial water situation and prior decisions regarding irrigation intensity. Using equations (1) and (2), pumping costs are adjusted each period to reflect the higher costs associated with reduced well yields and increased lift.

Labor supply on the representative farms is composed of operator labor and one full-time hired man. In addition, the operator can hire up to two additional full-time hired men on an

hourly basis. The operator is assumed to borrow operating and investment capital as needed at 10% and 8% simple interest, respectively. The model contains restrictions on land, labor, irrigable acres, and the quantity of irrigation water the system can pump by month. In addition to the conventional and reduced tillage cropping activities, a livestock activity for purchasing 400-pound stockers to utilize supplementary grazing is included.

Using a recursive linear programming model, optimum organizations are determined for a series of five-year periods based on well yields and pumping costs at the beginning of the period; that is, an optimum organization is determined for period 1 and is assumed to remain constant for a five-year period. At the end of five years, water use is calculated, drawdown and well yield for the following period are estimated, and pumping costs are adjusted. An optimum organization is reestablished and assumed constant for the next five-year period. This procedure continues for ten five-year periods, or for fifty years. Optimum organizations are developed for representative farms in poor, moderate, and good water resource situations for conventional versus reduced and conventional tillage practices, with both low and high crop prices, under conditions of constant and increasing natural gas prices. Only a portion of the results are discussed below.

Results

Rising Natural Gas Price

A series of programming runs were made to determine the potential effects on optimum farm organization, net returns, water use, and pumping costs over time of rising natural gas prices.[4] A comparison of the optimal production organizations during periods 1, 5, and 10 under constant and rising natural gas prices for representative farms using only conventional tillage practices is presented in table 2. As expected, rising natural gas prices increase pumping costs per acre inch and reduce net returns, but the magnitudes of the changes may be surprising. For example, pumping costs rise from $0.99 to $3.24 per acre inch over the fifty-year period with constant natural gas price and from $0.99 to $10.75 per acre inch for rising natural gas prices. Net returns decline by 45% under constant natural gas prices and by 63% under rising natural gas prices.

As pumping costs increase over time, a gradual shift occurs from irrigated to dryland production. One effect of rising natural gas prices is to speed the pace of this adjustment. Under constant natural gas prices, 350 acres of cropland remain in irrigated production in period 10. Under rising natural gas prices, a negative shadow price appears on the irrigation well activities in period 7, indicating an incentive for the producer to disinvest in irrigation facilities; that is, if he were forced to cover both fixed and variable costs in the short run, he would convert to dryland production. Irrigated production remains profitable throughout the fifty-year period under constant natural gas prices. The economic life of the water supply is reduced by at least fifteen years under rising natural gas prices.

Conventional versus Reduced and Conventional Tillage

To offset the decline in net returns caused by rising natural gas prices, producers may wish to consider more profitable reduced tillage production practices. The effects on optimal production organization of introducing reduced tillage practices for the medium water situation and high crop prices are also summarized in table 2. Introduction of reduced tillage activities greatly changes the production organization. For example, when only conventional tillage practices are considered, irrigated activities are limited to corn grain, wheat, sorghum, and soybeans. When conventional and reduced tillage practices are considered in the model, wheat and grain sorghum double crop, the two-year rotation of conventional and reduced tillage wheat, and reduced tillage corn grain are the predominant irrigated activities in the optimum organization. Wheat at the moderate irrigation level is the only conventional tillage irrigated activity in the period 1 solution.

Net returns are about 10% higher in period 1 when reduced and conventional tillage practices are included in the model. However, reduced and conventional tillage practices utilize more water and result in lower well

[4] It is assumed that the natural gas price increases from $0.75 per thousand cubic feet (mcf) in period 1 to $1.75 per mcf in period 2 and then gradually rises to $5.00 per mcf by period 10. These assumptions are arbitrary; $0.75 per mcf represents an average price for early 1976, and natural gas contracts are currently being renegotiated for $1.75–$1.85 per mcf in portions of the study area.

[b] HI, MI, and LI represent high level, moderate level, and low level of irrigation.

yields and higher pumping costs over time. By period 10, net returns for conventional and reduced and conventional tillage practices are approximately equal.

Cropping pattern shifts over time, when only conventional tillage is considered, involve a reduction in the number of irrigated acres of corn grain and sorghum and shifts to lower intensity irrigation levels for wheat and soybeans. When both conventional and reduced tillage practices are included, the changes in solutions over time are less orderly. However, under constant natural gas prices, about 284 acres remain in irrigated production in period 10 under conventional and reduced tillage versus nearly 350 acres when only conventional tillage practices are considered in the model. Under rising natural gas prices, a complete shift to dryland production occurs over the fifty-year period regardless of the tillage practices considered. The switch to dryland production is somewhat more rapid under reduced and conventional tillage.

A shift to reduced tillage production practices to offset the effects of rising natural gas prices increases net returns in the short run. However, over time the increased water use combines with rising natural gas prices to reduce net returns to the level achieved under conventional tillage practices.

Low versus High Product Prices

A series of programming runs were made to determine the potential effects on cropping pattern, net returns, water use, and pumping costs of variations in product prices. Table 3 presents optimal production organization for periods 1, 5, and 10 under low and high product prices for representative farms utilizing conventional tillage practices in poor and good water resource situations. The implications of product price variations are quite similar for farms across all three water resource situations. As expected, high product prices encourage more intensive irrigation practices, other things being equal.

In the poor water situation, high crop prices result in increased water use. Consequently, well capacity declines more rapidly, and pumping costs per acre inch increase more rapidly under high product prices. However, high product prices more than offset higher pumping costs, resulting in greater net returns. For low product prices, net returns decline from $67,775 to $42,967 (about 37%) over the fifty-year period. About 130 acres remain

[a] HI, MI, and LI refer to high level, moderate level, and low level of irrigation.

under irrigation, 90 acres of which are in wheat at the low irrigation level. Under high crop prices, the decline in net return is from $141,919 to $70,948, slightly more than 50%. Nearly the same number of acres remains under irrigation but in more intensive activities, such as corn grain and wheat at the moderate irrigation level.

The level of product prices appears to be a very important factor in determining the length of time over which producers will find irrigation profitable. For the poor water situation, a decline in product prices from high to target price levels would reduce the length of time horizon over which an irrigator could recover both fixed and variable irrigation costs by 50%. In the moderate and good water situations, the length of time horizon over which irrigation is profitable is reduced by 30% and 10%, respectively.

Conclusions

Rising natural gas prices have several potential effects. First, they increase the cost of pumping irrigation water and, other things being equal, reduce the level of net returns associated with irrigated crop production. Second, the pattern of irrigated crop production and the level of water use over time are similar for both constant and rising natural gas prices. Shifts from high to moderate levels of irrigation occur both under constant and increasing natural gas prices due to changes in the water table and pumping costs. Third, the shift from irrigated to dryland crop production occurs more rapidly under rising natural gas prices than under constant prices. About a two-thirds reduction in net returns accompanies rising natural gas prices and the return to dryland production. This result holds across water resource situations and for alternative tillage practices.

Adoption of reduced tillage production practices increases the level of water use under irrigated crop production. The optimum organization of production shifts from conventional tillage corn grain, wheat, sorghum, and soybeans to wheat and grain sorghum double crop, a two-year rotation of conventional and reduced tillage wheat, and reduced tillage corn grain. Net returns are higher during initial periods under reduced tillage technology. However, higher water use rates and the declining water table combine to increase pumping costs significantly and equalize net returns.

This analysis suggests that producers in the Oklahoma Panhandle have good reason for concern regarding the level of crop prices. Net returns under low crop prices are only 40% to 50% of net returns under high crop prices. In the poor water situation, the time horizon over which producers will find it profitable to irrigate under high crop prices is approximately twice as long as the time horizon under low crop prices. We have heard much discussion the past two years regarding the effects of changes in input prices. This analysis suggests farm operators, as well as those financing operating inputs, machinery purchases, and land, have a vested interest in the level of product prices.

Farm Management Implications of Reducing Agricultural Pollution Related to Cotton Production in Mississippi

David W. Parvin, Jr.

Sunflower county is located in the heart of the Mississippi Delta. Agricultural pesticides applied to the five major crops in this county total an estimated 3,997,440 pounds of active ingredients (unpublished estimate provided by Arthur). This amounts to 9 pounds per acre for every acre in the county.

Cotton is grown under numerous production strategies in Mississippi. However, cotton pesticide problems in Mississippi can be discussed by considering three cotton production situations: the sandy soils of the delta, the clay soils of the delta, and nondelta cotton production region (primarily the northern portion of the state).

A large percentage of the cotton grown in Mississippi is grown on the sandy soils of the delta. The cost of producing solid cotton on that soil resource under usual input practices (six-row equipment) is estimated to be $267.10 (Parvin et al.). Solid cotton grown on the sandy soils of the delta currently requires 34.02 pounds of pesticides per acre, 6.25 pounds of herbicide, 25.26 pounds of insecticide, 1.08 pounds of fungicide, and 1.43 pounds of defoliant. Cotton grown on clay soil in the Mississippi Delta requires higher herbicide rates per application. The nondelta cotton producers in Mississippi face more severe insect infestation (primarily boll weevil) than the delta cotton producers. Consequently, they apply additional insecticide applications.

Per acre returns to cotton production vary by region of the state and soil type (table 1). Total specified expenses vary about $10; however, differences in expected yield result in return estimates varying from approximately $95.00 to slightly more than $200.00.

What has been the effect of efforts to reduce agricultural pollution on cotton producers in Mississippi? The major pollutants are insecticides, herbicides, and soil erosion. Fungicides and defoliants are also listed as pesticides or pollutants. Fertilizer is occasionally listed as a pollutant but will not be discussed here. Ginning is a portion of the production process that has been identified as contributing to air pollution.

Regulatory Activities

The organochloride insecticide, DDT, has been banned. Mercury has been banned as a seed treatment. Pesticide applicators must be licensed. Field reentry standards have been established. The labeling of pesticides is now more difficult and expensive (Hamman). However, considerably more regulatory activity has been underway. Cotton ginners have been threatened with increased air pollution control standards. There has been the threat that other organochloride insecticides (especially Toxaphene) would be banned. The organophosphorus insecticide, Methyl Parathion, has been under attack. The organic arsenic herbicides, MSMA and DSMA, have also been under attack.

To date, the major effect of pollution-related activity on cotton production in Mississippi has been psychological rather than real. Most insect pests were highly resistant to DDT before it was banned. Numerous substitute seed treatment materials already existed for mercury when it was banned. The licensing of pesticide applicators and the establishing of field reentry standards have not measurably affected Mississippi cotton producers. However, there is confusion on the part of farmers. No one seems to know what material or activity might be banned or restricted next. However, everybody seems to know that most pollution-related activity is in the area of insecticides, insect resistance to

[a] Excludes land, management, and general farm overhead charges.

currently available insecticides continues to develop, stiffer standards covering the labeling of pesticides have significantly reduced the availability of new insecticides, and insect control on cotton in Mississippi is still heavily dependant upon insecticides.

Ginning

State air pollution standards and compliance dates have been established for cotton gins in Mississippi and all other states in the Cotton Belt. (This section is based on a 1974 study by Wilmot, Looney, and McCaskill.) All compliance deadlines have passed. However, in view of the extreme seasonality of the ginning operation and continuing economic plight of most ginners, air pollution control boards have adopted a "go-slow" policy on enforcement.

Although air pollution control standards have not been enforced, the threat of air quality standards has had an effect. Some ginners with inadequate volumes, already facing uncertain futures, have elected to cease operation rather than to make even moderate outlays for new pollution control equipment. Consequently, some older low capacity gins have been replaced by newer, higher capacity plants. However, even the newest plants are not up to anticipated standards. What are the alternatives? Presently, there are none. Should the regulations be enforced, ginners will have to comply or cease operation.

Fungicides

Fungicides are applied as a seed treatment and as a hopper box treatment at planting. In Mississippi, seed treatment materials are generally Cemosan and Terracost L21. These two materials amount to approximately 0.08 pounds of fungicide per acre. Soil treater XXX is applied as a hopper box treatment at the rate of 1.00 pound per acre. The purpose of these materials is to help insure a stand in cool, damp weather. Fungicides are a recommended production practice.

Defoliants

Most of the cotton acreage in Mississippi receives a defoliant treatment. Some of the acreage is double treated each year. The most popular materials are DEF or FOLEX applied at the rate of 1.30 pounds per acre. (1.43 pounds assumes 10% of the acreage is treated twice.) Defoliation is a recommended production practice, and it is unlikely that producers will not apply defoliant.

Erosion

Currently, no erosion control standards are in effect in Mississippi. However, pressure does exist to enact some standards. Research indicates that relatively flat land is also subject to erosion problems, which is true for sandy and even clay soils of the Mississippi Delta. While soil movement and loss cannot be stopped altogether, the processes of erosion and pollution can be reduced.

Mississippi Agricultural and Forestry Experiment Station (MAFES) is attempting to play a part in specifying the list of tillage operations that will be acceptable. Recommended tillage operations will vary by crop and by soil types. There are no recommended set of practices except for the delta soils. Apparently, erosion can be reduced from 15 tons per acre-year to approximately 5 tons per acre-year on sandy soils and from 13 tons per acre-year to 7 tons per acre-year on clay soils. (One acre inch of topsoil weighs 166 tons.) However, the tillage techniques that are currently being con-

sidered are not appropriate for approximately 75% of the cotton acreage in the state. Currently, MAFES does not have the technology to specify a set of recommended tillage practices for each specific land resource that could be used for cotton production.

Herbicides

At the present time no cotton herbicides have been banned. Table 2 lists the most common weed control program used by cotton producers on sandy soils in the Mississippi Delta, specifying eight trips over the field not counting planting and hoeing. Table 2 indicates 6.52 pounds of herbicides. Herbicide costs are $22.37 per acre, and total cost per acre including application cost are reported at $51.35. Are there alternatives to this program? Cotton production in Mississippi is currently not possible without the application of some herbicides. For example, farmers with severe weed control problems typically use eleven trips over the field for weed control. However, there is a group of cotton producers in Mississippi that have managed their weed problems continuously to the extent that they have relatively clean fields, and this group typically uses only five trips over the field for weed control. They closely supervise their weed control operations to insure proper timing and placement of materials. However, their clean fields are the result of the proper use of chemical herbicides for the previous several years. MSMA is the most popular grass herbicide. Under current technology cotton cannot be produced profitably on most fields in Mississippi without MSMA and cannot be produced in Mississippi utilizing chemical herbicide weed control alone. Producers are still dependent to some degree on hoe labor and mechanical cultivation.

There are indications that new packages of technology may be forthcoming in the future relative to weed control. However, none of these bundles of technology are suitable for use by cotton producers in Mississippi today, who are moving toward a system of weed management for the entire farm. This conceptualized weed management program will probably utilize a wide variety of herbicides on crops.

Insecticides

Table 3 lists current insect control cost per acre for usual input practices in the Mississippi Delta. These costs apply to sand and clay soils. Excluding planting, nine trips over the field are required. Bidrin is applied (usually in May) to control thrips. The other eight applications are applied in July, August, and September to control the bollworm and tobacco budworm. This program specifies 25.26 pounds of insecticides. Total insecticide costs are $32.57. The total per acre cost of this insect control program is $43.02.

The boll weevil is an economic pest in the nondelta area of Mississippi. Under usual input practices in the nondelta area of Mississippi, twelve applications excluding planting are required. The "usual input practices" in-

[b] Application cost charged to planting operation.
[c] Toxaphene and Methyl Parathion are sold as blended material.
[d] Nine trips over the field excluding planting.

secticide program for the nondelta region is 0.30 pound of Temik applied at planting (mid-May), 0.20 pound of Bidrin in late May, five applications of 0.25 pound of Guthion plus 0.20 pound of Fundal during July and August, five applications of 2.00 pounds of Toxaphene plus 1.00 pound of Methyl Parathion during August and September, and one application of 0.25 pound of Guthion in September. This program specifies 18.00 pounds of insecticide at a cost of $35.83. The total cost of the insect control program including application and scouting is $47.04 (Parvin, Hamill, and Toney).

No DDT was sold in 1972, so that 1973 was the first year without DDT. It was speculated that the banning of DDT would result in increased insecticide applications by most producers (Cooke); it has not (Cooke et al., Parvin et al.). However, the use of Methyl Parathion has increased approximately 300% (USDA). The number of applications has not increased for two reasons. First, the Cooperative Extension Service and others have had massive education programs dealing with integrated pest management, especially scouting techniques. Second, insecticide costs have increased drastically.

The current approach to cotton insect management in Mississippi is a prescription (scouting) insecticide program. This alleviates many of the problems associated with regularly scheduled insecticide applications. Environmental pollution is reduced, as are cost and insecticide selection pressure, and natural enemies are preserved during most of the season to combat new pest and pest resurgence problems. The speed with which scouting techniques have been adopted has undoubtedly been increased by efforts to reduce pollution. However, the basic control technique is still chemical insecticides.

Currently, the most serious cotton insect in Mississippi is the tobacco budworm. Problems encountered in tobacco budworm control in Mississippi during the 1975 crop year have emphasized the seriousness of the situation. Many producers failed to control the tobacco budworm with repeated applications of recommended insecticides, and costs were in excess of $60.00 per acre. The situation is very serious. If present practices continue, insecticide resistance in the tobacco budworm populations could eliminate cotton production in Mississippi, just as it was eliminated from northern Mexico (Lukefaher).

Since the number of approaches to tobacco budworm control other than insecticides are extremely limited, each one should be fully investigated to determine its potential. Four areas of research seem to offer the most promise for tobacco budworm control: insecticide testing, sterile release, host plant resistance, and pest management.

The past program of unilateral reliance on chemical pesticides not only resulted in some serious control failures but also had some undesirable side effects. The current practice of scouting cotton fields, using insecticides only when necessary, and relying on natural enemies as much as possible appears to be inadequate. The concept of integrated insect pest management appears to offer promise of long-term solution to the cotton insect problems (Harris, Laster, Newsom). However, a complete integrated insect pest management

system for cotton in Mississippi has only been conceptualized, and most of the visualized components are only in the research stage. Basic research needs to be completed, and agricultural economists need to evaluate the contribution of specific pest management strategies to an integrated cotton insect pest management program.

Research Implications

If a reasonable compromise to the problem of agricultural pollution related to cotton production is ever to be found, research scientists of all disciplines must be involved. The current emphasis has been on cotton insecticides, which is especially true at MAFES. However, pollution associated with cotton production involves gins, fungicides, defoliants, herbicides, and tillage (erosion), as well as insecticides. New systems of cotton production, which are both biologically and ecologically sound, will need to be developed. At a minimum these new systems of cotton production will probably include new insecticide, herbicide, and erosion components, which result in the reduction of the pounds of pesticides used per acre and vastly improved erosion control standards.

A problem of this magnitude requires the system approval to research management. However, research designed to investigate all of the ramifications of agricultural pollution related to cotton is probably beyond the capabilities of any single experiment station. What can MAFES (or other experiment stations) do to assist cotton producers meet the problems associated with reducing agricultural pollution? First, they need not await regulatory action and be forced to react in a hurried fashion. Much regulatory activity is predictable. For example, three cotton pesticides—MSMA, Toxaphene, and Methyl Parathion—are almost certain to be banned as soon as alternatives are available, and they may be banned sooner. Agricultural economists should evaluate the impact of banning these pesticides. By performing the analysis now, the study could be conducted in an unhurried fashion, and the results of the study might have an impact on the regulatory agency. Some erosion control regulations are certain to be forthcoming in the near future. Researchers should immediately move to develop erosion control alternatives and attempt to influence or even assist the selected regulatory agency to write erosion control standards.

Finally, partial systems analysis is the appropriate approach to use to investigate the problem of agricultural pollution relative to cotton. This approach involves identifying the key components of the system to be studied and concentrating research resources in those areas and is the approach taken at MAFES. Because insects are a serious problem on cotton in Mississippi and because insecticides make up approximately 74% of the pesticides applied to cotton in Mississippi, MAFES has concentrated on alternative strategies of insect management. A plant growth model is being developed to simulate the effect on yield of weather, plant nutrition, and insects. However, only the very rudimentary stages of using systems methods to develop insect management techniques are in process. The real impact of this technology on pest management is probably ten to fifteen years in the future.

Summary

What current alternatives does the Mississippi cotton producer have available for maintaining net income in the face of the current emphasis on a cleaner environment and pesticide regulations? Almost none. Soybeans are the competing crop for cotton in Mississippi. Net return figures for soybeans comparable to those reported in table 1 are delta-sandy soil—$73.34, delta-clay soil—$71.59, and nondelta soil—$53.80 (Parvin et al.; Parvin, Hamill, and Toney). Cotton producers will be sacrificing considerable net income if they shift to soybeans. There are no new cotton varieties that are near release that could significantly increase yield and reduce costs per pound of lint.

Four components of cotton production (weed control, insect control, harvesting, and ginning) make up over 80% of the cost of producing cotton in Mississippi. Regulatory activity associated with pesticide production is almost certain to increase weed and insect control costs (Day). Enforcement of pollution standards in gins will undoubtedly increase ginning costs. Harvesting costs total 24% of total costs. Reductions in the cost of harvesting cotton will require a technological breakthrough.

The development of resistance by the tobacco budworm to all available insecticides is dominating cotton production in Mississippi. Other than the proper use of an ovicide, the

only alternative available to Mississippi cotton producers is to increase the rate of Methyl Parathion. Unless this problem is solved in the next two to four years, the farm management implications of reducing agricultural pollution related to cotton production in Mississippi may not be relevant. When this immediate problem is resolved, we must move toward developing systems of cotton production that are consistant with current and anticipated regulations. This may involve drastic genetic modification of the cotton plant and will involve new systems of weed, insect, and erosion control.

Inflation and Crop Profitability: How Much Can Farmers Pay for Land?

Warren F. Lee and Norman Rask

The purchase of a parcel of farm land can be one of the most difficult investment decisions confronting farm operators. Compared with other production inputs, land is purchased infrequently and usually involves a large, long-term financial obligation. The land investment decision is especially critical today, when many are questioning the ability of farm income to support current land values at "normal" commodity prices.

Fairly stable relationships existed during the 1960s between land values, net returns to farming, and the general rate of inflation (see table 1). However, during the 1970s and especially since 1972, land prices have escalated sharply, net farm income has been very volatile at high levels, and nonland production costs have increased faster than the general price level (consumer price index). These recent trends raise serious questions not only of magnitude but also direction of movement for these important determinants of how much farmers can pay for land.

We accept the proposition that prospective buyers must evaluate investments and make decisions based on present conditions with appropriate allowances for future anticipated trends. In this paper, we have not attempted to guess the future direction nor magnitude of these important variables but have developed a framework for analyzing farmland investments. A capital budgeting decision model developed by Lee for evaluating farm real estate purchases is used to test the land price sensitivity of a set of decision variables. Specific case situations are analyzed by comparing buyers with different characteristics, each facing favorable and unfavorable economic trends. These specific situations are then compared to illustrate how much farmers can afford to pay for land under specified conditions and expectations. For purposes of analysis, a Corn Belt farm situation is assumed, although the general results and conclusions would apply to most parts of the country.

Warren F. Lee is an associate professor and Norman Rask is a professor in the Department of Agricultural Economics and Rural Sociology, Ohio State University.

The authors are indebted to Bernard L. Erven, D. Lynn Forster, and Edgar T. Shaudys for their helpful comments on an earlier draft. Any errors that remain are attributable solely to the authors.

A Model for Evaluating Land Prices

The traditional formula used by real estate appraisers to estimate land values is $V = I/r$, where V is the estimated value, I is the expected residual net return to land, and r is the capitalization rate (Suter, pp. 247–52). For example, if a parcel of land is expected to produce a net rental income of \$50 per acre and the opportunity cost of money is, say, 8% per annum, then the estimated land value is $V = I/r = \$50/0.08 = \$625$ per acre. As Crowley suggests, this formula provides an accurate estimate only if three conditions are met: (*a*) the investment is expected to produce the same annual net rent over time, (*b*) the capitalization rate used to discount future net rent remains constant, and (*c*) an infinite or very long investment time horizon is considered. Crowley goes on to show that these three conditions are rarely met and that the apparent rate of return on farmland, given by $r = I/V$, generally underestimates the actual rate of return.

Despite the obvious shortcomings of the traditional income capitalization approach, the price that a prospective purchaser can afford to pay for a parcel of land is strongly influenced by his income expectations and opportunity cost of capital. Land purchases are generally financed with borrowed capital, so that credit terms such as interest rates, down payments, and the length of the loan amortization period must be taken into consideration. An important but often overlooked variable is the extent to which anticipated annual net returns and long-term capital gains will be reduced by income taxes. A buyer's bidding position is

[b] Estimated.

also influenced by the length of the planning horizon and his expectations about future trends in land prices and the rate of growth in net returns to land.

This suggests that the land purchase decision can be evaluated using standard capital budgeting procedures. (Capital budgeting techniques are covered in Aplin and Casler; Hopkin, Barry, and Baker, chaps. 9, 10, and 11; and Nelson, Lee, and Murray, chap. 3.) In other words, purchasing a parcel of land is an acceptable investment alternative if the present value of net cash receipts is equal to or greater than the present value of the cash outlays (i.e., if the net present value is equal to or greater than zero) or if the yield or internal rate of return exceeds the opportunity cost of capital.

Capital budgeting is a widely accepted method of evaluating investments in short and intermediate term depreciable assets such as machinery (Aplin and Casler). Hopkin, Barry, and Baker have illustrated the potential use of capital budgeting for evaluating real estate investments as well (chap. 12).

The major cash inflows associated with an investment in real estate consist of the annual net returns to the land and the returns from selling the land at the end of the planning horizon. Cash outlays consist of the down payment, principal, and interest payments on the mortgage loan and income taxes.

The annual net returns to land should be regarded as a residual return to land after all production costs except interest charges on land debt have been deducted from gross receipts. In areas where there is an active rental market, real estate appraisers generally use the net rental method (landlord approach) to estimate this residual return. In areas where renting is less common, a budgeting approach can be used. A discounted cash flow model was developed with the objective of providing the individual land buyer with a method of evaluating a parcel of land using his particular discount rate, income expectations, credit terms, and income tax situation (Lee). The following notation is used: $\bar{P}$ is average price per acre from recent sales of comparable parcels; CC is the buyer's opportunity cost of capital after taxes; n is the buyer's planning horizon in years; ANI is expected annual net returns per acre before taxes; GNI is expected annual rate of growth in annual net returns per acre; MTR is the buyer's marginal income tax rate (combined federal and state tax rate based on estimated taxable income after the parcel is purchased); DP is the proportion of the purchase price paid down; IR is the nominal rate of interest charged on the mortgage loan; t is

the amortization period on the loan; *INF* is the expected annual rate of inflation in land values; T^* is the tax rate that will apply to capital gains income in year n when the parcel is sold;[1] and P^* is the maximum bid price, given values for the preceding eleven variables.

The maximum bid price (P^*) or the price that gives a net present value of zero is given by

$$P^* = \left\{ \sum_{t=1}^{n} \frac{(1+GNI)^t}{(1+CC)^t} (ANI)(1-MTR) + \frac{(1+INF)^n}{(1+CC)^n} (\bar{P})(1-T^*) \right\}$$

$$\div \left\{ DP + (1-DP)\left[\frac{(1+CC)^t - 1}{CC(1+CC)^t}\right]\left[\frac{IR(1+IR)^t}{(1+IR)^t - 1}\right] - (1-DP)(MTR)(IR) \right.$$

$$\left. \left[\frac{IR(1+IR)^t}{(1+IR)^t - 1}\right] \sum_{i=1}^{t} \frac{1}{(1+CC)^i} \left[\frac{(1+IR)^{t-i+1} - 1}{IR(1+IR)^{t-i+1}}\right] - \frac{T^*}{(1+CC)^n} \right\},$$

where $t \leq n$ (for details concerning the mathematical derivation of this equation, see Lee).

Although considerably more complicated than the traditional appraisal formula, this equation includes most of the major, economic variables that affect the land purchase decision.

Application

"Basic Case" Example

The input data for the "basic case" represent budgeted 1976 cost and income data for Corn Belt farms. Annual inflation rates for net returns and land values are set at 5%, closely approximating pre-1972 rates (table 1). A first mortgage loan for 75% of the purchase price at 10% interest is assumed. Again, these approximate 1976 Corn Belt values. The loan is repayable in equal annual installments over a twenty-five-year period.

The income stream from the investment will be subject to a 30% marginal tax rate, and the capital gains tax will amount to 25% of capital gain when the property is sold at the end of the twenty-five-year planning horizon. The investment must yield a minimum after-tax rate of return of 10% per annum.

The input data for the basic case can be summarized as follows: $\bar{P}$ is \$1,000 per acre; $CC = 0.10$; n is twenty-five years; *ANI* is \$70 per acre per year; *GNI* is 0.05 per annum; $MTR = 0.30$; $DP = 0.25$; *IR* is 0.10% per annum; t is twenty-five years; *INF* is 0.05 per annum; and $T^* = 0.25$.

The solution for the maximum bid price (P^*) given these values for the eleven input variables is P^* is \$1,172 per acre. In other words, under these assumptions farmers can bid up to \$172 per acre above average price of comparable farm sales in this area and still earn the required 10% after-tax rate of return.

Sensitivity Analysis

The basic case was used as a point of departure for examining the response of the maximum bid price to changes in the eleven input variables. The range over which each variable was examined reflects either the entire possible range (e.g., 0 to 1 for the down payment) or a reasonably comprehensive range (e.g., 0.06 to 0.14 for the rate of interest on the mortgage loan). In every case, values for all variables other than the one being examined were fixed as specified in the basic case.

Table 2 summarizes the sensitivity of the maximum bid price to changes in the input variables. In general, the three variables related to expected returns have the greatest effect on the maximum bid price. As *INF* is increased from 0 to 12% per annum, the maximum bid price increases from \$966 to \$2,344 per acre. The variable P^* is also very responsive to changes in values of expected annual net income per acre (*ANI*) and the ex-

[1] Since only half of capital gains income is taxable, T^* is equal to half the marginal tax rate that will apply in the year the parcel is sold. The variable T^* was substituted for $MTR/2$ to allow for the possibility that sale of the property will result in a significantly higher taxable income and hence a higher than usual tax rate in year n. It is also influenced by special provisions in the income tax law, such as those that provide for postponement of the capital gains tax when the farm is sold on a land contract. Such provisions could have the effect of reducing the value of T^*.

Table 2. Sensitivity of Maximum Bid Price (P^*) to Changes in the Input Variables

Input Variable	Range of Values of Input Variable	Corresponding Range in Maximum Bid Price (P^*)
Terms of mortgage financing		
Interest rate (IR)	0.06–0.14 per annum	1,423–976
Down payment (DP)	0–1.0	1,262–964
Opportunity cost of capital (CC)	0.06–0.14 per annum	1,647–885
Land prices and inflation		
Average price of land ($\overline{P}$)	\$500–\$1,500 per acre	1,026–1,317
Expected rate of inflation in land values (INF)	0–0.12 per annum	966–2,344
Income and tax variables		
Income per acre (ANI)	\$30–\$110 per acre	669–1,674
Growth in net income per acre (GNI)	−0.03–0.05 per acre	727–1,172
Marginal tax rate (MTR)	0–0.4	1,274–1,126
Capital gains tax (T^*)	0–0.25	1,233–1,172
Time horizon and loan amortization period (n, t)	10–40 years	1,058–1,251

pected rate of growth in net income per acre (GNI). The buyer's opportunity cost of capital (CC) is also an important determinant of the bid price. A prospective buyer who is content with a 6% after-tax rate of return on his investment can bid up to \$1,647 per acre. However, the maximum price that corresponds to a 14% rate of return is only \$885 per acre.

The terms of financing appear to be fairly important. High down payments and/or high interest rates cause significant decreases in the maximum bid price. As the interest rate (IR) is increased from 6% to 14% per annum, the maximum bid price drops to \$916 from \$1,423 per acre. A purchaser who can borrow the full amount of the purchase price at 10% per annum can bid up to \$1,262 per acre, while the buyer paying cash can earn the 10% opportunity cost of capital only if he can buy the parcel for \$964 per acre. This leverage effect will occur only if the opportunity cost of capital exceeds the after-tax rate of interest on the mortgage. In the basic case, the after-tax cost of capital is 10%, and with a 30% tax rate the after-tax rate of interest on the loan is 7%. Thus, for values of CC less than 7%, P^* would be highest for a cash purchase (DP = 1). In addition to the tax deductibility of the interest payments, inflation also encourages the use of credit because the value of the land and the income are increasing while the loan is being repaid with "inflated dollars."

Some variables used in the analysis have a comparatively minor effect on the maximum bid price. The value of P^* is relatively insensitive to changes in the marginal tax rate (MTR) because the annual net returns are largely offset by tax deductible interest payments on the mortgage loan. The small response of P^* to changes in the capital gain tax rate (T^*) occurs because the tax liability is discounted from twenty-five years into the future.

Analysis of Bidding Potential According to Buyer Characteristics

Four levels of possible economic trends (inflation) are considered for each of six buyer characteristic situations to study their relative bidding positions.

Economic Trend Levels

The two variables considered here are the expected annual growth rates in net returns (GNI) and land values (INF). Both have been at historically high levels since 1972. These two variables are related over time in that high net returns are very quickly capitalized into increased land values; however, while net returns are highly volatile from year to year, land values present a more uniform growth pattern over time and are notably sticky to down side movements in response to declining net returns. This behavior conditions the establishment of trend levels for the analysis. First, recent history would indicate that land prices are not likely to experience an absolute decline over the life of an investment. Thus, a lower boundary for INF is set at zero. On the other side, it is reasonable to assume that land value increases cannot maintain present levels over a twenty- to forty-year period. An 8% growth rate was selected for the boundary on the high side.

For the net return variable it is conceivable

that a return to more normal world production levels, and hence a buildup in world food supplies, coupled with a continued increase in nonland production costs could lead to a slightly negative trend in net returns when compared to present high levels. A lower boundary for growth in net returns is established at −3% and the high boundary was set at 5%.

Four specific trend alternatives were evaluated: (*a*) $GNI = -0.03$ and $INF = 0$; (*b*) $GNI = 0$ and $INF = 0.03$; (*c*) basic case values of $GNI = 0.05$ and $INF = 0.05$; and (*d*) $GNI = 0.05$ and $INF = 0.08$.

Farm Real Estate Buyer Characteristics

Bidders for farm land enter the market representing a broad spectrum of financial positions ranging from the initial land acquisition with little equity through add-on purchases by established farmers. Correspondingly, they bring to the investment decision different levels of operating efficiency (income generating potential), planning horizons, income levels (tax obligation), and initial equity positions (down payment). While each individual investor will have a unique set of circumstances, it was possible to specify six general cases that span most individual situations. Characteristics of the six cases examined are shown in table 3.

Case A portrays the young farmer making his initial land purchase. This purchase is assumed to be of modest size, therefore some size-related operating diseconomies would exist. The buyer would be at an early stage in his productive career and therefore would have a longer planning horizon. The smaller size would also result in less income, therefore a lower tax bracket. Three subcategories are specified for this initial purchase situation based largely on source of additional income. In case A1, income from the farm operation alone must support the purchase entirely and a low tax bracket is assumed. In case A2, off-farm income will increase the tax rate above that assumed in case A1. In case A3, additional land rented will result in some size economies. However, a modest size operation is still assumed, and some income reduction from the basic case occurs. The marginal tax rate is the same as in case A2.

Case B describes the situation of an absentee landlord. Size is assumed adequate for "normal" operational efficiency. Some reduction in income is expected to result from separation of management and operation. A higher marginal tax rate and shorter planning horizon are assumed.

Case C is the basic case described earlier. It assumes a complete farm purchase of adequate size representing normal or average conditions for all variables. Case C would represent an established farmer changing farms or a new entrant with sufficient equity to purchase an economic sized unit.

Case D typifies an established owner-operator who is purchasing an add-on unit. Some gains in size economies are assumed along with a shorter planning horizon and a higher marginal tax rate, compared to case C.

Table 3. Relative Bidding Potential for Assumed Real Estate Buyer Situations

	Initial Land Purchasers					
	No Additional Sources of Income	Additional Off-Farm Income	Additional Income as Tenant on Other Land	Absentee Landlord	Basic Case	Add-On Established Operator
Variables[a]	Case A1	Case A2	Case A3	Case B	Case C	Case D
Planning horizon	30	30	30	20	25	20
Income per acre (*ANI*)	$50	$50	$60	$60	$70	$75
Marginal tax rate (*MTR*)	0.10	0.20	0.20	0.35	0.30	0.35
Down payment	0.20	0.20	0.20	0.25	0.25	0.25
Loan amortization period (t)	30	30	30	20	25	20
Economic conditions			Maximum Bid Price ($/Acre)			
$GNI = -0.03, INF = 0$	404	393	461	484	521	569
$GNI = 0, INF = 0.03$	575	565	653	681	734	787
$GNI = 0.05, INF = 0.05$	976	960	1,108	1,010	1,172	1,169
$GNI = 0.05, INF = 0.08$	1,244	1,249	1,397	1,169	1,470	1,454

[a] Variables not shown were as specified in the basic case ($\overline{P}$ = $1,000, $CC = 0.10$, $IR = 0.10$, and $T^* = 0.25$).

Results

Interpretation of the results (table 3) should be based on relative changes in the maximum bid price (P^*) between specific case situations rather than on absolute values. The estimated maximum bid prices in table 3 demonstrate that anticipated future trends in land values and net returns to farming should have crucial impact on the current economic value of land. Depending on buyer characteristics, there is a two-and-one-half to a three-fold increase from the least favorable to the most favorable economic trend assumptions. Farm buyer situations also can create differential bidding potentials, though these differences become narrower on a percentage basis under favorable economic trends. Regardless of economic trends, however, established farmers and those able to purchase complete economic units (cases D and C, respectively) are clearly in a superior bidding situation. Farm transition data for the Corn Belt confirm this potential. In 1975, for example, 70% of the units purchased were added to established operations. An additional 22% were complete farm units, and only 8% were purchased as part-time units (Farm Real Estate Market Developments).

This analysis, however, does not explicitly account for the important issue of buyer behavior or, more specifically, his ability to bear risk and his willingness to support high land prices in the face of uncertain future trends in net returns and land values. Harris and Nehring have developed a similar model that does include variability in income per acre, the buyer's initial wealth position, and degree of risk aversion along with many of the variables included here. Their conclusions are generally similar to ours, although they note that "the largest farms may not have the greatest bidding advantage after all. A combination of higher marginal tax rate and diseconomies of size may cause (census) Class 0 farmers to have a lower maximum bid price than either Class I or Class II farmers" (p. 168).

The results in table 3 also fail to explain recent Corn Belt land sales in the $2,500 to $3,000 per acre range. Presumably, such prices are based on a more optimistic outlook, so the established operator case (case D) was changed to reflect a favorable outlook over a shorter time horizon. The time horizon n and loan repayment period t were set at ten years. The cost of capital (CC) was reduced to 8%, and equal growth rates were assumed for net income per acre (GNI) and land prices (INF). The average going price per acre ($\bar{P}$) was increased to $2,000 per acre to reflect the assumption that a buyer is unlikely to pay $2,500 to $3,000 per acre if all recent sales have been at only $1,000 per acre. Values of all other variables are as specified in case D (table 3). Values of GNI (= INF) were then increased to yield values of P^* in the $2,500 to $3,000 per acre price range.

The results indicate that while farmers who pay $2,500 to $3,000 for Corn Belt land may be overly optimistic in view of long-run trends, their assumptions are by no means unrealistic in view of the recent past. A 9% per annum rate of growth in both net returns and land prices produces a maximum bid price of $2,592. At 11%, the maximum bid price is $3,053. In other words, when the going price is $2,000 per acre, bid prices approaching $3,000 per acre can be justified on expected values of GNI and INF that are considerably less than actual values since 1972.

Concluding Observations

This modest attempt to synthesize the position of a prospective farmland buyer in a capital budgeting framework indicates that expectations regarding future economic trends and financial position at time of purchase are major determinants of the maximum bid price. We agree with Harris and Nehring, who conclude "The issues of ownership and control cannot be completely resolved until more accurate and complete specifications of the important parameters are made" (p. 169).

Research Needs and Priorities in the Food System: An Industry Viewpoint

Richard T. Crowder

For professional economists, the subject of this paper implies a gap between the subject matter interests of industry economists and emphasis of current academic research, a lack of communications between those doing research and those in industry who are impatient for answers to constantly changing problems, or both. While the nature of institutional research and the nature of economics training have been perennial themes of industry sessions at annual meetings, increasingly there are similar challenges coming from professionals in academia and government.

Robert A. Gordon, in his presidential address to the American Economic Association, said, "the mainstream of economic theory sacrifices far too much relevance in its pursuit of ever-increasing rigor" (p. 1). His challenge to the profession was "relevance with as much rigor as possible, not rigor regardless of relevance" (p. 12). This challenge is precisely the one industry economists have expressed for some time.

There have also been similar challenges from the leaders of the American Agricultural Economics Association. Bonnen, in his presidential address, stated, "There is evidence that we are failing also to update our conceptual base at a pace sufficient to keep up with the major changes in agriculture" (p. 756). Bottum, in his fellow's address, stated, "We need today in our universities, more individuals and groups with the ability and the courage to tackle fundamental issues facing U.S. citizens" (p. 765). Neilson, in his presidential address in 1974, said, "In the past decade, I believe that we have overinvested in the development and refinement of quantitative methods. We have spent too little time and energy on discovering and tackling the emerging economic and social problems that most trouble our society" (p. 869).

When only that minority of our profession who call themselves industry economists were questioning the relevance of the research of the profession, it could be dismissed as coming from a maverick group of the profession that perhaps did not appreciate the rigor of academic research. However, when it is brought into question by such professionals as those quoted above, it is time that all of us, as professionals, start listening. It is time for those in industry to insure that we are communicating our needs properly and effectively.

The objective of this session is to discuss research needs and priorities in the food system from an industry viewpoint. By no means would it be possible to delineate and rank all research needs of the food industry in a single session. Each of us has an endless list of needs and priorities. My objective is not to present a laundry list of needs ranked on some ordinal basis but to discuss basic procedures and key issues. Specifically, I want to (*a*) comment on criteria for good research, (*b*) identify some of the research needs in the food industry, (*c*) comment on the extent to which the profession is meeting these needs, and (*d*) finally, recommend measures to span the gap that has been identified.

The panel discussants for this session were Charles French of the National Academy of Sciences, Morton Sosland of Sosland Publishing Company, John Morrissey of Super Valu Stores, and Bill Helming of the Livestock Business Advisory Services.

Richard T. Crowder is vice-president and corporate economist of the Pillsbury Company.

The comments and suggestions of Paul Baumgart, Charles Erickson, Ted Rice, Bruce Scherr, and Ed Williams resulted in a substantial improvement of an earlier draft of this paper. However, since all comments and suggestions were not followed, the final paper and any errors therein are the responsibility of the writer.

Criteria for Research

Historically, research by the agricultural economics profession has made many significant contributions to the food industry. Despite this historical performance, there is a tendency for many in the profession to drift away from fundamental criteria in structuring and carrying out research. I think there are two reasons for this.

First, professional rewards and training encourage an emphasis on rigor at the expense of relevance. Let us face it—professional rewards and recognition of those who developed and expanded quantitative techniques have encouraged what Neilson referred to as an overinvestment and refinement of such models. Without the professional rewards and recognition, the pursuit would not have been as intense as it has been. In graduate programs, the emphasis is definitely on rigor, and with this training, the young professional, by nature, carries forward those things for which he has been duly rewarded in graduate school.

Second, the profession is slow to adjust to a changing environment. Therefore, research tends to lag the needs of decision makers, public and private. Once a new concept or program receives professional recognition, there is a "bandwagon" effect that is difficult to slow. For example, there has been a major shift in the location of cattle feeding and beef slaughtering in the United States. With the development and popularization of spatial equilibrium models and with a shift occurring in cattle feeding, a plethora of "optimum location of cattle feeding" studies were made. With the major shifts behind us, studies on the optimum location of cattle feeding continue. While we are after-the-fact studying shifts in the location of cattle feeding, there has been a major shift taking place in the meat industry that has yet to be studied properly, the shift to centralized breaking of cattle. The meat packing and retail industries have been in the midst of this change without any broad-based support from academic research. It is this type of inconsistency that results in the questioning of the relevancy of our research.

To overcome this problem, I recommend that the following criteria be applied to all research.

(*a*) The research must be problem oriented. This does not mean that we do not need theoretical as well as applied research. Quite the contrary, we need both. New problems require new tools and methods of analysis. As the system changes, new theories are needed to explain the operation of the system. Problem-oriented research is research that will improve the decision-making process or will improve the methods of observation, measurement, and interpretation of data that should be used in decision making, public or private. It is not applying a popular quantitative technique to obsolete data.

(*b*) The problem must be real. Research should not be done on a problem that does not exist. I was recently told of a potential study on the location of new lamb slaughtering plants. U.S. lamb slaughter has been declining for fifteen years, and in the past year I learned of four lamb slaughtering operations that have closed. To me, the real problem is one of lamb supply and demand and logically research should be directed to these areas and not on the location of new plants.

(*c*) Assumptions must be realistic and explicit. Two of the most frequent weaknesses of research are that assumptions are not stated explicitly and consequently a potential user does not know if or how the results apply to his particular problem, or that the problem is many times assumed away.

(*d*) The research results must be usable. There are three elements here: the proper technique must be applied to the problem, reliable data must be available on a timely and repetitive basis, and the results must be updatable as conditions change.

(*e*) Finally, the results must be timely. The results of the research must be available for use before the decision requiring the results has to be made. A time objective should be built into every research project.

Industry Orientation

To put in perspective the comments that follow in research needs and priorities, it is important to discuss the industry orientation to research. While there is variability in research emphasis from company to company and, to some extent, from industry to industry, the orientation is toward one goal—better decision making. In a firm, most decisions are based on expected supply, demand, price, and policy variables. Consequently, industry's greatest need is in assessing the future patterns of product demand, input costs, product prices, and input prices and in the policy decisions that influence each of the others. In addition, we concentrate on applied, short-term

problems rather than theoretical, long-term problems.

Because of this orientation and the fact that most company economic research groups are not staffed to be self-contained, industry is dependent on and looks to university and government researchers to fill three basic needs: theoretical research, long-term research, and well-trained people. To put it another way, we look to the public researchers to supply those needs that span company and industry boundaries.

Theoretical Research

Despite the persistent call for applied and relevant research, industries must face the fact that theoretical research and new techniques and methods of analysis are needed. We do use quantitative techniques in research that were developed in academia. We do use economic theories that were formulated by the theorist as a starting point for our analyses. If we reflect properly on the source of our frustrations, it is not necessarily found in the rigor of theoretical research but in the fact that while theory and technique are lagging our needs, the academic community is applying already-developed theory to problems that do not exist or at least are not involved in our decision-making needs.

Long-term Research

The time demands of those in industry for short-term answers are such that we do little long-term macrotype research. Our focus is on short-term company or industry problems. However, for many strategic decisions we need an evaluation of the long-term growth and shifts in the food industry. For example, plant location studies require a projection of long-term availability and location of raw materials. As a basis for such a projection, we evaluate production trends based on such "public" studies as optimum farm organizations and interregional studies. We also use analyses of long-term shifts in product demand and population shifts. Economies of scale dictate that such studies be done at the academic level for use across industries. Many of us in industry have made good use of such analyses.

People

No output from the academic system is more important than well-trained people. While the subject of training has been discussed at two AAEA meetings in recent years, I want to make one point. The primary deficiency of those we interview is a lack of understanding of the decision-making process and how economic research relates to it. I believe that this stems, in part, from the orientation of the research being done at the graduate level.

With this background, I now discuss needs and priorities as I see them.

Needs and Priorities

When we teach economic theory, static and dynamic analysis are separated. Unfortunately, many research efforts do not anticipate and, in many cases, do not keep up with the dynamics of our environment. This has been particularly true during the past four to five years. The environment just passed us by. Industry has been faced with a decision-making environment that it has not seen before and has had nowhere to turn for help. While everyone has his own priorities and an endless list of needs, there are three areas to discuss: risk analysis, market analysis, and policy.

Risk Analysis

For years, with the exception of that part of production economics that made appropriate distinctions between risk and uncertainty and calculated variances and covariances among returns from alternative farm enterprises, the primary emphasis of risk analysis and management was in using the futures market in inventory management. In this case, the teaching was that futures markets were reserved for commodities possessing certain characteristics, one being that the commodity must be storable. Of course, the market, and not research, has long since made these concepts obsolete and ineffective.

This obsolescence was brought about by a drastic change in the operating environment. We went from an environment of surplus commodities and stable prices to one of low stocks and volatile prices. With the exception of some commodity support prices and supply controls, we went from a relatively free market to one of price and margin controls. We went from a market where exports were promoted to one where exports were controlled, where the Soviet Union was not a factor to one where it is a swing factor, where farmers

had to concern themselves with not only cost minimization but also with the marketing of their crops and livestock, and where procurement in the food industry changed from primarily a physical process to an economic process.

In such an environment, new needs developed for measuring risk, determining acceptable risk levels for a particular business, and management tools for managing risk within the constraints of the first two needs.

Obviously, we, as a profession, did not offer to producers, processors, financiers, and distributors of agricultural commodities the decision tools needed to manage in such an environment, particularly the tools needed for measuring risk and determining acceptable levels of risk. The abstract concepts of risk averters and risk lovers are not sufficient for an individual firm. The individual firm must make specific, quantitative decisions concerning risk levels. If we had provided the appropriate tools, we would not have seen the severe financial losses and, in some cases, bankruptcy in the food industry. We would not have seen, and still see, major corporations reporting severe financial downturns as a result of volatile commodity markets. What went wrong? What can we do to avoid repeats? In terms of what went wrong, I think traditional models and our thinking with respect to the application of those models quickly became outdated. In terms of what can be done to avoid repeats, we need to expand our concepts of risk and risk management.

At Pillsbury, risk has been broken down into three categories according to the nature of the business. These categories are (*a*) risk associated with product held for inventory or merchandising, (*b*) risk associated with the erosion of finished product margins, and (*c*) risk associated with physical availability of the commodity.

The management of each risk varies. For the first type of risk, traditional hedging or cross-hedging models are used. For the second type, we have developed a modified game theory model illustrated in table 1. In this model, we attempt to assess the outcomes of alternative procurement and product inventory strategies, given alternative market outcomes and strategies by competition. Procurement decisions are based on the probabilities and magnitudes of the gains and losses of each strategy.

Table 1. Procurement Strategy Model

	Company Strategy and Market Outcome[a]			
	Market Up		Market Down	
Competitor Strategy	Long	PDS	Long	PDS
Long	G	LL	L	GG
PDS	GG	L	LL	G

[a] PDS is price date of shipment, G is gain as a result of strategy, and L is loss as a result of strategy.

While the model is presented in simplified form, there is a broad spectrum of inputs that go into the model. These include the likelihood of alternative competitor strategies and the likelihood of alternative market directions. In turn, the likelihood of alternative market directions is a function of our assessment of government policy, weather, foreign demand (particularly the level and timing of Soviet demand), and the standard errors of our forecasts.

In managing risk, we have a specific dollar level of risk that we are willing to assume and specific procedures for measuring the risk that we are willing to assume. Our measurement of risk is based on historical price levels, absolute price levels, and the errors associated with our forecasts. The error probabilities associated with forecasts are based upon a forecasting track record and not from standard errors of models we estimate. Four years ago I argued at the AAEA meeting that forecasting track records (the difference between actual price and the forecasted price) and not standard errors of equations should be the basis for assessing the probabilities of alternative price ranges (Crowder, pp. 781–82). Based on articles since then, obviously I did not make a strong impression.

While our model and methodology needs refinement, it is better than traditional approaches to the problem. With the increase in risk associated with weather, policy, and variation in foreign and domestic demand, there is an increasing demand for improved risk management models by decision makers, and I think it is a challenge to the profession to develop models that are not only theoretically sound but are also models that can be understood and applied by everyone in the food industry from producer to retailer, including the agricultural policy makers.

Market Analysis

Because agricultural economists have been making market analyses for years, this area for research emphasis might be overlooked. However, our past record and our current reputation in this area leaves something to be desired. The poor performance in market analysis over the past four to five years implies that too much time has been spent refining quantitative techniques and too little time on analyzing changes and structural shifts in the food industry.

Historically, market analyses have been price and quantity oriented. Price analyses have been made on the basis of a given supply, prices or supplies of competing products, and a demand shift variable such as income. Supply analyses have primarily been cobweb analyses—current supplies are a function of lagged prices.

Based on the work done, these simplistic descriptions of the system analyzed with complex quantitative models are not nearly as effective in helping the decision-making process as are simplistic models that properly reflect the market system and process. Let me illustrate with a simple model.

As major users of boneless beef, one of the major inputs to Pillsbury's procurement strategy is the cow kill during a year. Based upon an analysis of the decision-making process in the beef industry, we know that the number of cows killed in a given year is not a function of last year's or this year's cow prices but of the current and historical profitability of the cow-calf enterprise and of the number of cows available for slaughter. Figure 1 depicts the model used to forecast cow slaughter in a given year. The percentage of the 1 January cows slaughtered during the year is a function of current and lagged profits to cow-calf operators.

There are four important points about the

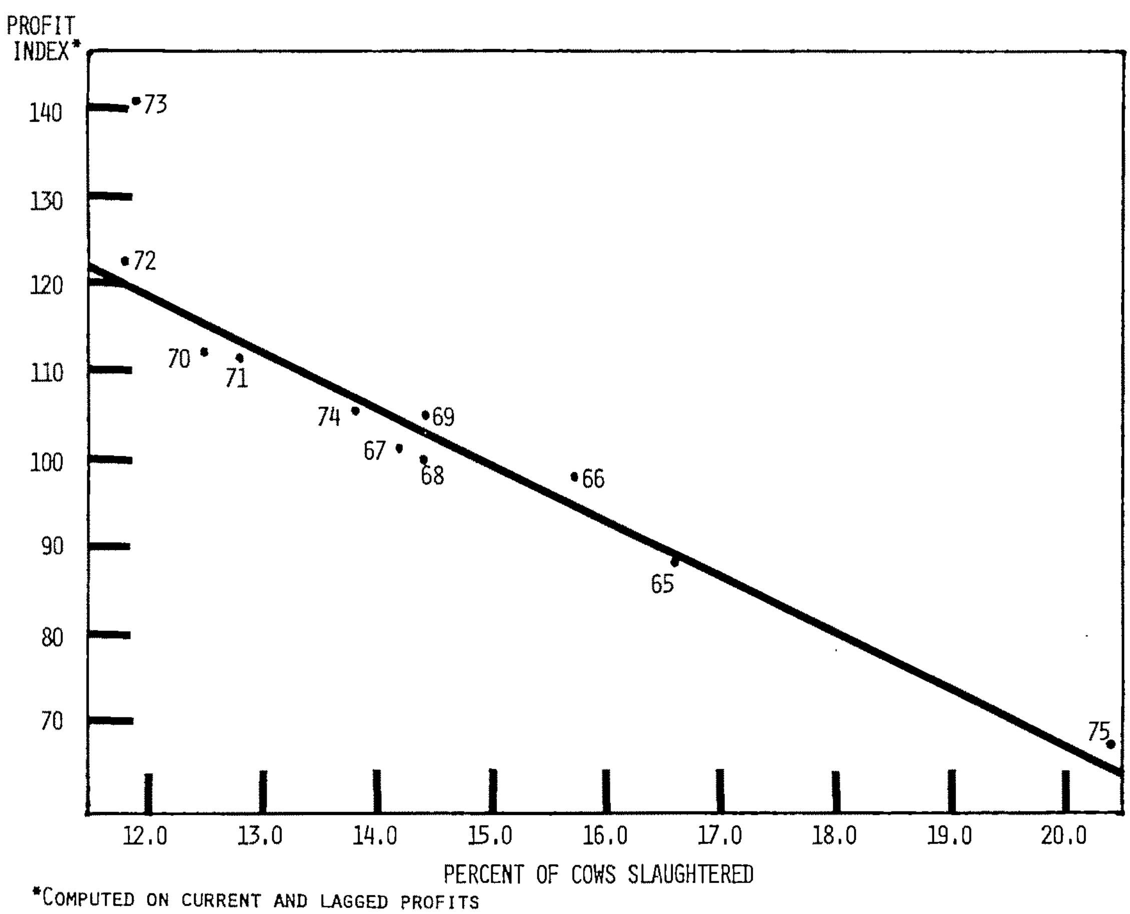

Figure 1. Percentage of 1 January cow slaughter and profit index, 1965–75

model. First, it reflects the decision-making process of the industry. The investment recovery in cow-calf operations is over an extended period. Therefore, the decision to keep or retain cows is a function of not only current profits but also of those that were accumulated in previous years.[1] Second, the model can be estimated by forecasting only one variable—this year's profitability. Third, the model is simple but yet describes the system. Finally, the model is easily understood and accepted by noneconomists.

The model uses profits, not prices. With the increases in levels and volatility of prices in the past several years, we have turned increasingly away from price variables to profit and dollar expenditure variables. For example, the dollars cattle feeders are willing and able to spend for feed grains is a function not so much of the price of the feed grain but of the dollars (profits) they have to spend for feed grain. Demand for a given item represents not only an ability but a willingness to pay for a given item. Ability is determined by the profits (income in case of the consumer) in hand or the credit available. The willingness is determined not only by current and expected profits (income) but by past profits (income).

From supply and expenditure levels, prices can be estimated. A theoretical problem with the approach is the variability of elasticities at different quantity levels. However, I have not found the theoretical problem here to be greater than the practical success resulting from an adequate description of the system. A real challenge to the profession is to determine the proper theoretical and practical basis for analyzing market forces and outcomes in the food industry.

Not only have many of the fundamentals of the cash markets eluded us but so also have those of the futures markets. The trading of nonstorable commodities caught the profession completely by surprise, and to date I have yet to see an acceptable theoretical or practical analysis of the live cattle or live hog futures markets. Neither have I seen any research designed to improve the management of converting margins through the simultaneous use of live cattle, feeder cattle, soybean meal, and corn futures. Logically, these four futures markets used properly would be a vehicle through which the cattle industry could transfer market risk to speculators. I suspect that part of the reason for lack of work in this area stems from the complexity of managing the four price bases involved and that many do not understand the nature of or function of a basis.[2]

In a talk to a seminar on futures markets sponsored by the Chicago Board of Trade, Amstutz said, "It has become increasingly clear to me over the past year that many, too many, do not understand basis. Understanding basis is fundamental to understanding futures and hedging. Your acceptance of this axiom should provide ample incentive to understand work in this area" (*Milling and Baking News*, pp. 35–36). In teaching of futures markets courses, we have traditionally taught the mechanics of transferring risk by hedging where hedging is defined as the sale (purchase) of a cash position offset by the purchase (sale) of a futures position. The risk involved in the ownership or the sale of the basis has been ignored. As all who have had basis positions know, there is risk in a basis position, and it must be managed just as the risk involved in a futures or a cash position.

With increasing price volatility, with an increasing need to manage risk, with new futures markets offering additional market alternatives, and with important rules governing commodity marketing trading being made by a new regulatory agency, the need and the professional incentive should exist to improve and intensify our research and education in understanding the function and mechanics of futures trading. Outside of a few people, such as Roger Gray, our profession has neglected a research area that has the potential for a large payoff.

In his comments, Amstutz stated, "I am totally unconcerned about the possible demise of the futures industry as a result in a 'breakthrough' in accurate, reliable, quantitative forecasting techniques" (*Milling and Baking News*, pp. 35–36). While I agree with a literal interpretation of this statement, realistic quantitative models are a useful vehicle for improving decision making. Our challenge is to spend more time in understanding market systems and less in developing more complex and sophisticated quantitative models.

---

[1] Additions to or liquidation of the cow herd is also a function of expected profits. With no explicit "expectations" variable in the model, the implicit assumption is that "expectations" are also a function of current and lagged profitability.

[2] Basis is defined as the difference between cash and futures price. In addition, there are geographical bases (price differences among geographical areas) that must be managed.

Policy

Of all the disappointments many of us have had with respect to our profession during the past five years, none has been greater than the lack of evaluation of key economic policy decisions. The response of the profession was silence during the many market interventions of recent years, and our analyses have been based on the premise that the price volatility during this period was due to market forces alone. However, in addition to an examination of policy options for unstable prices, we need an analysis of policy as a source of price instability.

It would be easy to dismiss the price controls that were imposed as a one-time phenomenon that is unlikely to recur. However, the sensitivity of consumers and political leaders to inflation suggests that we cannot summarily dismiss them as a one-time phenomenon, and neither does the fact that export controls have been applied and taken off again several times since price controls were first applied. Therefore, a key issue is an assessment of the costs of the distortions caused by such market interventions. We need, for example, an assessment of the costs to consumers and livestock producers of our market intervention. Perhaps, more importantly, we should have an analysis of how the need or apparent need for such interventions can be avoided. Finally, we need to communicate effectively the results to key policy makers.

While this paper is not the place for such an analysis, let me examine one example of such costs. Marketing patterns of the beef industry were severely disrupted by the price controls of 1973. During controls, cattle were inventoried in feedlots and on ranches. Then, when price controls were removed, beef came to the market at rates faster than the market could absorb. Returns to cattle feeders plummeted. So, in turn, did the feedlot demand for feed grains and feeder cattle. The result was severe losses on the part of cattle feeders and cow-calf operators.

Hasbargen and Egertson recently published estimates that the losses over feed costs for cattle feeding and cow herds were \$21.16 per hundredweight and \$139 per head, respectively, in 1974 (p. 5). This compares with losses of \$6.50 per hundredweight and \$39 per head, respectively, in 1953. Taking the difference in losses between the two periods and using the number of fed cattle marketings in 1974 and the 1 January 1974 cow inventory results in a loss of over \$7 billion to the cattle industry that, in my opinion, can be attributed to the effects of economic policy.[3] The consequences of this are predictable—the largest liquidation of the cow herd since the 1930s. This effectively reduces our ability to produce beef.

The net result of the price controls was sharply higher prices in the short run, abnormally high losses for beef producers in the intermediate period, and higher beef prices for the consumer in the long run. The beef industry is not an isolated case. There has been variability in returns to pork and poultry producers during this same period. Subsequent to the price controls, the variability of livestock producers' cost and returns as well as the returns to grain producers have been exaggerated by the on-again–off-again export controls.

My point is this: economic policy in recent years has been a source of instability and costs and, consequently, has contributed to rather than reduced inflation. As Bottum pointed out, "if there is more than one choice, and there usually is, the procedure is to identify and delineate the problem, develop possible solutions, set forth the consequences of each solution and make the decision" (p. 765). Agricultural economists have not only overlooked part of the problem—economic policy as a source of instability—but have and still are failing to analyze and set forth the consequences of alternative solutions. Price stability will remain an objective of those in public decision-making positions, if not among economists. However, with an ever-increasing demand for food and an ever-increasing interdependence in the world, it will remain an elusive objective. Therefore, it is our responsibility as economists to set forth the economic consequences of alternative solutions, particularly the artificial controls that create costly dislocations throughout the system.

Comments on Current Research

In summary, industry economists are not asking our profession to abandon rigorous,

[3] It can be argued that in 1973 returns to cattle feeders were higher than normal because of the artificially high prices during the

theoretical analyses. Analyses designed to provide a better theoretical understanding of our food industry and/or to provide better tools of measurement and analysis are needed. The concern is the energies expended on rigorous analyses of obsolete data or on problems that do not exist. Let me illustrate with the following "do" and "do not" examples.

Do provide an objective evaluation of the economic consequences of changes in beef grades. Do not provide an analysis of where new lamb slaughtering plants should be located.

Do give us an evaluation of central cutting and packaging of beef. Do not give us another study on the optimum location of cattle feeding.

Do give us an analysis of the nature and extent of shifts in demand for various products. Do not flood us with explanations of how coefficients vary from two-stage to three-stage least squares.

Do provide research that is current and useful in today's decisions. Do not provide an analysis of a decision we had to make yesterday and will not have to make tomorrow.

Do tackle key policy issues. Do not delay analyses until after the policy decisions have been made.

The responsibility for the gap that exists between the type of research that is being done and that we in industry would like is not entirely the responsibility of our colleagues in academia and government. Communication is a two-way street. The approach of using AAEA meetings as a once-a-year forum to vent industry's frustrations is not satisfactory. Our requirements and the contribution our academic and government colleagues can make are too great for a once-a-year exchange. Therefore, there are do's and do not's for those in industry also.

Do communicate problems immediately. Do not rely on the AAEA meetings as the only medium of communication.

Do take the initiative in establishing a meaningful dialogue with academic counterparts. Do not expect those in universities and government to understand our needs if we have not discussed our needs with them.

Do read the "rigorous" articles in the *Journal* and elsewhere with the thought of gaining new ideas or techniques that could be useful to you. Do not put the *Journal* aside because the articles do not provide specific answers that you have.

Do share new ideas or techniques with academic counterparts. Do not cloak your research in secrecy. In industry, implementation of an idea is as important as the idea itself.

"shortage." However, if one adjusted for this based on volume differences, the losses would still be massive.

Recommendations

While there are those of us in industry who, at times, threaten to abandon the AAEA, I think there are more positive approaches and recommend the following. First, since research efforts and funds flow to those areas that receive professional recognition, the AAEA should appoint a committee, including industry representatives, that would select for an award the article in the *Journal* or elsewhere that makes the most significant contribution to the industry decision-making process. This award would be in addition to the outstanding *Journal* article that is now made.

Second, the AAEA should set aside a section of the *Journal* for short, applied articles to be written by those in industry or in other decision-making roles. This would be a vehicle of communicating to the profession key areas of concern to decision makers. Of course, industry economists would have the responsibility of writing such articles.

Third, I would encourage academic institutions and government agencies to have industry participation in evaluating academic, professional, and research programs. This is done now by many business schools, and it is a prime reason for the success of masters of business administration in the corporate environment.

Finally, there should be AAEA-sponsored seminars in which there would be an industry-academic exchange of problems and methodology. The AAEA is rich in professional talent and technical expertise. The number one problem is identifying common problem areas and ordering priorities, which can be overcome only through effective communication. Hopefully, implementation of the above recommendations will provide a greater degree of continuity in the dialogue between the industry and academic economists in the AAEA. History has demonstrated that these once-a-year critiques are not satisfactory.

Public Food Assistance Programs: Impacts and Social Policy Role (Daniel I. Padberg, University of Illinois, Chairman)

Effects of the U.S. Food Stamp and National School Lunch Programs, Fiscal Year 1974

Paul E. Nelson, Jr., and John Perrin

The depressed thirties brought forth side by side the paradox of food surpluses and obvious need. Federally sponsored food programs simultaneously were aimed at raising farm income and improving diets (Gold, Hoffman, and Waugh, p. 1; Southworth and Klayman, p. 1). These pre-World War II objectives are embodied in current legislation, although emphasis has shifted from farm income support toward improved diets.

From their beginning, economists have recognized that an injection of funds by means of food assistance programs yields a different pattern of resource allocation than an equal injection by other means. For example, an injection to provide food assistance results in a different allocation of resources than an equal injection to support national defense.

In 1961 federal assistance to the food stamp, food distribution, and school lunch programs amounted to $466.5 million.[1] For 1975 the preliminary estimate is $6,139.1 million (USDA 1976). The 1975 figure is a 13.2 multiple of the 1961 statistic.

Programs of such magnitude deserve quantitative as well as philosophic analysis. The focus of this paper is on the quantitative. Its purpose is to measure the economic effects of these programs in terms of net changes in business receipts, household income, jobs, and gross national product (GNP). The analysis is based upon the assumption that the funding for food bonus stamps and the cash contribution to the schools is paid for by a tax increase.[2] The taxpayers' disposable income and, hence, expenditures were reduced prior to making the income transfers to the recipients.

The results of the analysis of food stamps, assuming a transfer from taxpayers to food stamp households in the form of bonus stamps, are reported in net terms because both the output increases associated with the income transfer to the participant household sector and the decreases in output linked to the increased personal income taxation of the nonparticipant household sector have been taken into account. The results of the analysis of school lunches, when the transfer is assumed to be in the form of a cash contribution, are also in net terms; however, the increases in output are linked to the federal cash transfer to the schools and not to the participant household sector.

Business receipt changes are reported on a sector-by-sector basis. As anticipated, some sectors were better off with than without the programs. Conversely, others would have

Paul E. Nelson, Jr., is an agricultural economist with the Economic Research Service, U.S. Department of Agriculture, and John Perrin was with the Division of Coordination Planning, Office of the Governor, Austin, Texas.

The following colleagues made constructive suggestions at various stages of manuscript development: Tom Carlin, Clark Edwards, Gar Forsht, Alden C. Manchester, Masao Matsumoto, Bob Reese, Gerald Schluter, and Abner Womack. Herbert Grubb of the Water Development Board, Texas, and A. C. Hoffman in Bull Shoals, Alabama, were also very helpful.

[1] These figures exclude special supplements to women, infants, and children (WIC), institutional distribution, and school milk activities.

[2] Alternative assumptions that could have been adopted include (*a*) all federal contributions were funded by deficit financing or (*b*) the 1967 data already included the needed funds.

been better off if there had been no programs. Overall, the economy gained. Of course, consideration of such changes would be incomplete without some treatment of a possible "output illusion," which in turn is associated with the flexibility of supply. Such considerations are treated at the close of this paper.

Food Stamp Program

The input-output technique is particularly well suited for measuring changes in business receipts and household income, which are associated with variations in the final demand for each sector's goods and services.[3] Additional computations are required and were made to compute the changes in gross national product.

Table 1 presents the increased business receipts (output), household income, and gross national product generated during fiscal year

[3] The 1967 U.S. Department of Commerce input-output model was adopted and adjusted for our analytical purposes. Details of the adjustments and assumptions are presented in a technical appendix developed to support two more extensive reports (Nelson and Perrin 1976a, b, c). Single copies may be obtained from the author upon request.

Table 1. Net Economic Effects of a Transfer from Taxpayers to Food Stamp Household in the Form of Bonus Stamps, Fiscal Year 1974

Sector	Change in Jobs (number)	Change in Business Receipts (1,000 $)
Agriculture, forestry, and fisheries	32,453	407,715
Mining	−182	−8,435
Construction	−157	−5,317
Food manufacturing		
Meat and poultry products	4,057	287,555
Dairy products	1,877	102,655
Grain mill products	1,036	89,529
Bakery products	2,267	59,181
Canned and preserved foods	4,178	171,873
Other foods and beverages	1,477	98,127
Subtotal	14,892	808,920
Nonfood manufacturing		
Clothing	−4,448	−43,803
Other manufacturing	−7,666	−237,523
Subtotal	−12,114	−281,326
Local and suburban transportation	−285	−3,566
All other transportation	−177	−5,449
Communications	−662	−15,327
Gas, electric, water and sanitary utilities	0	−707
Wholesale trade	11,463	249,145
Retail trade	48,980	461,343
Finance, insurance, and real estate	−4,248	−211,480
Personal services	−6,832	−45,728
Physicians and dentists	−1,237	−36,498
Hospitals and laboratory services	−1,910	−15,037
Education (private)	−685	−23,856
School lunch	−21	—
Other sectors[a]	−2,717	−77,850
Total	76,561	1,196,547

Sector	Change in GNP (1,000 $)
Combined Household Sectors	
Bonus stamps received	2,718,000
Plus income from new jobs	10,750
Minus increase in savings and taxes	72,447
Equals change in consumption expenditures	2,656,303
Nonparticipant Household Sector	
Income from new jobs	281,683
Plus decrease in savings and taxes	208,780
Minus tax to fund stamps	2,718,000
Equals change in consumption expenditures	−2,227,537
Net change in combined sector consumption expenditures	428,766
Plus change in school lunch expenditures	−1,905
Equals change in gross national product	426,861

Note: The nonparticipant household sector was taxed $2,718 million to fund bonus stamps. The expenditure of the bonus stamps was treated as an increase in final demand of this amount. Meeting this increase in final demand required additional economic activity.
[a] Other sectors is an aggregate composed of direct and transferred imports; business travel, gifts; office supplies; federal, state, and local government enterprises; and other services.

1974 by the injection of $2,718 million of bonus stamp expenditures. Column 2 indicates the net impact of the food stamp program upon specified sectors of the economy. Column 3 reports the net impact upon household income along with the net addition to gross national product.

In interpreting these figures, it should be noted that 55% of the bonus stamp expenditures were assumed to be spent for food and 45% for nonfood items.[4] This assumption provides the basis for identifying the extent to which business receipts and household income increments are associated with a change in the expenditure pattern rather than to an increase in total final demand.

Business Receipts, Household Income, and GNP

Estimates for 1974 indicate that total business receipts, household income, and gross national product increased as a result of the food stamp program. Business receipts rose about $1.2 billion, net household sector income, $292.4 million, and gross national product, $427 million.

Table 1 also shows that while some sectors benefited, others were less fortunate. Food and food-related sectors were expected to benefit. In 1974 the income distribution of nonparticipant households was skewed heavily to the right—above $10,000. The income distribution for participant households was skewed to the left—below $5,000. This meant that the marginal propensity to consume was much higher for participant than for nonparticipant households. In addition, the regulations that required participants to buy stamps valid only for the purchase of foods led to increased food purchases and services related to food marketing.

The agriculture, forestry, and fisheries sector experienced increases in business receipts of $408 million; food manufacturing's business receipts were $809 million higher than if there had been no program. Corresponding increases in business receipts for the wholesale and retail trade sectors were approximately $249.1 and $461.3 million, respectively. Much of this gain was probably contributed by the food wholesale and retail trade sectors. The precise amount cannot be determined because the U.S. Department of Commerce 1967 model does not disaggregate its sectors to that level. (Complete data on the U.S. Department of Commerce 1967 model can be obtained only on tape from that department.)

Of the food manufacturing sectors, meat and poultry, canned and preserved foods, and dairy products gained more than did the grain mill and bakery products sectors. When the dairy products sector is combined with the meat and poultry products sector, these protein sectors accounted for 48.2% of the total increase in food manufacturing business receipts.

Other sectors were less fortunate. These sectors experienced decreases in output associated with the direct tax increase that outweighed the increase in output due to the indirect and induced effects stimulated by bonus stamp expenditures. Specifically, the nonfood manufacturing sectors' output was $281 million less than it would have been without the program. The output for services other than the wholesale and retail trades was $358 million less. Among the services, finance, insurance, and real estate had the greatest difference in size of output, which would have been maintained if there had been no program. Its output (business receipts) would have been greater by $211.5 million.

Numbers of Jobs

Increased business receipts (output) are also associated with an increase in the number of jobs needed to meet the increase in final demand. Thus, the figures reported in table 1 reflect the increase or decrease in the numbers of jobs by sector as a result of the food stamp program. The number of job changes reported for the entire economy represents the algebraic sum of the job numbers by which the sector totals increased or decreased as a result of the program.[5] For 1974 there were 76,561 more jobs with the program than there would have been without it.

[4] The food-nonfood distribution is based upon the Reese et al. report and discussions of the basic data on which it is based. Technically, even though each food stamp issued is spent for food, there is the possibility of substitution of nonfood for food purchases if prior to participation the household spent a higher proportion of its net income for food than the rules for participation required.

[5] The total number of job-holding people within each sector in 1967 was divided into the total business receipts (output) for each sector in 1967. This business receipts per employee ratio was the factor divided into the change in business receipts, sector by sector, to estimate changes in job numbers.

The agriculture, forestry, and fisheries; food manufacturing; and retail and wholesale trade sectors added new jobs, while in contrast mining, construction, service, and nonfood manufacturing sectors had fewer jobs than they would have had without the program. The former sectors added 107,788 more than they would have without the program, while the latter had 31,227 fewer jobs.

The National School Lunch Program

Federal contributions to the school lunch program are made both as cash and as commodities.

Business Receipts, Household Income, and GNP

The injection of the federal cash contribution into the U.S. economy occurs when schools use the contributed funds to purchase food and labor required by the program. Table 2 reports net changes in business receipts, household income, and gross national product resulting from the schools' receipt and expenditure of the income transfer. With the transfer, business receipts were $573 million more than without it. Household income was $378.6 million and gross national product $397. 5 million higher because of the program. Again, as expected, the sectors that benefited most were the food sectors and those providing them direct services, e.g., wholesale trade.

The increases in business receipts on the part of the meat, poultry, and dairy products sectors appear to reflect nutritional requirements built into the school lunch program. In 1974 the combined meat, poultry, and dairy products sectors had a business receipts increase of $392.8 million. The combined rise of these sectors represent 70.3% of the total increase in business receipts by the food manufacturing sectors. (The corresponding figure cited above for the food stamp program was 48.2%.) The business receipts in the canned and preserved foods and the wholesale trade sectors also increased substantially, by $100.6 million and $52.0 million, respectively.

In contrast, other sectors whose output was less with than without the federal cash contribution were retail trade; clothing and all other manufacturing; finance, insurance, and real estate; physicians and dentists; and hospitals and laboratory services. Of these, the sector that would have gained most without the contribution was the finance, insurance, and real estate sector, whose increase without the contribution would have been $134.1 million more.

Numbers of Jobs

Table 2 also presents the number of new jobs derived from the change in business receipts. On balance, the economy had 26,383 more jobs because there was a federal cash contribution to the schools. Again, sectors that had the greatest change in business receipts tended to experience the greatest change in job numbers. Agriculture, forestry, and fisheries reported job additions of 26,389 and food manufacturing sectors, 10,445. Of these, the meat and poultry sector contributed 1,942; dairy products, 4,665; and the canned and preserved foods sector, 2,447. Two other sectors that added many jobs were wholesale trade (2,392) and school lunch (11,806).

Some sectors had fewer jobs than if there had been no federal cash contribution. For example, schools buy mostly from manufacturers and wholesalers. Thus, the retail trade would have had 11,265 more jobs without a federal cash contribution. All nonfood manufacturing (including clothing) would have had 3,689 more jobs without the program. Such differences among sectors are part of the fabric of the economy. Very few, if any, actions can be taken that would result in every sector gaining equally.

Supply Flexibility and a Possible "Output Illusion"

Although input-output models are useful in studying changes in an economy, the input-output technique implicitly assumes perfect flexibility of supply; its measure of change in real additional final demand is accurate only to the extent that supply flexibility provides the required additional goods and services. To the extent supply did not have sufficient flexibility to furnish these added goods, the increase in output and gross national product would be illusory in the sense that these would be exaggerated by our figures.

There are two particular questions that must be examined: (*a*) to what extent was there supply flexibility in 1967, the year of the base model's technical coefficients; and (*b*) was

Table 2. Net Economic Effects of a Transfer from Taxpayers to Schools by Means of a Federal Cash Contribution, Fiscal Year 1974

Sector	Changes in Job (number)	Changes in Business Receipts (1,000 $)	Sector	Change in GNP (1,000 $)
Agriculture, forestry,				
and fisheries	26,389	331,535		
Mining	15	710		
Construction	269	9,126		
Food manufacturing			Combined Household Sectors	
Meat and poultry			Income from new jobs	378,648
products	1,942	137,662	Plus decrease in taxes	
Dairy products	4,665	255,161	and savings	28,002
Grain mill products	304	26,236	Minus tax increase to fund	
Bakery products	815	21,282	federal school contribution	1,085,000
Canned and			Equals change in	
preserved foods	2,447	100,649	consumption expenditures	−678,350
Other foods				
and beverages	272	18,084		
Subtotal	10,445	559,074		
Nonfood manufacturing				
Clothing	−2,744	−27,025		
Other manufacturing	−945	−29,270		
Subtotal	−3,689	−56,295		
Local and suburban				
transportation	−276	−3,453		
All other transportation	584	17,952	School Lunch Sector	
Communications	−372	−8,600	Change in school lunch expenditures	1,083,382
Gas, electric, water, and			Minus increase in	
sanitary utilities	56	3,618	factor payments[b]	7,498
Wholesale trade	2,392	51,994	Equals change in	
Retail trade	−11,265	−106,109	consumption expenditures	1,075,884
Finance, insurance, and				
real estate	−2,694	−134,115		
Personal services	−2,648	−17,726		
Physicians and dentists	−613	−18,086		
Hospitals and				
laboratory services	−2,121	−16,703		
Education (private)	−262	−9,132		
School lunch	11,806	—	Net change in combined	
Other sectors[a]	−1,633	−30,596	sector consumption expenditures	
Total change in			Equals change in gross	
business receipts	26,383	573,194	national product	397,534

Note: The nonparticipant household sector was taxed $1,085,000 to fund the federal contribution to schools. The schools' expenditure of the cash contribution was treated as an increase in final demand of this amount. Meeting this increase in final demand required additional economic activity. This increased activity resulted in a contribution to gross national product of $397,534,000.

[a] Other sectors is an aggregate composed of direct and transferred imports; business travel, gifts; office supplies; federal, state, and local government enterprises; and other services.

[b] In this sector, it is composed primarily of depreciation of school lunch equipment.

there sufficient supply flexibility in 1974 to meet the increased final demand generated by the income transfers? The flexibility in some of the major sectors is discussed below.

Base Model Year—1967

Farm products supply. Cropland acreages harvested provides an indication of supply flexibility, including the impact of weather.[6] The acreage harvested in 1949 was an historic high. If these 352 million harvested acres are treated as representing a realistic capacity, the acres harvested in 1967 were equivalent to 85.5% of capacity (USDA 1975, p. 8). The historic high for livestock production was in 1973. In terms of units of livestock (animal equivalent basis) in 1967, the farm sector produced at 91.8% capacity (Allen and Devers, p. 6).

Manufacturing sector supply. At the manufacturing level the Bureau of Economic Analysis,

[6] Between 1964 and 1969, total land in farms declined from 1,110 million to 1,064 million acres or by 4.1% (USDA 1976a, p. 420).

U.S. Department of Commerce, reports two manufacturing capacity figures (Hertzberg et al., pp. 48–49). The first measures the respondents' concept of a maximum practical capacity. The second reports what the respondents believe to be the capacity level that would maximize their company's profits or other objectives.

If the actual rate is greater than the preferred, overutilization is implied. If the inverse pertains, undercapacity is assumed. For all manufacturing sectors, the 1967 actual capacity utilization rate was 84.0. Food, including beverages, was 79.5. The corresponding figures for the preferred rates of capacity utilization were 94.0 for all manufacturing and 90.0 for food.

Wholesale and retail trade sector supply flexibility. Corresponding estimates of capacity utilization are not available for these sectors. Retail stores have increased both square footages of sales space and the hours that stores remain open. The wholesale trade sector has modernized storage facilities, including computerization of order handling and mecnanization and containerization for storage and delivery.

The comparison of the increase in final demand for the retail and wholesale sectors generated by these two food assistance programs with the total business receipts for merchant wholesalers and retailers provides an indication of these sectors' capability to handle such added final demand without further expansion of their facilities and staff. The program-related increase in final demand amounted to 0.6% of 1967 total retail business receipts, and 0.9% for the receipts for the merchant wholesale sector.

1974 Comparison

Using the same measures for comparison for 1974 yielded a farm products index of 0.923 for crop land harvested (USDA 1975, p. 8) and 0.988 for animal units of livestock. This latter figure was down slightly from 1973, which equaled 100.0 (Allen and Devers, p. 6). The maximum practical capacity ratio for all manufacturing sectors was 82.5 and for food, including beverages, 79.8 (U.S. Dep. Commerce, p. 18). Thus, the companies were operating at less than their preferred capacity. The retail sector's increase in final demand generated by the food programs amounted to 0.3% of total 1974 retail business receipts. The corresponding figure for the 1974 merchant wholesale sector was 0.4%.

Summary

This evidence implies there was sufficient supply flexibility to meet the increase in final demand created by these programs. The increase in final demand may be considered "real" rather than illusory. The program's impact upon patterns of resource allocation is of sufficient magnitude to merit particular consideration in policy deliberations respecting food assistance and publicly sponsored income transfers.

Administrative Aspects of Food Programs as Renewable Resources

Rodney E. Leonard

The topic of this paper is administrative aspects of food programs, particularly the stamp program. It is not viewed as an invitation to say how the job could be done better, although that was a temptation. Nor is the topic seen as an opportunity to castigate Ed Hekman and his minions, even though I would do so with relish.

Instead, the purpose is to describe an administrative concept for the food stamp program (and other food assistance programs) as an integral part of a consumer food policy. I will explore some of the philosophical concepts that guide food programs, discuss some of the techniques for monitoring and evaluating public service programs, and suggest an approach to administering public services that is a little different from that now practiced by the U. S. Department of Agriculture. In short, I want to discuss program philosophy as it relates to monitoring and evaluation within the context of public service management, all to achieve sound program administration.

The food programs seem to be caught today in the web of conflicting policies—policies in addition to those surrounding the debate over categorical aid versus income maintenance. On the one hand, an imperial presidency and an imperial Congress created the food stamp program as the magnificent gesture of an enlightened elite. Benefits are provided for the poor, who abuse the program or show it disrespect only at the peril of their class. For example, an administration that could, with the stroke of the proverbial pen, cause 10 million people to suffer a diet less adequate today than yesterday, is simply an enlightened despot dressed up in democracy's cloak. Yet, it nearly happened, and only a lawsuit stood in the way. A Congress that could propose a set of changes that would do much the same thing is just a crowd of Lady Bountifuls arguing that the Thanksgiving package is much too good for the poor folks.

On the other hand, there are nearly 32 million Americans for whom the lack of an adequate income gets translated into an inadequate diet, which inevitably leads to poor nutrition, poorer health, and all the related problems. They are citizens who live in communities that have begun to employ various federal programs to enable the community to better serve its residents. The food stamp program is one of those programs. It is a community service.

But food programs are more than a community service. They are a renewable resource. They are an act of God, as much as the flow of the river, the tree growing on the hill, or the birth of new life. They differ in that they are the result of an intellectual, or human process, while the others spring from a biological process. As a renewable resource, these programs have meaning only in their use, in the capacity to contribute to the quality of life for the individual in the community. The value of the program exists in its application, not its creation.

If the food stamp program is a renewable resource, then the administrative focus of the executive agency changes drastically. The function of administration within the imperial form is protective not only of the program but also of the virtue and reputation of the executive and legislative branches. Criticism of abuses and arguments over the ethics of using public funds to reduce hunger are implicit threats to these branches. An effective bureaucrat, in this context, is one who knows how best to keep the congressional committee and the White House happy, or at least to keep discontent at these levels at a minimum. The crucial point is that the administrative focus is on those who have an indirect interest in the program. Responses to these interests tend to cause administrative forms that hinder

Rodney E. Leonard is executive director of the Community Nutrition Institute, Washington.

or restrict access to the program, a condition more harmful to the innocent user than to the program critics.

As a renewable community resource, the food stamp program requires a much different administrative process. The program administrator and staff are responsible to prevent or eliminate barriers to the program and to insure access by the community and its citizens. The administrator and the program staff perform a service function rather than act as guardians of the imperial dignity.

The legislative function, as a footnote observation, also shifts from a policing function to an evaluative role. The Congress would tend to assess the food stamp program in relation to a legislative emphasis on how best to insure the community is able to respond to the needs of all its citizens.

A crucial area for administration of a renewable resource program is the relationship between the federal, state, and local governments. Currently, administration tends to be a process for limiting responsibility rather than insuring performance. The general criticism of public service programs is not that they are unnecessary but they are unavailable or inadequate. (More is being heard lately about limited resources, but that is an issue of choices rather than limits.)

An imperial administration emphasizes the need to protect one's rear instead of securing performance. If a program is authorized and funded but does not reach many or most of those it is intended to serve, an imperial administrator will try to avoid blame or criticism or to structure his or her role to minimize responsibility. For example, it has become clear over the last ten years that an essential function of program operation is to identify, locate, and contact individuals eligible for food stamps, to explain the program and the process for establishing eligibility, and to assist those who need help in finding their way through this bureaucratic maze to obtain food stamps.

Outreach is a primary administrative responsibility for public service delivery, required by law since 1971. The federal courts have ruled that service programs without an outreach component are incomplete. The USDA only requires that state governments submit a plan as to how they would conduct outreach. With minor changes, most of these plans were approved; without great exception, none would provide the intensive outreach that is essential. It took a federal court order to require both the USDA and the state agencies to junk their "no-action" plans and to begin planning a process to insure performance. What the USDA was willing to accept was to be able to say, if criticized, is: the states had responsibility for planning outreach and did not do what they said they were planning to do.

A plan is an agreement to perform and not a treaty to limit responsibility. A federal-state food stamp plan should specify where outreach is most needed, state the number of individuals who will be contacted through an outreach program, include a timetable of program milestones that should be met, describe the staffing requirements (including job descriptions), state the supervisory relationships (including in the milestones the number and frequency of program performance reviews), and list the cost of outreach projects by communities.

The federal role in a renewable resource program is to assist states and local communities in developing operational plans for service delivery, to help in the development and training of competent staff, to support and encourage community participation in the development of the plans, to monitor the implementation of the plan and the operation of the program, and to provide support and technical resources to help solve the problems identified through the monitoring and evaluation process. The federal government, in addition, must act decisively to halt fraud and other criminal actions in relation to the program and to maintain federal standards where state or local authority chose to act contrary to the law.

Federal administration should emphasize these program administrative skills: planning, communications, monitoring, evaluation, community organizing, training, technical assistance, as well as regulation development, rule making, record keeping, public relations, personnel management, and financial management. Federally sponsored training should be provided on a regular and continuing basis, and employment and promotion should be based on participation in the training.

The administrative focus should view the food stamp program not as a service flowing from the office of the president or a congressperson but as a service flowing to the individual as a community resident. In the de-

velopment of program rules and procedures, a primary concern should be to assess the impact of a proposed rule or regulation on program access. If the impact analysis shows the likely result is to create a barrier to participation, then some other procedure to serve administrative needs should be found.

Similarly, the administrative view of evaluation should be as a process to identify areas where federal assistance is needed and can be offered. As program evaluation is often practiced currently, there is a tendency for evaluators to look upon themselves as investigators, cops in plain clothes. Even if an evaluator thinks otherwise, experience has taught state and local program staff to look upon them as someone whose visit always is followed by trouble. Evaluation is one step in the process of helping improve performance, not in assessing whom to punish.

Evaluation should be carried out under explicit conditions. Everyone should know what practices and activities are being evaluated and why. This is one of the basic arguments for as specific a state or community plan as possible. If a plan is viable, then the evaluation should identify problem areas and probable causes that can be corrected.

In a program as large (nearly 18 million participants) and as extensive (every county in the United States and Puerto Rico) as food stamps, a major and continuing problem is fraud and errors. Both tend to be lumped together in the public eye as losses of public funds due to dishonesty, deceit, and other skulduggery. There is probably some virtue to the generalization.

But the monitoring and the response to problems that surface in the evaluation are different for fraud than for error. Fraud or dishonesty can be practiced by everyone—by the food stamp staff, by the business community involved in handling stamps, and by the participant. Suppressing dishonesty requires both an acceptance by the community of the food stamp program (and thus peer pressure to stop abuses) as well as the normal skills of investigation, detection, and arrest. Fraud is a major problem in every public service program, and the effort put forth by the government to check and control fraud needs to be thorough and complete. It is one of those situations where public assurance of action is placed on the substance of procedure rather than on the reports of its effectiveness. In the case of food stamps, for example, this would involve a five-stage federal effort to build the capacity of state agencies to deal with fraud.

(*a*) Evaluate the current state agency efforts through a literature search, and select five or more of the most effective state agencies for further study.

(*b*) Develop surveys that will evaluate legislative and administrative practices on essential elements of fraud control and handling, such as staffing, procedures for investigating, administering, and restitution and for prosecution referral.

(*c*) Collect, using the survey instruments, information from states' public assistance agencies, fraud investigative units, and the state and district attorney's offices.

(*d*) Compile the information into a "Best Practices Report" for each state covering the administrative and policy relationships that have led to an efficient means of detecting, investigating, and prosecuting food stamp fraud cases. These reports could be used in information programs and in training and technical assistance efforts provided by the federal government to state and community agencies.

(*e*) Develop, as a major product of the analysis of survey materials, a "Federal Options Paper." This would identify possible changes in policy, in administrative procedures, and in organization practices such as the system of accountability for investigating and reporting fraud, administrative and legal sanctions, procedures for handling those who defraud the program, range of corrective actions available, and legal remedies.

The actual distinction between error and fraud, while important in efforts to investigate and prosecute recipient fraud, does not significantly change the methods for error detection. In other words, most corrective actions taken in the determination and retermination processes will reduce both error and fraud. The essential function, once an error is determined, is to distinguish if it is a fraud or an error and to take an appropriate action.

Errors are predominantly a staff problem, although participant error also exists, and work both ways. Some cause the federal government to pay more in benefits than an individual is entitled to receive; some cause individuals to receive less than they should. In one case the public is defrauded; in the other the individual citizen is defrauded. However,

where the problem is human error, program administration will have to rely primarily on administrative, as opposed to judicial, procedures to minimize the problem. The task is to improve staff skills to overcome institutional weaknesses.

This defines more explicitly the administrative or managerial problem. It is possible to educate individuals to fill certain staff functions, but education in no way trains the individual for the institutional role and the institutional problems. The food stamp program is an institutional mechanism, operating within the federal system of government to insure the delivery of a renewable resource to individual citizens in the community where they and their families reside.

The administrative resource needed to overcome institutional weaknesses, such as staff or other human error, is training and technical assistance (TTA). TTA is a crucial instrument for building institutional capability. Through TTA it is not only possible to communicate the necessary skills to overcome an operational problem but also to explain the various individual functions and skills within the context of the program and its purposes. It relates—or should relate—what one person at the federal level is doing to what another at the state level is doing, and what both are doing in relation to the certification worker in the community program. Training and technical assistance is not a function that universities or colleges perform well or easily, although it is a service in which they profess competency. Although there are several reasons, the basic problem is that TTA is ineffective in an academic form. A person can learn the principles of good program management, for example, but the institutional problems that occur because of bad management will go unchecked unless principles are demonstrated and used as organizationally specific practices applied to organizational or program goals.

The basic value of TTA is in its application as a problem-solving technique by program managers and administrators within a uniform program standard; that is, TTA is a continuous and on-going activity to be used by administrators to communicate the value and purpose of the program, an awareness of problems, and their desire and intent to solve them. One of the spin-off values of TTA is to provide a basis for evaluating individual performances and for determining the allocation of rewards, such as in-grade pay increases and promotions. There are other virtues and some real potential problems with TTA as an institutional support mechanism, but that is the topic for another paper. My purpose here was to present a new administrative concept, to discuss how it might affect the conventional administrative approach, and to examine some of its features.

Food stamps are a renewable resource program, serving a consumer function, and must be viewed as a resource coming toward the individual, not away from the producer, or, in this instance, the imperial form of government. The imperial presidency ended in 1968, although the ghost did not depart until August 1974 after all the president's men had gone. The imperial bureaucracy is still with us, although that is about to change. When it does, there will not be less government; the imperial presidency is gone, but the executive and its institution continues. The bureaucracy will remain as will its purpose, but its function will be different as will its perception of the bureaucracy. There will be a new procedural emphasis on planning, on citizen participation, on monitoring and evaluation, on training and technical assistance as part of the substance of service delivery, and, one can hope, on the quality of life for the consumer, poor and rich.

Social Policy Role of Food Assistance Programs

James R. Storey

In fiscal year 1977, the federal government will spend $9.2 billion on food stamps and child nutrition programs. These benefits represent the bulk of the government's direct efforts to improve nutrition. Viewed more generally, these programs are only a few among many federal mechanisms for transferring income from one group of people to another to improve the recipients' financial status. Food programs account for only 5% of all such transfer payments, but food assistance constitutes a higher proportion of benefits (24%) directed to low-income groups. Thus, food assistance is a very important element in federal income support.

There have been a number of studies of the impact of food stamps and the school lunch program on the nutritional well-being of program participants (USDA). Viewed as a body of knowledge, these studies tell a nonexpert decision maker several things: (*a*) the programs do increase food consumption; (*b*) although the evidence is less convincing, there does seem to be nutritional improvement as well; (*c*) to be more efficient in achieving these two goals, food programs would have to be more carefully targeted, both in people served and in food and nutritional services delivered; and (*d*) nonfood income transfer programs also increase food consumption, although probably to a lesser degree than do food programs.

However, it is necessary that not only food programs but other types of aid as well be related to other social goals in order to understand in broader perspective why we are transferring $187.9 billion of American tax dollars through the various income transfer programs and what it is that we are accomplishing with these sizable expenditures.

Of course, the narrower goal of good nutrition underlies many other broader social goals such as longevity, equal opportunity for education and work, and freedom from disease. Given the limits on our knowledge on achieving all these objectives and the limited funds with which to pursue them, there will always be a struggle over the emphasis any particular goal receives.

Taking the three largest food programs as examples, each seems to typify a different way of pursuing broader social goals through programs that transfer income by subsidizing food purchasing power. For instance, the special supplements for women, infants, and children (the WIC program) carefully target a relatively small amount of money ($250 million) to purchase high-nutrition foodstuffs for people that clearly have special nutritional needs, thereby emphasizing a nutritional goal over all other possible results and constituting an important effort to improve maternal and child health. The school lunch program, which spends $2.4 billion a year, serves more of an educational purpose, presumably helping poor children do better in school by providing them with free lunches and freeing up state educational funds for other more directly educational purposes by subsidizing school cafeteria operation. The food stamp program, with fiscal 1977 outlays estimated at $6.2 billion, has its nutritional goals so diluted by the broader population served and the total reliance on consumer choice that it relates much more to the purposes of general income maintenance and to programs such as aid to families with dependent children (AFDC) and supplemental security income (SSI) than to a nutrition program such as WIC. Given the importance of food stamps as a welfare program and the likelihood that the income maintenance policy debate will intensify next year, it is the linkage between food programs and income transfer policy that this paper addresses. The health and educational aspects of food assistance cannot be treated adequately in a paper of this length.

James R. Storey is senior counsel for Human Resources, Senate Budget Committee, Washington.

The views expressed are the author's and do not necessarily reflect the view of the Budget Committee or any member thereof.

Food stamps are an integral part of the larger income transfer system. As the only public program to serve all categories of low-income people in all parts of the country, food stamp recipients also benefit from many other programs. A 1974 survey found that 60% of food stamp households also received cash aid, 30% participated in medicaid, and 36% received social security checks (U.S. Congress). This concurrent effect of numerous programs on a group of people means that social goals and policy issues cannot be viewed in isolation for food stamps or any other program but must be considered for the system as a whole.

What goals should income transfer payments serve? There are three basic goals that most people would agree stand above all others: all Americans (*a*) should have incomes sufficient to live at a level considered adequate by society, (*b*) should have incomes that are judged equitable with respect to past or present efforts at self-help and in light of any particular circumstances requiring extraordinary remedies, and (*c*) should receive those incomes in a manner least disruptive to the working of the private economy. These ideals form a good framework for evaluating income transfer policy.

Income Transfers and the Federal Budget

Importance of Income Transfers to the Budget

Income transfer policy is a major determinant of our fiscal policy. Income transfer payments to increase the real income of beneficiary groups through cash payments and subsidized health care, food, and shelter will account for $187.9 billion, or 45%, of the $413 billion outlay total in the 1977 Congressional Budget Resolution.[1] This sector of the budget is not only the largest but also the most rapidly growing sector and the most difficult to affect in terms of short-run budget outlays.

[1] The programs considered in this paper are those in which the government provides financial benefits rather than services to recipients. Excluded are benefits tied to investment in human capital, such as GI bill benefits. Taking a broader view, one could view such programs as income transfer programs. Also excluded are $36.1 billion in tax expenditures that serve the same purpose as the expenditure programs discussed in this paper. For example, double exemptions for the aged and blind and the exclusion of transfer payments from taxable income are tax measures that transfer income to selected categories of individuals.

Types of Income Transfer Programs

There are three ways in which it is useful to classify income transfer programs: (*a*) those that pay cash benefits to recipients and those that offer aid in the form of subsidized food, medical care, or rent, (*b*) those that are contributory or self-financing and those that are not, and (*c*) those that base benefits explicitly on need and those that do not.

The bulk of income transfers (71%) are funded by earmarked taxes (table 1). Social security and medicare alone account for 56%. Cash benefits based on need make up only 9% of federal income transfers, a proportion now exceeded by noncash welfare programs (12%) and nonwelfare cash benefits (9%). The relative decline in importance of cash welfare benefits is recent, resulting from the rapid growth of noncash aid (e.g., food stamps, medicaid) and nonwelfare programs (e.g., coal miners' benefits, military retirement, temporary unemployment benefits).

Trends in Growth of Income Transfers

Over the last twenty years, income transfer payments have quadrupled on a constant dollar basis. Based on the current services budget the president submitted to Congress last year, these payments will account for $22 billion of the $46 billion of "automatic" growth in the federal budget from 1976 to 1977. Thus, concern has arisen over what the future growth pattern may be.

The Congressional Budget Office (CBO) projected benefits under current law to the year 2000. These projections show that payments in 2000 will be two-and-one-half times the present level in constant dollars (U.S. Congressional Budget Office). This growth will result simply from growing beneficiary populations, the impact of real wage growth on benefits, and the indexing of benefits to inflation. But as a share of the gross national product (GNP), the projections show the present 9.3% of GNP for income transfers staying about the same. If provisions in current law that overcompensate for inflation are corrected, only two programs would experience significant growth in share of GNP: medicare, due to expected cost inflation, and federal employee retirement, because of the many employees hired in the 1940s, 1950s, and 1960s who will be retiring and the growth in pay over those decades.

Table 1. Income Transfer Budget Outlays and Beneficiaries by Program Type, Fiscal Year 1977

Income Transfer Programs	Average No. of Beneficiaries (millions)	Federal Benefit Outlays (billion $)	Outlays as Percentage of Total
Total, income transfer programs		187.9	100.0
Cash benefit programs		144.3	76.8
Contributory		111.8	59.5
Social Security (OASDI)	33.3	83.4	44.4
Civil Service retirement	1.5[a]	10.1	5.4
Unemployment compensation	9.2	14.5	7.7
Noncontributory		16.3	8.7
Military retirement	1.2	8.5	4.5
VA disability compensation	2.6	5.6	3.0
Noncontributory (need-based)		16.2	8.6
AFDC	11.3	6.8	3.6
SSI	4.6	6.0	3.2
VA pensions	2.2	3.2	1.7
Noncash benefit programs		43.6	23.2
Contributory (Medicare)	24.9	21.6	11.5
Noncontributory (need-based)		22.0	11.7
Medicaid	23.6	9.6	5.1
Food stamps	18.9	6.2	3.3
Child nutrition programs	26.3	3.0	1.6
Subsidized housing programs	7.7	3.2	1.7

Note: Detail shown as non-add entries because the smaller programs are not shown in this table.
[a] End of year number.

Of course, further growth over and above the CBO's current law projections may occur through new legislation, but program expansion is unlikely to match the pace of the past twenty years, which saw many landmark changes, such as the establishment of new programs (medicaid, medicare, food stamps, coal miners' benefits, mortgage subsidies, liberalization of social security coverage and benefit rules, automatic cost-of-living adjustments, and greater sharing in state welfare payments). But should the past growth rate be duplicated over the next twenty-five years, transfer payments in the year 2000 would be more than three times the level projected for current law.

There are numerous pressure points for greater spending on income transfers. Despite the rapid growth in payments, the bottom 20% of American households still receive only 8% of total personal income, about the same share as twenty years ago. A large poverty population in absolute terms still remains as well. To eliminate poverty through transfers would require additional payments of at least $8 billion and probably much more to minimize adverse effects of a poverty-level income guarantee on work incentives.

Further pressures arise from demands to rectify inequities in the hodgepodge of programs. For example, the AFDC payment level in Wisconsin is six times that in Mississippi. AFDC and medicaid are available to low-income female-headed families in all states, to intact families headed by unemployed fathers in about half the states, but to intact families with fathers working full-time in no state. Social security does not benefit working wives upon retirement at a level commensurate with their contributions, since wives receive 50% of their husbands' benefits without ever working for wages. To remedy inequities costs money, since the payments to persons benefiting from reforms usually outweigh reductions in the benefits of other recipients.

Controllability of Income Transfers

An important fiscal characteristic of these programs is their uncontrollable nature. Given the legal, moral, and political necessity of making payments to which people are entitled

under law, initiatives to curb normal growth, reduce expenditures, or reprogram spending can have relatively little impact in a period as short as the next budget year.[2] The traditional budgetary process has involved marginal changes in the budget base for the fiscal year that begins a few months after the preparation of the new budget. Given this amount of lead time, substantial discretionary changes in income transfer outlays are unlikely since most would require legislation, a lengthy process when controversial matters such as income redistribution are involved.

Even if legislation moves quickly, budgetary effects may be overshadowed by program responsiveness to inflation (83% of transfers are indexed for price increases), unemployment (a percentage point rise in unemployment adds about $3 billion to transfer payments), or the behavior of beneficiary groups, who may change their rates of retirement, childbearing, divorce, or school attendance. Such changes can offset the effects of policies aimed at budgetary change.

Control over spending is also hampered by difficulty in implementing administrative improvements. Probably several billion dollars of transfer payments are improperly made, mostly due to inadequate program administration.[3] Although this money could be saved, actually doing so is difficult. First, the offending administrative practices may be based on statutes or court decisions with remedies requiring new law. Second, administrative problems may result from inadequate staff, complex laws and regulations, poor coordination among multiple agencies, and lack of resources in the judicial system for prosecution of fraud. None of these factors is easily overcome in the short span of a year, and those improvements that are possible must be worked through enormous federal agencies or, with even more difficulty, through federal agencies that only regulate the administrative practices of fifty states and over 3,000 counties. Finally, benefit savings may be offset in whole or in part by increased administrative costs.

[2] The Congressional Budget Resolution for fiscal 1977 assumed legislative savings for income transfer programs of $1.4 billion, or less than 1% of total benefits. Only a small part of these savings (no more than $0.2 billion) will probably be realized.

[3] The actual net loss of benefits that results from overpayments, underpayments, and eligibility errors is not precisely known. This rough estimate is drawn from materials collected by the U.S. General Accounting Office for the Senate Budget Committee.

Taking a longer view, however, there are opportunities to curb growth in income transfer payments. For example, the CBO's projections to the year 2000 illustrate that $19 billion per year in 1975 dollars could be saved by eliminating automatic provisions that overcompensate for inflation. Finding ways to slow the rise in health care costs would save billions in outlays under medicare and medicaid. For example, if the rate of price increase that the CBO projections assumed was halved (from 10% to 5% yearly for hospital costs), expenditure savings would total $28 billion annually by 2000. However, to achieve such annual savings in the short run ($47 billion for the above examples) would require eliminating whole programs or substantially reducing social security benefits. Relatively small initiatives taken now could produce sizable shifts in program costs over the long run.

Effects of Income Transfers on the Income Distribution

Although total income transfers will average about $875 per capita this year, and despite the rapid growth in payments, there has been no major change in the distribution of income, and the nation still has a sizable poverty population. In part, this paradox results from the Bureau of Census's failure to count noncash transfers (e.g., food stamps, medicaid) in official statistics. But the data problem is only a partial answer, since noncash benefits are only 23% of total transfer payments.

The main reason for the ineffectiveness of transfers in redistributing income is the dominance of social insurance benefits over benefits strictly for the needy. Social insurance programs were designed to transfer income from wage earners to those no longer in the work force. Thus, the relative neutrality of these programs with respect to the income distribution comes as no surprise. Since social insurance programs such as social security account for 80% of all transfer payments, while cash welfare benefits are only 9% of the total, social insurance payments tend to dominate the overall results produced by the income transfer system.

The primary effect of welfare-type programs is to transfer income from higher- to lower-income classes with funds drawn from

the progressive federal income tax. But social insurance benefits are mainly transfers within the working class population, from current workers to former workers and their families. Furthermore, these transfers are financed by payroll taxes that are regressive in nature; i.e., they are relatively heavier for low-income workers than for others. All workers pay the same social security tax rate (5.85% on both employer and employee), but only the first $15,300 of annual earnings are taxed.

Reynolds and Smolensky have measured the change in posttax, posttransfer income shares from 1950 to 1970. Their study shows that the income share for the bottom 20% of the income distribution rose from 7.2% of all income in 1950 to 7.9% in 1970. Over that period, income transfer payments quadrupled in real value and rose from 3.7% to 8.6% of the GNP. The study shows that government activity did serve to reduce income inequality to a greater extent in 1970 than in 1950. The relative importance of transfers in reducing inequality tripled over that time period, while taxes became less progressive and play only a small role in equalizing income.

There are still 24.3 million Americans living in poverty (less than $5,500 for an urban family of four).[4] The number has declined from 28.5 million in 1966, but the decrease occurred during periods of economic growth. The number of poor people is actually about the same as in 1969, despite the rapid growth in transfer payments.

A book by Plotnick and Skidmore contains an analysis of the impact transfer payments have had on the extent of poverty. The number of households that would have been poor if no transfer income were available actually increased from 1965 to 1972 by 2 million to a total of 17.6 million. The income gap, the aggregate dollar value of income required to eliminate poverty, grew by $5 billion to $34.3 billion. The effect of transfer payments was to offset the potential growth in poverty, with posttransfer poor households remaining about the same in number (9.9 million in 1972). The posttransfer income gap declined from $13.8 billion to $12.5 billion. Over this period, the proportion of transfer payments received by pretransfer poor households that was not needed to remove them from poverty increased from 31% to 36%, and half of all transfer payments went to households that would not have been poor even without those payments. Thus, about two-thirds of transfer payments did not reduce the poverty income gap at all (the 50% that went to the nonpoor plus 36% of the 50% that went to poor households).

The impact of transfer payments on poverty differs greatly among demographic groups. In 1972, transfers removed 63% of otherwise poor households with aged heads from poverty, social security alone accounting for 51%. For nonaged households, only about one-fourth of pretransfer poor households were pushed out of poverty, with social security and public assistance playing comparable roles.

Plotnick and Skidmore indicate the estimated proportion of transfer payments going to pretransfer poor households. AFDC, SSI, medicaid, and food stamps are the more efficient programs in reaching the poor (over 75% of payments go to poor households). One welfare-type program, subsidizing housing, is no more poverty-effective than the social security program, which serves a much wider clientele, but still pays a little more than half its benefits to pretransfer poor households. Unemployment insurance, surprisingly, has the lowest proportion of payments going to such households (only 21%).

Criteria for Evaluating Policy Alternatives

Instead of forming a coordinated system to achieve well-defined goals, income transfer programs are an assortment of fragmented efforts that distribute income to a variety of persons for a variety of purposes, on conflicting terms, and with unforeseen effects. Two primary factors have inhibited a uniform system of equitable aid: a tradition of local responsibility for the needy and a habit of approaching social problems in isolation, developing new programs to attack newly perceived problems. Only with passage of the 1970 food stamp amendments and the enactment of SSI in 1972 did the federal government set national eligibility rules and benefit levels for welfare aid to groups other than veterans.

Our past practice of approaching problems in isolation has led to fragmented and inconsistent legislation and administration. Our income transfer programs are shaped by at least

[4] The number of poor people is an overstatement since noncash benefits such as food stamps are not included in the computation.

nineteen committees of Congress,[5] fifty state legislatures, six cabinet departments, three other federal agencies, fifty-four state-level welfare agencies and more than 1,500 county welfare departments, the U.S. Supreme Court, and many lesser courts.

Each congressional committee typically deals only with its own subject area, although changes in one benefit program, such as AFDC or social security, commonly affect another, such as food stamps or veterans' pensions. Because of the categorical nature of the "system" and the restricted viewpoints of agencies and congressional committees, attempts to remedy one problem may create another. For example, if the House Ways and Means Committee alters AFDC eligibility, this affects eligibility for food stamps (Agriculture Committee) and medicaid (Interstate and Foreign Commerce Committee) in ways these committees may not favor.

None of the committees has the duty to appraise the total effect of congressional decisions. As a result, for example, persons can be enrolled in several programs, the terms of which discourage work and provide income that far exceeds their earning potential, but no one committee can easily deal with such a cumulative result.

In considering income transfer policy alternatives, it is not the effect of each separate program but of the whole system as it applies to each eligible family or individual that is important to evaluate. Important criteria for such evaluation include the following.

(*a*) Equity—are all groups treated fairly based on a consistent set of principles? The groups excluded from AFDC and medicaid constitute 38% of the poor but receive only 13% of transfer payments. Benefits are lowest in the South and are lower nationally in areas that are poorer, more rural, or more black than average.

(*b*) Adequacy—are benefits at appropriate levels to achieve program objectives? Payments are often too low, e.g., $60 a month for a family of four on AFDC in Mississippi, but in urban states cumulative benefits often exceed the after-tax earnings of the average working woman.

(*c*) Incentives—does program design or operation encourage undesirable behavior by recipients? Combined benefit-loss rates allow a person on AFDC and food stamps to keep only 23¢ out of an extra dollar earned. Participation in other programs reduces work incentives further. AFDC and medicaid also discourage marriage for a woman with children due to exclusion of working males from eligibility.

(*d*) Administrative integrity—do program rules permit a reasonable level of enforcement and a high degree of accuracy in administrative actions? Errors in benefit determination run high, over 33% for AFDC, about 25% for SSI, and over 50% for food stamp recipients not on AFDC or SSI. Much of this error is linked to specific laws or regulations that are difficult to enforce.

(*e*) Federal-state-local fiscal relations—is financing equitable with respect to state and local fiscal efforts and with their need for federal funds? Problems clearly exist. For instance, New York City pays 25% of the cost of AFDC and medicaid, while most cities pay nothing. Lower federal matching rates for administrative costs than for benefit payments or provision of services offer states little financial incentive to strengthen program management.

Suggested Policy Directions for Food Programs

Given the enormous commitment of public funds to income transfers and the fact that many social objectives have yet to be reached, we seem to have entered an era in which restructuring the system will be considered more seriously than ever before. Adding to the urgency is the breakdown at the local office level in operating such programs as food stamps, medicaid, and SSI and the policy confusion in Washington in coping with a system legislated by nineteen congressional committees and administered by nine executive agencies. The interest in budgetary control and more efficient targeting of funds sparked by the congressional budget process also adds to the pressures for systematic reform. Such reform should include a restructuring of food assistance programs.

If Congress wants to devote more funds specifically to improvement of nutrition, the WIC type of program would seem to offer more payoff by carefully selecting a clientele in need of help and directly dispensing to them

[5] These committees include the Appropriations, Agriculture, Veterans', Post Office and Civil Service, Banking, and Armed Services Committees in both houses, plus the Senate Finance and Labor and Public Welfare Committees and the House Ways and Means, Education and Labor, and Interstate and Foreign Commerce Committees.

the kinds of food they require. If a more general approach is desired, perhaps greater efforts at nutrition education should be tried.

The food stamp program should be replaced by a federally administered cash payment system for income maintenance. It already comes closest to approximating the type of program that welfare reform advocates have considered preferable. By setting benefits at levels sufficient to replace food stamps, AFDC, and local general assistance, a more adequate and equitable program could be established that would also be easier to administer. It could be designed to reduce the incentives that now exist that are economically and socially disruptive, and the financial burden that states and localities now shoulder could be lessened.

Short of total welfare reform, enactment of food stamp reforms such as the Senate passed this year would help rectify the administrative problems besetting the program and achieve greater equity among the different groups of recipients. Elimination of the purchase requirement would be a further program reform that would bring additional relief to administrators and would bring in some of the neediest nonparticipants who cannot afford the prices now charged for the stamps. The school lunch program is enmeshed in school finance and should be discussed in that context, which is beyond the scope of this paper.

U.S. Congressional Budget Office. *Growth of Government Spending for Income Assistance: A Matter of Choice*. Senate Budget Committee Print No. 62-2280, Dec. 1975.

———. Unpublished tabulations prepared for the Senate Budget Committee. Washington, Aug. 1976.

U.S. Department of Agriculture. *Program Evaluation Status Reports—Completed Studies*. Food and Nutrition Service, Office of the Administrator, Jan. 1976.

U.S. General Accounting Office. Unpublished data distributed to the Senate Budget Committee. Washington, March 1976.

U.S. Office of Management Budget. *The President's Budget for 1977*. Washington, Jan. 1976.

Abstracts

Contributed Papers

Agricultural Finance (John Brake, Michigan State University, Chairman)

"New Equity: A Look at Texas Agricultural Limited Partnerships and the Investors Who Fund Them." Ted M. Abele, Raymond A. Dietrich, and Donald R. Levi (Texas A&M University).
Data drawn from certificates of limited partnership and two independent surveys relate the number, kind, and character of limited partnerships investing in Texas agriculture. Also set forth is a socioeconomic profile of limited partners investing in such funds as well as an overview of the investment objectives.

"Correspondent Banking in Agricultural Finance: An Analysis of Profit Requirements and Pricing Procedures." Peter J. Barry (Texas A&M University)
The principles of customer profitability analysis are applied to overline participation in farm loans by correspondent banks. A simulated borrowing situation is used to measure the level of participation and profit requirements on overline farm loans of a sample of correspondent banks with implications drawn for rural bank management.

"Impact of Capital Gains Taxation on Farm Organization: Implications for Meat Animals Production on Diversified Farms." Wesley N. Musser and Fred B. Saunders (University of Georgia) and Neil R. Martin, Jr. (CED-ERS-USDA, Athens, Georgia)
Differential income taxation of capital gains applied to components of enterprise net income for representative farm situations in Georgia resulted in increased hog production and a shift in production system. Maximum aftertax income objectives have larger impacts on farms with higher family incomes. Efficiency implications warrant further research.

"Farm Financial Management and Tax-Deferred Retirement Plans: Some Economic Aspects of Alternative Investments." Darrel L. Acker and Paul L. Wright (Ohio State University), Gerald A. Harrison (Purdue University), and Julian H. Atkinson (CIC-AID)
Many people may be misled by advertising on tax-deferred retirement plans. Comparisons of accumulated retirement benefits from alternative earnings and tax rates for both "tax-shelter" and no tax-shelter investments is wise financial management. Tax-deferred retirement plans should be integrated with the individual's estate management strategy.

"Explaining Farm Operators Debt: An Application of the Automatic Interaction Detector Technique." David A. Lins and Timothy R. Donaldson (University of Illinois)
The Automatic Interaction Detector technique is used to examine variations in farm operator debt. Results suggest that size and expenditure variables are the most important in explaining variations in the amount of farm operator debt. Geographic, demographic, and structural variables were found to be of less importance.

Energy and Environmental Issues Re Agriculture (James Wade, University of Arizona, Chairman)

"Impact of Crop Selection on the Costs of Wastewater Land Treatment." Edward B. Bradley (Pennsylvania State University)
Crop production can be an integral part of land treatment. Net total treatment costs are simulated for systems growing corn, alfalfa, and reed canary grass. Growing reed canary grass minimizes treatment costs, due to its longer irrigation season. Assuming an 85% capital subsidy, growing corn grain minimizes local costs.

"Regional Effects of Imposing Pollution Control Regulations on the Egg Producing Industry." Jawahar L. Kaul and P. Geoffrey Allen (University of Massachusetts)
A six-region econometric model of the U.S. egg producing industry combined with a modified transportation program generated the efficient production, consumption, and transshipment pattern. Production cost increases with pollution control of 5% and 10% were assumed to investigate impacts on net social costs and optimum pattern.

"Accounting for Tillage Equipment and Other Machinery in Energy Analysis." Otto C. Doering III, Timothy J. Considine, and Catherine E. Harling (Purdue University)
The energy value of different tillage equipment and farm machinery is presented in this paper based on industry sources. Discounting, scrappage, and utilization are discussed. Comparisons are made between the new disaggregated data and original attempts to determine farm machinery energy content based on the energy content of automobiles.

"Energy Scarcity and Nonpoint Source Pollution in Midwestern Agriculture." D. Lynn Forster and Norman Rask (Ohio State University)
Reduced tillage systems are primary methods of lessening erosion. This study investigates the impacts of energy prices on these systems. Results indicate that energy prices substantially affect corn

and soybean production costs; however, energy prices have little impact on the choice of tillage systems.

"Economic and Environmental Impacts of Energy Rationing in Agricultural Production." Dan Dvoskin and Earl O. Heady (Iowa State University)
The economic and environmental impacts of energy rationing are compared with high energy prices in agricultural production. Energy rationing leads to a much larger increase in commodity prices than high energy prices. Environmental impacts of the two policies are very similar. But regional production patterns change substantially between policies.

Forecasting and Projecting (David Dyer, Food and Nutrition Service, USDA, Chairman)

"Combining Linear Programming Results and Time Series Data for Prediction of Supply: Two Approaches." C. Richard Shumway and Hovav Talpaz (Texas A&M University)
Because of the lack of any empirical reference with which to compare predictions, validation of long-run linear programming models is extremely difficult. This paper reports two procedures for combining time-series data with results from a long-run linear programming supply model in order to make verifiable short-run predictions.

"Projecting State Agricultural Production Quantities with a Cobb-Douglas Programming Model." David L. Watt (USDA, Michigan State University) and George E. Rossmiller (Michigan State University)
A Cobb-Douglas programming model of Michigan agriculture sector production was developed for thirteen commodities using twenty-four input categories and tested for the period 1955–62. Input supply and commodity demand schedules are used by the algorithm to solve for input and output quantities by year.

"The Use Of Scenarios in ERS's Economic Projections Program." Leroy Quance (ERS, USDA)
As a general world food scenario, the Economic Research Service advocates a supply-demand management scenario with serious but manageable problems. By bracketing uncertainties ranges of future supply-demand attributes, scenarios permit a systematic analysis of emerging and recurring issues. Probabilities of alternative futures resulting from studied scenarios will also be estimated.

"The Ability of the Futures Market to Forecast Profit Margins in the Broiler Industry." David E. Kenyon and Neil P. Shapiro (Virginia Polytechnic Institute and State University)
Broiler integrators experience fluctuating profit margins. Expected net profit margins can be generated by using the corn, soybean meal, and iced broiler futures contracts with their appropriate basis estimates. The expected net profit margins based on these futures prices were found to be ineffective forecasters of actual profit margins.

"An Annual Projection Model for Selected Price Indexes and Expenditures Related to Food." Chung J. Yeh (ERS, USDA)
An ordinary least squares technique based on inputs derived from component models of the Economic Research Service's NIRAP system is used to project food prices and related indicators. Results indicate that food prices in the decade ahead will continue to rise but at a much slower rate than prices in general.

Issues and Techniques in Extension (John S. Bottum, Federal Extension Service, USDA, Chairman)

"Motivation of Professional Scholars: The Role of Administrative Evaluations." Russell L. Berry (South Dakota State University)
How to motivate professional scholars? Give them full freedom to seek the truth and report what they have found. This "freedom to" can only exist when there is freedom from improper evaluations and sanctions. Continuous evaluation with "one-shot" awards or punishment is recommended. Annual competitive evaluations destroy morale and motivation.

"Using Educational Television as a Delivery System for Teaching Futures Market Concepts." Larry D. Jones, D. Milton Shuffett, Steven Callahan, John C. Gamble, and Charles L. Moore (University of Kentucky)
Thirteen weekly programs on futures markets were taught to farmers using television as a delivery system. Agricultural economists were responsible for technical accuracy, while professional writers and announcers were responsible for communicating ideas. Five thousand individuals preenrolled in the series. More than half watched ten or more programs.

"An Extension Education Approach to Community Resource Development: Implications from Virginia's Title V Rural Development Program." Marilyn H. Grantham and Dennis K. Smith (Virginia Polytechnic Institute and State University)
Implications from Virginia's Title V program call for more involvement of local residents and extension agents in problem definition and program development. More in-service training is needed by local extension agents. An expanded body of research theory and tools is needed relative to all of the problems encountered.

Structure of Agricultural Economics Teaching Programs (Dean Tuthill, University of Maryland, Chairman)

"Computer Capabilities and Usage for Under-

graduate Grading and Reporting." Sandra Kay McDonald (Texas A&M University)
This paper reviews the latest computer application for scoring, reporting, and evaluating effectiveness of examinations. Strengths, weaknesses, and costs are all examined.

"Reflections on Graduate Training in Agricultural Economics for Asian Students." Ray W. Nightingale (ERS, USDA)
Program characteristics and locational advantage afford graduate students in agricultural economics at the American University of Beirut an exceptional training opportunity free of some of the generally existent dilemmas in U.S. international educational programs. The experience suggests a program design better suited for preparing Asian students for likely future careers.

"The Use of Electronic Calculators by Students in Examinations and for Course Assignments." Lyle P. Fettig (University of Illinois)
Potential benefits and problems associated with the use of electronic pocket calculators for course assignments and examinations are discussed and illustrated. Conditions necessary for the effective use of electronic calculators in learning situations, requiring the solution of new types of problems involving arithmetic, are suggested.

"Current Structure and Status of Undergraduate Programs in Agricultural Economics." Robert L. Beck, A. Frank Bordeaux, Jr., Joe T. Davis, Russell H. Brannon, and Loys L. Mather (University of Kentucky)
This paper reports the results of a survey of undergraduate programs in agricultural economics.The primary focus was on the current structure and status of agricultural economics programs, departmental characteristics and faculty involvement, and growth areas and new directions. Implications of some trends and developments are explored.

Energy (R. J. McConnen, Montana State University, Chairman)

"The Economic Impact of a New Electrical Plant on a Rural County: The Case of Sullivan County, Indiana." John Gordon and David Darling (Purdue University)
The economic impacts of a new electrical generating plant on a rural community were quantified using a partial budgeting model. Annual impacts were estimated over a fifteen-year period. Private sector impacts are positive throughout, but public sector impacts are negative in the early years before turning positive.

"The Economics of Solar Home Heating Systems for the Southwest Region." Thomas H. Stevens (New Mexico State University)
The probability of solar space heating systems being economically competitive with conventional systems is examined. The results indicate that solar systems are competitive with electric and LP gas systems in several locations throughout the Southwest. However, they are not competitive with natural gas systems under most market conditions examined.

"Interregional Structure of the United States Coal Economy." James D. Libbin and Michael D. Boehlje (Iowa State University)
A multiperiod mathematical programming model of the national coal economy is developed and used to appraise future interregional shifts in coal production. The effects of alternative sulfur dioxide emission standards on coal production (location and type of mining), the coal processing sector, transportation industry, and capital markets are analyzed.

"Determining Energy Requirements for Agriculture: Some Methodological Issues." C. Gopalakrishnan (University of Hawaii), N. A. Patrick (New Mexico State University), and W. J. Chancellor (University of California, Davis)
The current methodology for determining energy requirements in agriculture leaves much to be desired. This paper develops an alternate approach embodied in an energy-flow model for agriculture. It also identifies six dimensions crucial to the determination of energy needs of agriculture and examines their implications from a methodological perspective.

"Rural Electrification in India: Bio-gas versus Large Scale Power." Wallace E. Tyner (Cornell University) and John Adams (Maryland University)
In contrast to previous major studies, it is found that centralized power enjoys a cost advantage over local bio-gas generation. If, however, technical, administrative, and village equity problems are solved, 50,000 to 100,000 units might be installed in remoter villages.

Industry Research and Structure (Bob Olson, South Dakota State University, Chairman)

"The Impact of Collective Bargaining on Grower Returns and Processor Efficiency in the Ohio Concord Grape Industry." Dennis R. Henderson (Ohio State University) and John R. Schmelzer (University of Wisconsin)
Many potential economic benefits have been hypothetically attributed to collective bargaining by farmers. A case study measured pecuniary gains and their sources associated with voluntary collective bargaining in the grape industry. Results show positive integrative gains associated with price stability but no distributive gains nor improved grower-handler coordinative efficiencies.

"Mutual Benefits from Joint University-Agribusiness

Research." Lynn W. Robbins (University of Kentucky), Stephen B. Harsh, and John W. Allen (Michigan State University)
Universities and agribusiness firms are working as two almost entirely separate cultures. Fear of discriminating subsidization and classified information disclosure is among the objections blocking increased interaction. Carefully planned contracted research provides benefits to both components, negates collaboration costs, and demonstrates the desirability of encouraging other university-agribusiness cooperation.

"The Effect of Government Policy Instruments on the Market Structure of the Ohio Fluid Milk Processing Industry." Richard L. Kilmer (ERS, USDA) and David E. Hahn (Ohio State University)
Effect of market share and merger restrictions on seller concentration and related factors is explored using an intertemporal production-distribution model. Plant size constraints are predicated on Markovian transition probabilities. Policy instruments are found to have differing effects on size distribution, distribution patterns, costs, top four market share, and numbers.

"Market Performance in the United States Vegetable Oil Industry: An Application of Simulation for Market Analysis." R. McFall Lamm, Jr. (Virginia Polytechnic Institute and State University)
A simulation model of the processing sector of the domestic vegetable oil industry was used to estimate the rates of return for five products by months over the period from January 1974 to December 1975. The results indicated no great degree of market power in the industry.

"Optimal Number, Size, and Location of Milk Manufacturing Plants in the Southeast with Implications for Industry Policy." W. T. Boehm and M. C. Conner (Virginia Polytechnic Institute and State University)
The optimal number, size, and location of milk manufacturing plants in the Southeast was determined subject to seasonal fluctuations in production and practical restrictions on the assembly, movement, and processing of milk. Substantial technical efficiencies could apparently be gained from an industry wide reorganization that would permit the milk movement patterns shown in this research.

Water—Information and Management Issues (E. L. Michalson, University of Idaho, Chairman)

"Do Drouth Cycles Exist? Applications to Supply-Demand Analysis." J. Roy Black and Stanley R. Thompson (Michigan State University)
The evidence for the existence of "drouth cycles" in the U.S. Corn Belt and Great Plains is empirically tested using econometrics. An application to the forecast of U.S. seasonal average corn prices is presented. Some issues surrounding the existence of drouth cycles and alternative climatic models are discussed.

"The Economic Feasibility of Nuclear Desalination of Groundwater in New Mexico." Robert R. Lansford, Raymond J. Supalla, William D. Gorman, D. B. Wilson, Thomas H. Stevens, Bobby J. Creel (New Mexico State University), Lynn Gelhar, Marshall Reiter, Allen R. Sanford (New Mexico Institute of Mining and Technology), Stanley E. Logan, Richard Mead, William Schulze, Shaul Ben-David, and Fred Roach (University of New Mexico)
The economic feasibility of a proposed energy-water complex is examined. The complex was found infeasible because current desalting technology is too costly in comparison to any reasonable projections of water value. However, the concept of a nuclear energy park that uses brine water for cooling warrants further investigation.

"Value of Data Acquisition in Water Quality Management." Cleve E. Willis and Richard McAniff (University of Massachusetts)
This paper develops a Bayesian framework for estimating the value of information associated with water quality monitoring systems. This framework is demonstrated for an existing regional situation in western Massachusetts. It is shown how the empirical results obtained can be used in selecting "optimal" monitoring systems.

"Rural Residential Water Demand." O. C. Grunewald, David L. Debertin, and C. T. Haan (University of Kentucky)
This study proposes that demand management through pricing policies can be used to solve water supply problems. A demand function for water was developed using cross-sectional water data. The demand function was used in a simulation analysis to determine reservoir capacity needed to supply water for a rural community.

"Alternative Models for Estimating the Time-Series Components of Water Consumption Data." Hiroshi Yamauchi and Wen-yuan Huang (University of Hawaii)
Additive and multiplicative models are used to analyze the trend, cyclical, seasonal, and irregular components of water consumption time-series data. Evaluation of these components opens up important opportunities for improving on existing water management practices and for more intelligent evaluation of alternative policy measures.

Health, Consumption, and Estate Management Planning (Sam Cordes, Pennsylvania State University, Chairman)

"Effects of Economic Variables and Food Delivery Programs on Nutrient Intake." David W. Price,

Donald A. West, and Genevieve E. Scheier (Washington State University)
A sample of 849 Washington school children showed the national school lunch program to be increasing intakes of some nutrients for children receiving free lunches. Liquid assets and school breakfast participation influenced intakes of some nutrients, while current income had little impact. The effects of food stamps are inconclusive.

"The Economics of Consumer Protection." Rachel Dardis and Diane Hyman (University of Maryland)
There has been increased interest in consumer protection in recent years, particularly in the area of product safety. This paper investigates the role of cost-benefit analysis in determining whether mandatory safety standards are in the public interest and applies such analysis to an evaluation of flammability standards for children's sleepwear.

"Estimation of Factors Affecting Rural Health and Legal Services Needs—A Comparison of Methods." Douglas Chiriboga and Cleve Willis (University of Massachusetts)
This paper summarizes the limitations of least squares estimation procedures for dichotomous dependent variables and outlines the essential features of probit analysis as an alternative. The results of two sets of empirical estimations using least squares and probit are compared. Probit results are superior in at least one case.

"A Simple Human Investment Model for Analyzing Personal Health Investments: Theoretical Development." Thaine H. Allison, Jr. (Inland Countries Comprehensive Health Planning Council, San Bernardino)
The general case of human investment occurs when some portion of income is devoted to investment over the full life of the investor. This simple theoretical micromodel is expanded to identify how the individual investment decisions are made to maximize utility where investment enters the utility function.

"A Decision Model for Estate Management Planning." Michael Boehlje (Iowa State University)
A decision model that evaluates how well alternative legal and financial tools satisfy specified estate management goals is developed. The results of computer simulation of a case estate are presented to illustrate how the model could be utilized as an operational tool of an estate management service.

Regional Development and Planning (Daniel Swope, Agricultural Research Service, USDA, Chairman)

"Developing Economic Information for Regional Planning: A Case Study." M. C. Conner and Dilip Pendse (Virginia Polytechnic Institute and State University)
A comprehensive economic information package was developed within a constrained time frame to help a planning district in Virginia formulate its development strategies. The study involves an analysis of several major aspects of the local economy and a coordinated evaluation of the regional development potentials using an input-output model.

"Adapting Shift-Share Analysis to Rural Development Planning." Gerald Marousek (University of Idaho)
Shift-share analysis of population changes in northern Idaho is presented as an early stage planning tool in rural development. It enables isolation of a national industry's growth relative to the total economy and a local industry's growth in relation to the national industry. This knowledge can be valuable to local development planners.

"Extending the Life Cycle of an Old Product—A Source of New Rural Industry." Daniel A. Swope (ARS, USDA)
Establishing plants with modern equipment to produce sorghum sirup would provide new industry and employment opportunities in rural areas. Adopting improved harvesting and handling equipment would increase labor efficiency and returns to farmers. Availability of assured supplies of higher quality sirup would meet blenders' requirements and should increase consumer use.

"An Evaluation of the Impact of Growth on the Urban Fringe Using Two Methods of Estimating Public Service Costs." Robert E. Lee II (Illinois Department of Conservation) and Robert L. Christensen (University of Massachusetts)
Population growth on the urban fringe gives rise to both financial and land-use planning problems for communities. This paper describes differences in normative land-use and housing patterns and the financial impacts resulting from use of two alternative approaches for estimation of municipal costs.

Agricultural Trade and Development Policy Issues (Lee Blakeslee, Washington State University, Chairman)

"Price Supports versus an Equilibrium Exchange Rate: A Comparison of Income Distribution Consequences." Mauro Lopes and G. Edward Schuh (Purdue University)
Floyd's estimates of the effects of farm price supports on the returns to land and labor in agriculture are used to evaluate the effect of the overvalued dollar on relative factor returns. The results suggest that labor was forced to bear the burden of disequilibrium in the foreign exchange market.

"Grain Exports Possibilities as a Function of Domestic Human and Animal Nutrition." Doeke C. Faber, Earl O. Heady (Iowa State University), and Steven T. Sonka (University of Illinois)

The study indicates the possibilities that exist for alleviating the world food shortage through changes in human diets and animal production patterns. Using a linear-programming model, it is found that exports of wheat, feed grains, and soybeans can be more than doubled relative to the 1971–73 average quantities exported.

"An Extension Approach to Discussion of Bilateral Grain Trade Agreements." Ed Watkins and E. Dean Baldwin (Ohio State University)
Proponents of trade agreements argue that these agreements help stabilize grain and meat prices. Opponents argue that these policies distort world grain markets. To identify the issues underlying these agreements, this paper examines the annual U.S. grain supply, export volumes, variations, destinations, and the theoretical impact of trade agreements.

"Grain Reserves—An Evaluation of National and International Policies." Anne del Castillo (University of Maryland)
A successful international grain reserve system requires the consensus of the world's major grain producers and consumers. The policy recommendations from the United States, the European Community, and the Food and Agriculture Organization are evaluated and contrasted.

"The Famine Prevention and Freedom from Hunger Amendment: Issues and Compromises in International Development Policy Making." Harold D. Guither (University of Illinois)
The Famine Prevention and Freedom from Hunger Amendment is part of the International Development and Food Assistance Act of 1975. Its purpose is to enlist U.S. agricultural colleges to increase food supplies in developing countries. It could become landmark legislation. Much will depend upon public support and government policies.

Subjects in Agricultural Marketing and Price Analysis (Bruce Wright, Economic Research Service, USDA, Purdue University, Chairman)

"Variation in Measurement of Corn Grade Factors." T. E. Elam and L. D. Hill (University of Illinois)
The USDA grain grading system has drawn considerable attention due to allegations of misgrading. An analysis of the potential role of random error in the grading system is presented. It is concluded that random variation may be a major cause of changes in grain grades under conditions of repeated sampling.

"Risk Reduction Through Marketing Frequency." Joseph C. Meisner (University of Missouri-Columbia)
Market price risk is a major concern to the agricultural firm. This study examines the distribution of profits and loss for cattle-feeding operations. Frequency of marketing over a nine-year period is varied from monthly to one time yearly. Data suggests increased frequency of marketing can greatly modify risk.

"Efficiency Analysis of Pricing Alternatives for Long-Term Contracts." Steven T. Buccola (Virginia Polytechnic Institute and State University) and Ben C. French (University of California, Davis)
Market, cost-plus, and sales-minus prices for a cooperative's long-term marketing contracts are considered in an E-V framework. A simulation model generates prediction probability moments from historical and subjective data. Optimal purchase and sales portfolios are interdependent; both are highly responsive to cost-plus and sales-minus parameters.

"Analysis of the Impact of Market Characteristics on City Food Prices." Gerald E. Grinnell, Terry L. Crawford, and J. Gerald Feaster (ERS, USDA)
Variation in retail food prices, measured by the consumer price index, among nineteen large U.S. cities using cross-section analysis of time-series data was related to distance, income, wages, and per capita food store sales. Market concentration effects were sensitive to model specification. Models including only market concentration are subject to misspecification.

"Transmission of Week-To-Week Changes in Choice Beef Prices between Farm, Carcass, and Retail Levels." Richard A. King (North Carolina State University)
Rates at which weekly changes in farm prices were transmitted to carcass and retail levels from October 1973 through September 1975 are compared using first difference and polynomial distributed lag models. While farm and carcass prices were closely associated, the retail price response is shown to extend over several weeks.

Resource Planning, Development, and Management—Part A (Nelson Bills, Economic Research Service, USDA, Cornell University, Chairman)

"Subsidizing Agriculture in Urbanizing Regions." Barry C. Field and P. Geoffrey Allen (University of Massachusetts)
Conventional welfare principles are used to examine regional programs of agricultural protection. Optimal subsidies depend on the degree of irreversibility of contractions in regional output. Because of input substitution, they are lower when applied to the irreversible input than when on output. Income redistributions from consumers to producers are considered.

"A Game Theory Approach to an Environmental Land Use Problem." David Y. Chen (North Carolina A&T State University)

An attempt exploring the application of a two-player nonconstant sum static game with a built-in decision scheme is made to a rural town and a major phosphate operation in North Carolina. Comparison on the discounted net benefits suggests that mutual cooperation be the best policy.

"Social Returns to Containing and Eradicating Witchweed in the United States." Gerald E. Plato and Peter M. Emerson (ERS, USDA)
Ex ante estimates of returns to U.S. society of at least 35% from two alternate U.S. Department of Agriculture witchweed programs were found. Witchweed is a semiparasitic plant that reduces corn and grain sorghum yields. Critical elements determining returns are witchweed's potential spread rate and program costs.

"Private Property, Market Trade, and Wildlife Conservation." Jeffrey C. Stier and Richard C. Bishop (University of Wisconsin)
It has been suggested that a policy of wildlife conservation based upon private ownership and market exchange of wildlife and wildlife products would be more efficient than the traditional protectionist policy. However, the economic implications of such a policy indicate that it may be of limited value for conserving wildlife.

Production Changes in Developing Countries (Donald W. Larson, Ohio State University, Chairman)

"A Methodology for Measuring Benefits of Integrated Rural Development Projects." J. Gerald Feaster (ERS, USDA)
A regression model for measuring the impacts of the components of regional development projects was tested using data from Colombia. Credit, technical assistance, and roads were among the components found to have significant effects on farm development. Other variables included in the model were time and farm size.

"The Effects of HYV on the Regional, Seasonal, and Varietal Changes in Rice Production in the Philippines." Ernesto C. Lucas, T. T. Williams (Southern University), and Leah B. Sereno (University of the Philippines)
The objective of this study is to evaluate the impact of the high yield varieties on the traditional rice agriculture in the Philippines. The results indicate decreased regional specialization in rice production, increased seasonality of harvest, and displacement of traditional varieties for high yield varieties. These changes affect marketing, pricing, and transportation of rice.

"Agricultural Development in India's Districts: Sources of Productivity Differences in Rajasthan, 1971." Balu Bumb (University of Maryland)
A factor analysis model was used to study differences in agricultural productivity in Rajasthan, India. Because of multicollinearity among variables, factor analysis yielded better results than regression models. Besides labor, animal power, and capital, the importance of infrastructure, technology, and ecology variables in explaining productivity differences was established.

"Corn Production by Tenure Types in Nicaragua." Waldo Hooker and Melvin G. Blase (University of Missouri-Columbia)
The impact of type of tenure on the production of selected crops in Nicaragua was analyzed. Security of tenure was found to be closely related to output as expected. In addition, the productivity of selected inputs was estimated in the production function analysis by tenure groups. Policy recommendations were offered.

Risk and Uncertainty in Agricultural Production and Marketing (George Irwin, Farm Credit Administration, Chairman)

"Incorporation of Risk Variables in Econometric Supply Response Analysis." W. Bruce Traill (Cornell University)
A methodology is developed for estimating supply equations that specify risk variables in terms of deviations between expected and actual outcomes. The method, which is iterative in nature, allows considerable flexibility in selecting the form of the lag structures and precisely defining the risk variables. Empirical results for onion acreage response are presented.

"A Risk-Return Analysis for the Midwest Cattle Feeder." Larry D. Trede and Michael D. Boehlje (Iowa State University)
With increased price volatility, cattle feeders are becoming increasingly concerned about risk management. This paper utilizes a marginal risk constrained linear programming model to analyze the key variables affecting the profits of the midwestern cattle feeder. Implications for enterprise organization and specialization versus diversification are developed.

"A Risk Programming Model of Beef-Cow Forage Production." R. A. Schoney (University of Wisconsin) and T. K. White (Purdue University)
A linear programming model was developed to examine the potential impact of hay stackers on beef-cow farms. The model included three decision stages and risk generated by weather-related variables on three parameters: field days, haying days, and forage yields. Optimal annual, average, and standard deviation of returns were derived.

"The Impact of Uncertainty on Pesticide Application." Gershon Feder (World Bank)
Uncertainty is introduced into several components of a simple pest management model. Risk aversion

leads to higher quantities of pesticides and to a decline in economic thresholds, implying higher frequency of applications. The reduction of uncertainty via better dissemination of information is thus recommended.

"The Expected Income-Risk Trade-Off Among Corn Belt Crop Farmers." Lars Brink (Purdue University)
The risk aversion coefficient in the expected utility function of a sample of Corn Belt crop farmers was estimated. The measure of risk was similar to the mean absolute deviation. In general, the estimate was close to zero, and the sensitivity of the farm plan to varying parameters was low.

Factor Markets and Productivity (Burt Sundquist, University of Minnesota, Chairman)

"Measuring Labor Productivity: An Economy-Wide Study of the Production of Food for Personal Consumption." Eric C. Howe, Gerald E. Schluter, and Charles R. Handy (ERS, USDA)
Labor productivity for each of four components of personal consumption expenditures for food is measured for four selected years. The labor productivity estimates include both direct and supporting labor needs because, using input-output analysis, it was possible to identify labor inputs irregardless of their sectoral location in the economy.

"Quantifying Management as a Production Cost." Gary S. Kemph and Gerald D. Schwab (Michigan State University)
Congress has directed that cost of production figures be established for selected agricultural commodities. Pricing of management is required in these cost estimates. Five alternative calculations for estimating management costs are presented to illustrate the wide variation in cost of production that can result from this one item.

"Measuring Changes in Economic Well-Being of Factor Owners: Approaches and Problems." Jagjit S. Brar (Washington State University)
This study for the first time underscores empirical problems encountered in the estimation of changes in economic well-being of factor owners. Changes in well-being were estimated by different approaches. Estimates exhibited significant differences depending upon the length of run of supply curve, concept of economic rent, and elasticity of supply.

"Whose Skills are Demanded? An Empirical Study of the Distributional Impacts of U.S. Forest Service Policies on Local Job Markets." James Baskett and Harry Ayer (University of Arizona)
Estimates are made of the impact of alternative U.S. forest service policies on the distribution of jobs among skill levels of people in local rural communities. The analysis uses primary data and employs several refinements of interindustry analysis. Policy implications pertaining to the income (skill level) distribution problem are given.

Fishery and Marine Resources (Fred Prochaska, University of Florida, Chairman)

"Factors Affecting Monthly Florida Mullet Prices with Special Emphasis on Landings and Market Development." James C. Cato (University of Florida)
Florida mullet prices vary seasonally due to several factors. Particular emphasis is given to the effect of lagged quantities landed on prices and the resultant price flexibilities. Market development programs have also shifted demand. Industry implications of these effects are also discussed. A polynomial distributed lag model is used.

"Stock and Congestion Externalities in the Fishery: The Case of the Georges Bank Scallop." Jon M. Conrad (University of Massachusetts) and Marilyn A. Altobello (ERS, USDA)
Estimation of U.S. and Canadian yield functions in a bioeconomic model of the Georges Bank scallop fishery indicated stock and congestion externalities. The latter resulted in nonconcavity of the combined yield function, thus generating the possibility of steady-state corner solutions where one nation would be eliminated from the fishery.

"Consumer Surplus, Producer Surplus, Is there a Country Surplus?" Fred L. Olson (U.S. Department of Commerce)
A description of the theoretical characteristics of the developing market for fishery resources used by distant water fleets as a result of the Fishery Conservation and Management Act of 1976, P.L. 94-265, and the Third Law of the Sea Conference, in progress.

"Bioeconomic Models of Marine Recreational Fishing: Some Implications for Policy and Future Research." K. E. McConnell and J. G. Sutinen (University of Rhode Island)
An optimal control bioeconomic model of a recreational fishery is developed and examined for insights into policy and research issues. Important areas for future economic research include the role of catch per outing in demand for recreational fishing and the impact of stock changes on the catch per outing.

Development Processes Outside the U.S. (T. T. Williams, Southern University, Chairman)

"East African Markets and Tanzanian Policies for Pricing and Plant Location—Livestock and Meat." Donald E. Farris, Gregory M. Sullivan (Texas A&M University), and Kenneth W. Stokes (USAID-TAMU/Tanzania)
Tanzania pricing policies for livestock and meat fail to provide the necessary seasonal, spatial, and qual-

ity price differences to achieve the objectives of national policy. A linear programming model is used to provide guides for efficient pricing and packing plant location. Plants in the interior would save $10 per head.

"Factors Affecting the Supply of Off-Farm Labor Among Small Farmers: The Case of Taiwan." Donald W. Larson and Hung Yu Hu (Ohio State University)
The issue of low income among small farmers in a developing agriculture is discussed. An off-farm labor supply function for rural Taiwanese households is estimated for 329 farm families. Dual employment was found to be a viable alternative to effectively deal with the low income problem of small farmers.

"The Schools of Thought on Small-Farm Development in the Developing Countries." Marcelino Avila and Melvin G. Blase (University of Missouri)
The paper presents an informative analysis on the most important contributions to the literature on small-farm development in the developing countries by dividing them into four schools of thought: community development, "green revolution," integrated rural development, and collectives. Subsequently, selected observations on small-farm development strategies are made.

"Labor Productivity on Small Farms: The Case of Nicaragua." Gustavo Arcia and Philip F. Warnken (University of Missouri-Columbia)
This study examines labor productivity of hired and family labor on small farms in Nicaragua. Two hypotheses are tested relating to the MVP_L and AVP_L with respect to the wage rate. Policy implications are drawn regarding rural to urban migration and rural and urban unemployment for developing nations.

"Modeling Transportation and Storage Systems in Developing Areas as Capacitated Networks." Charles L. Wright and Richard L. Meyer (Ohio State University)
Capacitated network models are presented as more appropriate instruments for studying commodity transportation-storage systems in developing areas than traditional linear programming models. Illustrations incorporate realistic features of capacity constraints, multiple transshipment points, storage, intermodal transfer costs, and convex costs. A solution is obtained using the efficient Fulkerson algorithm.

Computers as Teaching Aids (Melvin R. Janssen, Economic Research Service, USDA, Chairman)

"A Teaching Package for Portfolio Selection Analysis Using a Quadratic Programming Approach." Kerry K. Litzenberg and James G. Beierlein (Purdue University)
The Markowitz portfolio theory has been used by economists for many years. To apply this procedure to a classroom situation requires students well versed in portfolio theory and quadratic programming. The procedure described in this paper removes one or both of these barriers and is adaptive for classroom use.

"Computer Graphics: An Educational Tool for Understanding Agricultural Production Functions." David L. Debertin, Angelos Pagoulatos, and Garnett L. Bradford (University of Kentucky)
Computer graphics can be used as a tool for teaching courses in agricultural production economics. Computer graphics enables students to generate three dimensional illustrations of surfaces of two input production functions. The role of second order conditions for ensuring solutions to optimization problems can be illustrated with computer graphics.

"Teaching the Policy-Making Process." Fred C. White and Sherry K. White (University of Georgia)
Simulation, an exciting technique that places the student in the role of economist and policy maker, has been used in undergraduate agricultural policy classes to teach the policy-making process. Simulation allows students to make critical judgments on important policy issues. This realistic approach is described in this paper.

Theory and Technique (Ben French, University of California, Davis, Chairman)

"The Effects of Real Multiplier versus Inflationary Effects on Output and Income Generation in Input-Output Models." Gene K. Lee and Gerald Schluter (NEAD, ERS, USDA)
A modified input-output model that incorporates price changes as well as changes in the volume of final demand demonstrates that changes in the price and changes in the volume of final demand have different effects on the economy but also influence different segments of the economy.

"Adapting Portfolio Theory for Asset Indivisibility: A Conceptual Approach." Lindon J. Robison (ERS, USDA) and Peter J. Barry (Texas A&M University)
Portfolio theory is used to explore the kinds of risk-return effects induced by investments in indivisible assets. Risk-return economics require higher levels of return and risk as the size of the fixed investment increases, and portfolio choices can be limited using Baumol's E-V criterion.

"Orthogonalization and Variable Deletion in Regression Analysis: The Problem Revisited." Ron C. Mittelhammer and John L. Baritelle (Washington State University)
This paper briefly reviews artificial orthogonalization and component deletion in regression analysis.

Confusion exists over which elements to delete in the orthogonal frame of analysis. This paper developed the theory of component deletion via the characteristic root and t-value and interprets the meaning of each criterion. A simulation model is employed.

"A Method for Computing Optimal Production, Investment, Financing, and Consumption Strategies under Uncertainty." James F. O'Connor (University of Iowa)
Under price and production uncertainty, expected utility maximizing strategies for production, investment, financing, and consumption can be computed by a combination of quadratic programming and algebra when the entrepreneur displays constant absolute risk aversion and faces linear programming production technology and when the uncertain quantities are normally distributed.

"The Use of the Gini Ratio in Measuring Distributional Impacts." Charles H. Riemenschneider (Michigan State University)
Economists often use the Gini ratio for measuring inequality in income or program benefit distributions without fully understanding its implications and limitations. This paper delineates some of the limitations in the use of the Gini ratio as commonly calculated and examines several new techniques for calculating the Gini ratio.

Estimation Methods (Rueben Buse, University of Wisconsin, Chairman)

"A Test for the Statistical Significance of a Frontier Production Function in Dairying." Bill R. Miller (University of Georgia) and Clifford M. Carman (ERS, USDA)
The authors hypothesize that a frontier production function is influenced by some unspecified set of information. Using a multivariate discriminate model, they test for specification error of the function. They conclude that a frontier function appears to effectively sort dairy farms into groups that differ in a statistically significant manner.

"Improved Estimation of Cattle Slaughter Through Generalized Least Squares." Thomas Spreen and Glenn Nelson (Purdue University)
The problem of improving the estimation of cattle slaughter is addressed by making suggestions for a better model specification and exploiting more fully the available statistical information through use of generalized least squares. The results are contrasted with ordinary least squares estimation and illustrated by estimating withholding in 1973.

"A New Approach to Small Area Crop-Acreage Estimation." Harold F. Huddleston (SRS, USDA) and Robert M. Ray III (University of Illinois)
This research was undertaken to assess the practicalities of improving the accuracy of crop acreages using remote sensing data. In obtaining state estimates, small area estimates are made that are partitioned into county estimates. The accuracy of the small area estimates is significantly improved, leading to useful county estimates.

"Stochastic Specification of Production Functions: Econometric Convenience or Nonsense?" Rulon D. Pope and Richard E. Just (University of California, Berkeley)
The stochastic specification of input-output response is examined. Postulates are set forth that seem reasonable on the basis of a priori theorizing and observed behavior. Commonly used formulations are restrictive and may lead to inefficient and biased results. A function that satisfies the postulates is suggested.

Wastes—Issues and Utilization Alternatives (Gerald Horner, Economic Research Service, USDA, University of California, Davis, Chairman)

"Vector Optimization for Selecting Municipal Sludge Disposal Systems." Bruce E. Lindsay and Cleve E. Willis (University of Massachusetts)
An application of the constraint method of vector optimization is used to evaluate alternative sewage sludge disposal systems within a multiobjective decision-making framework for the metropolitan district commission area of Boston. The objectives of economic efficiency, environmental impact, and uncertainty associated with impact were selected for this investigation.

"Equity and Efficiency in Pricing Local Public Services: The Case of Wastewater." David H. Peterson and Daniel W. Bromley (University of Wisconsin)
Pricing decisions for local wastewater services can play a crucial role in the attainment of efficiency with equity. Normative judgments about equitable service should include concepts of ability-to-pay across users of the service and concepts of spatial equity. The determination of a price for wastewater service, using the objectives of efficiency, equity, and simplicity, may better suit the goals and policies of local officials than the traditional determination of price through the cost-of-service method.

"Partial Technology Assessments of Products Derived from Tannery Unhairing Effluent for Use in Poultry Rations Using Linear Parametric Programming Techniques." Harold H. Taylor (ERS, USDA) and Reed D. Taylor (Ohio State University)
The possible usefulness of products derived from tannery unhairing effluent for use in poultry rations were analyzed using linear parametric programming techniques. Intrinsic demand curves obtained indicated that these products could compete with other ingredients in poultry rations provided that production costs do not exceed acceptance level prices.

"An Economic Analysis of the Utilization of Municipal Wastewater for Crop Production." Lee A. Christensen (NRED, ERS, USDA)
Sensitivity analysis was used to estimate changes in farm revenues utilizing waste-water irrigation. Variables evaluated were yield response, rotations, prices, irrigation costs, and cost sharing. Corn was the most profitable crop evaluated, soybeans the least profitable. Net farm revenues were evaluated assuming alternative cost sharing levels by the waste supplying municipality.

"Economics of Nonmetropolitan Solid Waste Resource Recovery: A Case Study and Some Extensions." Mark Luttner (Environmental Protection Agency) and Fred Hitzhusen (Ohio State University)
A nonmetropolitan coal burning steam-electric plant in northeastern Ohio was analyzed to determine the technical and economic feasibility of converting the plant to solid waste as a supplementary fuel. Benefit-cost sensitivity analysis showed the proposed system economically feasible under a wide range of technical and economic parameter values.

Regional Development—Strategies, Indicators, and Impacts (Larry Morgan, Texas A&M University, Chairman)

"Nonmetropolitan Job Creation in a Post-Industrial Society: Problems and Prospects." Stephen M. Smith and Glen C. Pulver (University of Wisconsin-Madison)
Employment trends, population and industry movements, and changing economic development goals are examined. The prospects of various industrial sectors for meeting nonmetropolitan employment and development goals are assessed. In conclusion, particular service sector industries may provide a more solid base for long-run job creation and economic growth strategies.

"An Analytic Comparison of Multivariate Regional Rural Development Economic Well-Being Indices." Richard A. March and Dennis K. Smith (Virginia Polytechnic Institute and State University)
Four different multivariate indices of economic well-being were computed and compared for Virginia localities. These indices were highly correlated. Multivariate techniques should use specific problem related variables. A simple income-based index is as valid as a multivariate index incorporating large masses of intercorrelated data.

"Trade Interdependencies: The Case of Alaska and Washington." Kenneth L. Casavant (Washington State University) and Wayne C. Thomas (University of Alaska).
Alaska's economic activity and Washington's geographical proximity have created strong trade interdependencies. This paper presents findings as to the impact of, and opportunities for, more trade between the two states, as derived from an historical review, an input-output model, a profile of water movements, and a trade barriers survey.

"Toward a National Program of State and Regional Agricultural Safety and Health Statistics." Conrad F. Fritsch and John M. Zimmer (ERS, USDA)
A national program of state and regional occupational safety and health data can improve the information base from which proposed Occupational Safety and Health Act standards are discussed. Such data also provide the basis for documenting state safety and health education program content. Two data sources are evaluated for usefulness toward meeting these objectives.

Transportation (Orlo Sorenson, Kansas State University, Chairman)

"Demand for Freight Cars in the Movement of Grains." Erhardt O. Rupprecht, Jr. (NEAD, ERS, USDA)
The recent Railroad Act calls for rates reflecting peak demands. Carloadings of grain exhibit peaking and smoothing out movements could reduce the grain car fleet needed. However, this measure may not be entirely suitable in framing a pricing policy. Increased storage capacity would offset savings from a smaller car fleet.

"Changing Transport Demands by Agricultural Shippers in Response to Rail Restructuring." Arvin R. Bunker (ERS, USDA)
Changes in marketing-transportation activities in response to rail abandonment were evaluated for three alternative scenarios using a mathematical programming model. The total bill, ton miles of traffic by mode and highway type, highway maintenance costs, and changes in grain-fertilizer transportation were measured and related to the three scenarios.

"Simulation Analysis of Export Grain Flows Through Gulf Ports." Jerome J. Hammond (NEAD, ERS, USDA) and Michael S. Salvador (Ernst and Ernst)
A simulation model is used to determine circumstances that may constrain the export of grains through U.S. gulf ports. Results of analyses indicate that there is adequate capacity for increased exports of grains through these ports. Congestion does occur but diminishes substantially with increases in elevator-operating hours.

"Waterborne Transportation Benefits Received by Iowa Corn Farmers from the Mississippi River." Freeman K. Buxton (AMS, USDA)
Grain farmers along the upper Mississippi River receive low-cost water transportation benefits. Therefore, for water benefit continuation, Locks and Dam No. 26 near Alton, Illinois, must be repaired. This paper shows that low-cost barge rate

benefits are reflected back to eastern Iowa farmers in terms of prices received.

"Improving Michigan's Rail Service Through Group Action." Michael Patrick (Michigan State University)
Abandonment has been the traditional solution to the light-density rail line problem. Alternatives to abandonment exist, however. This paper argues that analysis and understanding of the interrelationships between carriers and shippers can lead to policies promoting improved rail service, increased rail shipments, and revenues on many light-density lines.

Impacts of Agricultural Trade on the U.S. (B. H. Robinson, Clemson University, Chairman)

"The Changing Structure of U.S. Trade: Implications for Agriculture." Antonio Brandao and G. Edward Schuh (Purdue University)
There has been a major change in the structure of U.S. trade, with the deficit on the account in nonagricultural trade becoming increasingly large while the surplus in agricultural trade simultaneously grows. The paper suggests some explanations for this phenomenon and draws implications for future policy.

"The Domestic Welfare Effects of U.S. Wheat Export Controls." Shun-Yi Shei and Robert L. Thompson (Purdue University)
A framework is developed to evaluate the domestic welfare effect of export controls. By imposing export restrictions on wheat in a short crop year, the United States could gain sizable short-run welfare benefits, export earnings could be substantially increased, and, unless the government intervenes, exporters reap most of the benefits.

"An Analysis of the Effects of Alternative U.S. Dairy Import Policies." Larry Salathe, W. D. Dobson, and G. A. Peterson (University of Wisconsin-Madison).
Wisconsin farm milk prices initially would fall by 16% if butter and cheese imports rose to 25% of U.S. requirements. Within four years milk prices would recover. But this recovery would occur only after 10% of the state's dairy farmers were forced out of business by the larger imports.

"Effects of Changes in the Level of U.S. Grain Exports." James N. Trapp and Stanley R. Thompson (Michigan State University)
The magnitude and duration of economic responses in U.S. crop and livestock markets to increased grain exports during 1972 are examined using an agricultural sector simulation model. In light of the 1972 case, consideration is given to the effectiveness of alternative government stock levels in "cushioning" grain export "shocks."

"The Impact of Trade Policies on the Demand for and Revenue from U.S. Feed Grains." Francis Walker and Kleo-Thong Hetrakul (Ohio State University)
U.S. exports of and total revenue from feed grains depend on trade policies of the United States, the importing countries, and other exporting countries. U.S. export demand functions for each of four importing countries are estimated. The impacts of selected trade policies on feed grain exports and revenue are determined.

Resource Planning, Development, and Management—Part B (Verner Hurt, Mississippi State University, Chairman)

"Investment in Information and Production of Natural Resources—A Stochastic Control Approach." Bruce L. Dixon and Richard E. Howitt (University of California, Davis)
Production from unexploited natural resources is of increasing concern to policy makers. Currently, optimal resource production models ignore the effect of uncertainty about resource stocks and the production process. The stochastic control formulation explicitly derives the conditions of optimal resource production under uncertainty and the cost of uncertainty in production.

"Economic Implications of Entropy and Materials Balance in Managing Exhaustible and Nonrenewable Resources." Angelos Pagoulatos (University of Kentucky)
From the extension and fusion of the entropy law and the materials balance, the economic implications of physical constraints in managing exhaustible resources are identified. Exhaustion is exemplified with the decreased availability of options of management. The trade-offs between options, technical efficiency, and uses in resource conversion processes are derived.

"An Analysis of the Opportunity Costs of Channelization and Land-Use Change in the Obion-Forked Deer River Basin." George F. Smith and M. B. Badenhop (University of Tennessee)
The value of floodplain lands in agricultural use following channelization and the resulting foregone value of these lands were estimated. The latter estimates were incomplete because of the inability to predict effects on potentially important parameters. Estimated differences provide a threshold for decision making. Policy implications are discussed.

"Improving the Framework for Estimation of Agricultural Benefits of Small Watershed Projects." Robert B. Jensen and Leonard A. Shabman (Virginia Polytechnic Institute and State University)
Techniques of agricultural benefit estimation for small watershed projects have recently become the focus of increasing study and controversy. An alternative approach to agricultural benefit estima-

tion is compared to current techniques on both a general level and by reference to a case study. Improvements in estimation techniques may be possible.

Trends and Factors in International Trade and Development (Philip Warnken, University of Missouri, Chairman)

"Brazilian Trade Policy and Its Impact on the Regional Distribution of Income." Marshall A. Martin and G. Edward Schuh (Purdue University)
Brazil's trade policies have affected regional income distribution. In the 1950s a sizable flow of capital was transferred into the state of Sao Paulo from the rest of Brazil, especially from the Northeast. More liberal trade policies and higher world commodity prices reversed the interregional resource flow in the 1960s.

"The U.S. Sugar Position in the World Sugar Economy." Ahmed Abou-Bakr (FDCD, ERS, USDA) and Albert Harrington (Washington State University)
Different marketing possibilities that would face the U.S. sugar industry are investigated. The U.S. sugar industry is competitive at a price that results from a world stocks-consumption ratio of 20%. At a price resulting from 30% stock-consumption ratio, the U.S. domestic sugar industry is clearly not competitive.

"Estimates of Income Coefficients of Final Demand for Food in Japan." Bruce L. Greenshields (ERS, USDA) and Kent B. Gates (College of William and Mary)
Estimates are made for both short-run and long-run marginal propensities to consume and income elasticities of demand for food. Consumers responded inelastically in the short run, but there was a positive, elastic response in the long run for several commodities and a negative, elastic response with respect to expenditures on rice.

"Agricultural Imports by Major Developing Countries—Their Growth in the Last Decade and Prospects for 1976." John B. Parker, Jr. (FDCD, ERS, USDA)
India was the leading importer of agricultural commodities among developing countries during nine of the last ten years, but in 1976 Egypt and South Korea are likely to move ahead of India. Other contenders for leading positions among food importers of developing nations include Iran, Iraq, Saudi Arabia, and Indonesia. Rapid growth in food imports by developing countries creates new opportunities for U.S. agricultural exports.

Structure and Organization of Agriculture (Kenneth R. Krause, Economic Research Service, USDA, Chairman)

"Seed Corn Purchasing Behavior of Corn Growers." David E. Hahn (Ohio State University)
Key factors affecting seed corn purchasing habits of farmers were examined. Hybrid performance was the primary differentiating measurement used by growers. Relative importance of alternative information sources for assessing performance was evaluated. Test plots, neighbors and other farmers, university extension personnel, seed corn dealers, and advertising was the rank order.

"Part-Time and Full-Time Farm Operators: Some Comparisons." K. C. Schneeberger (University of Missouri), Sam Comer (Tennessee State University), and Richard Edwards (ERS, USDA, Tennessee State University)
Are part-time and full-time farms different in organizational and operational characteristics? Do operators respond differently to changing economic and technologic conditions? Large, full-time farmers reported practices and attitudes most consistent with efficiency and profit maximization. Part-time farmers had an investment strategy, and small, full-time operators appeared survival-oriented.

"Management, Capital Structure, and Farm Firm Growth Revisited." George F. Patrick (Purdue University)
Three levels of managerial ability, capital availability, and interest rates were simulated for periods comparing the 1960s and 1970s. Managerial ability was the major determinant of firm growth, but impacts of capital availability and interest rates were greater under conditions of the 1970s than they were in the 1960s.

"Identification of Growth Potential for Locally Owned Farmer Cooperatives." Gary T. Devino, Stephen E. Mathis, and Francis P. McCamley (University of Missouri-Columbia)
Eleven financial ratios associated with firm growth were utilized in a linear probability model for predicting growth of locally owned farmer cooperatives. The models developed were accurate in predicting growth 82% of the time for High Plains cooperatives and 73% of the time for Midwest cooperatives.

Award-Winning Theses

Hu, Hung-Yu. "Analysis of Factors Affecting Supply of Off-Farm Labor Among Taiwanese Farmers." M.S. thesis, Ohio State University, 1975.

The objective of this study was to explore the main factors affecting farmers' off-farm labor supply in Taiwan. The conclusions are: (*a*) Taiwan's agriculture has changed from a unimodal pattern to a bimodal pattern, (*b*) eight quantitative variables and two dummy variables significantly affected farmers' off-farm labor supply, and (*c*) the elasticity of off-farm labor supply with respect to the ratio of nonfarm wages to net farm income for the pooled sample was inelastic. However, after classifying into two subgroups, the elasticity of off-farm labor supply for "small" farmers was significantly higher than that for "larger" farmers.

Pieri, Renato G. "The North American-Japanese Pork Industries: An Economic Analysis." M.S. thesis, University of Guelph, 1975.

The main objective of this study was to develop a quarterly recursive programming model of the Japanese-North American pork industries, including the spatial and temporal aspects of the sector, for use in evaluating policy alternatives.

The study outlines the structure of the Japanese pork industry and develops a five-region (eastern Canada, western Canada, United States, Japan, and the rest of the world) quadratic programming model that is able to incorporate the Japanese pork price stabilization policy that includes import quotas, a variable duty, and an *ad valorem* duty. Supply, consumption, and storage functions were estimated using data from 1961 through 1974.

The validated model was used to analyze the effects of exchange rate variations, Japanese domestic agricultural policies, and long-term export contracts on the volume and origin of North American-Japanese trade.

Staatz, John. "The Economic and Nutritional Impact of Changes in Agricultural Production Patterns: The Case of the Philippines." M.S. thesis, Cornell University, 1975.

This study estimates the costs of carrying out agricultural policies to encourage the production of certain nutritious foods and evaluates the effect that the resulting changes in production would have on the nutritional status of the Filipino poor. In doing so, the effects on food prices, incomes, and consumption patterns of specified increases in the production of rice, root crops, pulses, and fish from fresh water ponds are evaluated. From this information, the relative effectiveness of different programs designed to increase calorie and protein consumption is determined. This is then contrasted with the nutritional impact that would accompany the introduction of high-protein rice in the Philippines.

Various studies of food availability and dietary intake in the Philippines are reviewed, and the major nutritional problems of the country are identified. A methodology is developed that incorporates input-output analysis to trace through the input requirements and income-generating effects of different agricultural production programs. A 63-sector input-output model for the Philippines is presented and discussed. Applying the methodology developed here to the analysis of specific agricultural production programs reveals that all approaches would incur very significant support costs. The regional impact varies substantially, and data on the intrafamily distribution of food suggest that little of the increased production would go to children and to pregnant and lactating women, who are the most nutritionally needy members of the population. For these groups, additional programs would be needed if their nutritional status is to be improved.

Kraft, Daryl Frank. "Economics of Agricultural Adjustments to Water Quality Standards in an Irrigated River Basin." Ph.D. thesis, Washington State University, 1975.

Many waste products linked to agricultural production are nonpoint source residuals. This study utilized neoclassical production theory to compare the economic efficiency of abatement programs for point and nonpoint source pollutants from agricultural activity and municipalities in a river basin.

A nonlinear separable programming model was developed to analyze abatement policies designed to reduce the concentration of dissolved nitrogen in the Yakima River of eastern Washington. To reduce nitrogen concentration in the river, farmers were given options of (*a*) adopting more capital-intensive irrigation systems, (*b*) reducing nitrogen fertilizer application, (*c*) reducing cropped acreage, (*d*) changing the crop mix, or (*e*) doing any combination of the former, while municipalities could choose to install a tertiary sewage treatment process. The analysis considered policy alternatives of constraining the instream nitrogen concentration to achieve the desired water quality standard, placing a water users surcharge on irrigation diversions, uniformly reducing rights for water diversion throughout the river basin, or taxing nitrogen fertilizer.

The abatement costs, measured as net social costs, were lowest when resources allocated for crop production and sewage treatment were required to meet a specified level of water quality throughout the waterway. The equilibria derived from limiting the instream concentration of nitrogen are only theoretical optima but do provide a norm to compare the administratively feasible but less efficient water quality programs.

Among the feasible policies, taxing nitrogen fertilizer was the most economically efficient, while a water user surcharge was slightly less costly than water rationing. The differences in abatement costs among the feasible policies were small. The most important factor influencing the cost of abatement was the desired level of abatement rather than the policy instrument utilized to achieve the standard.

Robison, Lindon Joel. "Portfolio Adjustments Under Uncertainty: An Application to Agricultural Financing by Commercial Banks." Ph.D. thesis, Texas A&M University, 1975.

This study uses portfolio theory as the basis for a theoretical model from which theorems relating to bank behavior are deduced. Demand curves for assets are derived and separated into income and substitution effects. The sign of the income effect is related to a decision maker's risk aversion coefficient.

Some of the theoretical results imply that, for the decreasingly risk averse banker, the demand for risky assets will increase with expected returns and decrease with variance. Cross-price effects and covariance effects are shown to depend on whether assets are substitutes or complements in the portfolio. Increasing the deposit feedback effect from loans will increase the demand for loans by the banker. Increasing the liquidity of assets may increase or decrease the banker's holdings of risky assets, but the banker with constant or increasing aversion to risk will decrease his holdings of risky assets.

A quadratic programming model is constructed to demonstrate empirically the application of the theory to a particular bank. Variance and expected returns are calculated, and a basic model solution is found using efficiency criteria discussed in the study. Equilibrium adjustments to changes in selected parameters are then observed and compared to previous model solutions. Finally, policy implications are made based on the theoretical model. Some issues considered relating to the impact on agricultural lending by banks were seasonal borrowing privileges for rural banks from the Federal Reserve System, the development of secondary markets for bank's paper, and increasing deposit costs.

Sexton, Roger Nell. "Determinants of Multiple Job-Holding by Farm Operators." Ph.D. thesis, North Carolina State University, 1975.

The objective of this study was to analyze the factors affecting the amount of labor time supplied to off-farm work by farm operators. A model of multiple job-holding by farm operators was developed to predict the effects of changes in the wage rates received from farm and off-farm jobs on the labor-leisure choices of farm operators engaged in off-farm employment. This analysis was extended using the modern theory of household behavior to take account of the influence of the farm family in determining the amount of time allocated to off-farm work by farm operators.

Off-farm labor supply equations based on the model were estimated using cross-section data from a regional survey of farm operators in the flue-cured tobacco-producing areas of three southern states (Virginia, North Carolina, and South Carolina) as well as from a statewide survey of farm operators in Illinois.

The off-farm supply of farm operators was found to be positively related to the off-farm wage rate received by operators and negatively related to the wage rate received from farm work. The off-farm labor supply of low farm income operators was generally found to be much more responsive to changes in off-farm wage rates than was the off-farm labor supply of farm operators in the data sets taken as a whole. The off-farm wage rate earned by farm wives was not found to have a significant influence on the amount of time supplied to off-farm work by farm operators.

Committee Reports

Report of the President

This has been an eventful and challenging year, both personally and for the AAEA. So many different kinds of activities have been begun or brought to fruition that it is hard to know how to report them briefly. I report first on a number of major events. Then, I shall examine what I believe to be the AAEA's major long-run problem and the actions taken on it this year.

A new *Handbook-Directory* has been prepared this year and will be published as part II of the November 1976 issue of the *Journal*. Since the *Handbook-Directory* normally contains a copy of the Constitution and bylaws, I asked Neil Harl to chair a committee to review our Constitution and bylaws and to make recommendations for changes to the Board. He and his committee have done a first-rate job. I cannot recount the individual changes, most of which incorporate into the bylaws the policy actions of the Executive Board from the last five years. No recommendation for change was made for the Constitution.

After an extensive evaluation of a wide range of publication alternatives, a contract was signed with the University of Minnesota Press for the publication of volume I of the *Review of the Literature of Agricultural Economics since World War II*. This volume will be available in early 1977 and paid-up AAEA members may now order copies at a prepublication discount price. Volume II should also be published in 1977.

The Agricultural Economics Literature Retrieval System, which was sponsored in cooperation with the U.S Department of Agriculture, has been computerized and placed on line and is now accessible by members. Materials on how to use the system have been distributed to all academic departments and governmental agencies, as well as to individual AAEA members. As the capacity of the system increases, it will be an exceedingly valuable research tool for the profession.

The Resident Instruction Committee has continued to work on the development of a new format for student participation in the AAEA annual meetings and for greater emphasis on the problems of teaching and curriculum development. They presented a fine program at the Pennsylvania State University meetings, and I look forward to even further developments by next year. The committee is doing a good job.

The Economics Statistics Committee continues to work on improvement in the data-base of agricultural economics. A workshop on agricultural and world data has been scheduled for early spring in cooperation with the U.S. Department of Agriculture.

The Registry for Agricultural Economists has been financed entirely by a grant from the U.S. Department of Labor. In anticipation of the longer-run decisions that must be made, I appointed a Committee on National Professional Employment Registries, chaired by David Boyne. They are to work with the Employment Services Committee to recommend to the Board some long-run pattern of stable financing and organization for the National Registry.

The directors have begun a systematic evaluation of the annual program format. With the help of several past chairmen of the contributed papers program, the Board directors have reviewed the experience and the policies and rules governing that part of the annual program. Several ideas for change have been discussed, and a committee will be asked to examine some of the problems and to make recommendations for action at the Board's winter meeting. I also appointed this year a committee to evaluate the annual program, chaired by Henry Meenan of the University of Arkansas. The committee's evaluation of the overall format each year will aid the president and Board in planning better programs. If you have any suggestions, get them to the committee.

I put a great deal of effort early this year into reviewing the balance and the distribution of the membership on AAEA committees. One of the primary objectives was to assure that participation in committees is, as the Board has directed, shared widely among the AAEA membership. I found that this was already the case, undoubtably the product of the efforts of other AAEA presidents who have worked hard on the same objective. I have continued in this effort.

Let me report to you on what I think is the primary long-run problem facing the AAEA and on which I spent most of my energies this past year. The problem is exposed in the context of our financial difficulties.

As you well know, we have faced rapidly rising costs, primarily in publication, but in other expenditures as well. The AAEA experienced deficit budgets in 1974 and 1975. By virtue of great effort by the Board and AAEA officers and with the help of members, we appear to be in the black for 1976. However, financial pressures still exist. Obviously we cannot sustain continuing deficits. In such a situation, draconian measures to reduce services would be necessary within a very short period. The more desirable solution lies in two directions—through increasing income directly and through a larger membership.

With a dues increase and page charges instituted last year, I addressed the question of how membership might be increased. The Membership Commit-

tee has concluded that only about half of all agricultural economists are now AAEA members. Why? I believe at least part of the answer lies in the following problem.

Twenty year ago, to be an agricultural economist was automatically to be a member of the AAEA. That was the way in which one identified oneself; it was universally expected. Dues were low, and usually very little thought was given to the decision to join. We have now moved into an era where increasingly individuals ask first, "What is in it for me?" Or, "What do I gain relative to the cost of joining?" In other words, for some reason it has become more of a rational economic decision than a matter of professional obligation, pride, or identification.

Why should this be? I am not sure that I really have all of the answer, but a good part of it must be found in the increasing specialization in what agricultural economists do and value today. We used to do a few closely interrelated things, but now we are fragmented into many more, far narrower specialties that have less immediate commonality. Professional needs have grown equally specialized. At the same time, AAEA services have remained quite general, unspecialized, and very collective in nature—in other words, most of our services are available to members and nonmembers alike! Thus, it becomes more difficult for many to identify closely with the AAEA, and it is not all that surprising that more individuals question whether the value of being a paying member is worth the dues required, especially when you can gain most of the benefits as a nonmember. The same conclusion can be drawn less directly from the increasing number of critical comments about the kind of services that the AAEA renders its members.

The only way to increase membership in the face of this set of problems is to put more systematic effort into recruiting members and to improve the attractiveness of AAEA membership. This we have started to do. We are increasing the energy going into recruiting and are attempting to form a cooperative membership recruiting venture with the other regional agricultural economics associations and the Canadian Agricultural Economic Association. This is only in its earliest stages, but I have great hopes for it.

One way of improving the attractiveness of AAEA membership would be by limiting access to AAEA services to paying AAEA members. The Board and I feel quite strongly that, with dues at higher levels, we have a responsibility to members to see that their resources are used for services to members and not for those looking for a "free lunch." To that end, the following policies governing existing services were approved by the board at its meeting at Penn State: (*a*) the AAEA should, in general, limit committee membership to AAEA members; (*b*) higher registration fees should be charged nonmembers registering to attend the annual meeting; (*c*) the privilege of presenting contributed papers at the annual meeting should be limited to AAEA members, except in special cases in which the condition is waived by the president; (*d*) the privilege of presenting and discussing invited papers and all invited addresses at the annual meeting should be reserved for AAEA members, except in special cases in which the condition is waived by the president. In addition, committees will be debating other questions that may result in additional policy changes. These include consideration of changes in policies governing access to other AAEA activities and services, such as the *Journal* and awards.

The Board is moving as carefully and thoughtfully as possible to transform what have been collective goods, available to all, into selective goods available only to members or available at preferential rates to members. We believe this is only fair to the members to pay the AAEA's bills.

Finally, if we are to increase the value of membership, we must also design new AAEA services to respond to today's more specialized professional interests. In doing this we have to be very careful to maintain the philosophic and organizational integrity that is the nature of our professional association. To pursue this final objective, I have reactivated the Professional Activities Committee under Paul Barkley's leadership to examine our current services and to develop a philosophy and pattern of services that is responsive to members' specialized needs. They are well under way.

I have also asked several other committees to develop recommendations for possible services to members of the AAEA. These include the Extension Affairs Committee and the Industry Advisory Committee. I have also asked the Visiting Lecturer Committee to do the same for the four-year predominantly non-land grant college faculties, where we now have a considerable number of agricultural economists, many of whom are already AAEA members. In another vein, I have appointed an Alternative Publication Committee under the chairmanship of Verner Hurt of Mississippi State University to explore the possibilities and the alternative purposes and design for an eventual new AAEA publication, as recommended by the Smith Committee. Obviously, if our financial situation is not substantially improved over the next few years, a new publication, however modest in scope, would be extremely difficult of attainment.

Over the next three to five years, I am hopeful that what was begun this year will result in a better designed pattern of overall services of greater value to members and a substantial increase in membership.

Respectfully submitted,
James T. Bonnen
President

Resolution

We wish to acknowledge the warm and cordial hospitality shown the AAEA members, their families, and guests on the occasion of the annual meeting held at Penn State University on 15–18 August 1976.

Therefore, be it resolved that the AAEA expresses its sincere gratitude to President John Oswald, Dean James Beattie, College of Agriculture, and to John W. Malone, Jr., chairman of the Department of Agricultural Economics and Rural Sociology, and the faculty, staff, and students, and their families for their hospitality.

All of these, under the able and devoted leadership of Jim Holt, Chairman of the Local Arrangements Committee, as constituted and reported on page 44 of the program, have served us effectively and graciously.

Be it further resolved that a copy of this resolution be sent to President John Oswald, Dr. Malone, Dr. Holt and each member of his committees, and to others at the Penn State University as appropriate.

Report of the Secretary-Treasurer

The AAEA membership for 1975 increased by 191 over 1974 and by 488 over the 1973 low (table 1). Most of the increase this year came from the junior membership, while most of the 1974 increase came from regular members. Considerable effort is being exerted presently to increase membership in all categories.

The 1975 operating statement shows a deficit of $13,845.83 (table 2). Caution must be exercised in examining such statements because extraordinary items often convey normal activity. When the grant received from the U.S. Department of Labor (USDL) to support the activities of the Employment Committee is subtracted from the income and the amount spent by that committee is subtracted from the expense, the actual deficit experienced by the AAEA for 1975 was $15,255.95. The deficit was $2,487.51 in 1973, $22,229.42 in 1974, and $15,255.95 in 1975, making a total deficit of $39,972.88 during the past three years.

One significant point should be made on the income side pertaining to reprints and page charges. Since these activities are interrelated, they were combined for 1975. The miscellaneous income includes a $75 gift, $184.61 for brochures sold, $979.80 as royalties from University Microfilms, and $203.84 in postage collected. On the miscellaneous expense side, the $849.66 includes $81 spent on *Literature Review*, $1.00 for Iowa registration fee, $112.93 for printing of brochures for sale, $24.00 for copyright fees, $564.50 in refunds, and $66.23 in foreign exchange charges not accounted for in reduced income.

The *American Bibliography of Agricultural Economics (ABAE)* ceased publication at the end of 1974. During 1975 refunds were made to those subscribers already paid. All activity is now being directed toward the development of a computerized retrieval system. At this time, it is desirable to make an income-expense summary of this activity (table 3).

Income was from subscriptions, and expenses were the direct cost of preparation of copy and printing. The AAEA assumed all money costs associated with postage, handling, and operating essentially another association, while the U.S. Department of Agriculture assumed the time for preparation of copy. The surplus for 1972 resulted from a $5,000 order by the Agency for International Development to have the *ABAE* sent to all foreign libraries. Considerable quantities of resources are being allocated currently to this activity, and time will tell eventually if they are productive.

In accordance with the policy established in 1973, the income-expense statement for editorial support, as provided by Editor Tomek, is incorporated as a part of this report (table 4).

The balance sheet for the AAEA has deteriorated rapidly over the past three years (table 5). The

1975 statement showed a decrease of $13,845.83 in net worth, but we received $1,410.12 more in grant money than spent, making an actual decrease of $15,255.95.

Since the USDL grant funds were comingled and the AAEA is merely the custodian, it is desirable to point out that the $25,100.34 unspent funds in 1973 reduced our actual net worth to $127,644.74; the $7,434.10 unspent funds in 1974 reduced the actual net worth to $105,415.32; and in 1975 we had $8,844.22 in unspent funds, which decreased our actual net worth to $90,159.37. In three years, our net worth declined by $39,972.88. Our stock is carried on the books at cost.

Last year an increase in dues was voted, which was necessary to have a breakeven budget. Whether or not our financial position will improve during the next year or two remains in doubt.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Report of the Audit Committee

The Audit Committee employed the accounting firm of Moore, Wilson, and Smith to examine the financial records of the AAEA of 1975. Their report is as follows.

"We have examined the balance sheet of the American Agricultural Economics Association as of December 31, 1975 and the related statement of receipts and disbursements, fund balance and changes in financial position for the year then ended. Our examination was made in accordance with generally accepted auditing standards, and accordingly included such tests of the accounting records and such other auditing procedures as we considered necessary in the circumstances. In our opinion, the financial statements referred to above present fairly the financial position of the American Agricultural Economics Association as of December 31, 1975, and the results of its operations and the changes in its financial position for the year then ended, in conformity with generally accepted accounting principles applied on a basis consistent with that of the preceding year."

James E. Criswell
Larry D. Jones

Report of the Investment Committee

The portfolio of investments by the AAEA did not change during 1975. The stocks carried on the books at cost of $102,551.99 had a market value of $159,310.125 at the close of the business year, increasing by $22,878.50 from the previous year (table 1). Our investments in stocks yielded $9,040.60 in dividends (table 2).

The AAEA had only one stock—Standard Oil of Indiana, which was worth less at the end of 1975 than at the beginning. However, all stocks took a beating last year. Based on cost, an 8.82% rate of earnings was realized, but when based on market value at the beginning of the year 6.63% was realized.

Respectfully submitted,
John C. Redman

Report of the Finance Committee

This committee was established as a standing AAEA committee by vote of the membership at its annual meeting in August 1975. The responsibilities of the committee were established as follows: (*a*) annually review the AAEA investment portfolio, obtain assistance of professional counsel as deemed appropriate, and make recommendations to the Executive Board; (*b*) annually prepare a proposed budget for the AAEA, including review and projections of income and expenditure commitments, and present the proposal to the Executive Board; (*c*) assist with special assignments as requested by the

president and the Executive Board; and (*d*) initiate recommendations for consideration by the AAEA Board that are intended to enhance the AAEA's financial well-being. The secretary-treasurer, John Redman, as the AAEA's principal financial officer, is a critical and key member of this new committee. Two members of the Board and two other AAEA members make up the rest of the five-man committee.

Because of the deficits sustained in 1974 and 1975, the committee has been concerned with the implementation of the new schedule of dues and subscription rates as well as the several enterprises and activities of the AAEA that require annual expenditures. Individual members of the committee have taken responsibility to assist in the evaluation of proposed activities for the AAEA and the expected costs if implemented as enterprises. Special concern during the past year has been given to (*a*) the choice of a publisher for the *Postwar Literature Review*, (*b*) the choice of publishers for the *Journal* at the time of contract renewal in 1976, (*c*) operation of the retrospective search and bibliographic work, and (*d*) grants for the support of the National Professional Employment Registry.

The committee in cooperation with the secretary-treasurer develops basic materials with which the Board can finally establish an annual budget for operations for the coming year at the summer meeting consistent with actions taken on committee recommendations and proposals presented to the Board. The committee intends to give high priority to its budget responsibility and to present a balanced budget for Board approval.

The Finance Committee met in Washington, D.C., on 4 March 1976 to review its responsibilities and establish procedures for assisting the secretary-treasurer and AAEA committees in developing necessary financial data that would allow the Board to make decisions with as much information as possible. During the year the following individuals took special responsibility for keeping informed about these activities: *Journal* and Editorial Service—B. F. Stanton, National Professional Employment Registry—M. Boehlje, Retrospective Search—P. Barry, and Office of Secretary-Treasurer—W. Barr. In addition, Barr and Boehlje assisted in the review of bids for publication of the *Journal*. Stanton met with Babb's committee to evaluate the bids of potential publishers of the *Postwar Literature Review*. President Bonnen has involved appropriate members of the committee whenever budget or important financial issues have been considered throughout the year. Worksheets

[a] Basis for estimate of income for 1977 from dues and subscriptions: regular members—3300 × $25 = $82,500; junior members—500 × $12.50 = $6,250; libraries—1100 × $31.50 = $34,650 and 650 × $35 = $22,750; and institutional members—25 × $100 = $2,500.
[b] Actual commitments for volumes I and II were made in 1976 by special action of the Board, in the amount of $15,000.
[c] Primary payment for the *Directory* will be made in 1977—about $2,000 in 1976.
[d] Employment committee funded by a grant from U.S. Department of Labor. All expenses associated with the National Professional Employment Registry have come from grant funds. The proposed new grant will meet expenses through 30 June 1977.

and initial estimates for the AAEA 1977 budget are attached to this report (tables 1, 2, and 3).

One of the responsibilities of this committee is to make recommendations to the Board with respect to the AAEA's equity and investment holdings. At the March 1976 meeting of the committee, substantial discussion was devoted to the management of the AAEA's assets. The committee agreed to encourage the Board to establish some definite objectives or priorities with respect to the use of its capital. If these objectives were established, then alternative mechanisms to manage the portfolio could be proposed for discussion and approval at the winter meeting of the Board. During 1975 the market value of the AAEA's holdings recovered about $23,000 of the loss in value sustained in the two previous years. A yield of slightly more than 6% on average value was realized.

The capital assets of the AAEA provide an important equity base, which makes it easy for the secretary-treasurer to obtain credit whenever necessary and provides assurance to contractors that AAEA bills will be paid. This underlying objective of maintaining the portfolio should continue

Notes: (*a*) An important part of the expenses associated with the office of the secretary-treasurer is directed to support of *Journal* activities. (*b*) A new editor of the *Journal* will be appointed for the 1978–80 issues. Funds to operate during the transfer of the editor position have been budgeted starting in July 1977. (*c*) Page charges are assumed collected on 600 pages at $40 per page. (*d*) New printing contracts from either Heffernan or Edwards provide similar estimates of costs for an issue of about 1100 pages. (*e*) No income from submission fees is included.
[a] Transferred and combined with postage and supplies item in the enterprise account of the AAEA's secretary-treasurer.

Table 3. Enterprise Budget for General Expenses of AAEA and Office of Secretary-Treasurer

Expense Items	1975 Actual	1975 Budget	1976 Budget	1977 Budget
Secretarial assistance	$14,001	$16,800	$18,500	$16,000
Honorarium, secretary-treasurer	4,000	4,000	4,000	4,000
Postage, phone, supplies	6,610	6,750	7,500	11,000
Awards program	1,500	1,500	1,500	1,500
Travel and committee expense	460	4,400	4,400	1,200
Audit and other expense	2,842	3,350	3,500	6,000
Total	29,413	36,800	39,400	39,700

Notes: (*a*) Resident instruction and other committees of the AAEA have not received funds for meetings or other expenses during the past two years unless specifically authorized by the president or Board. Actual expenditure has been smaller than budgeted. (*b*) Audit and other expense includes the net cost of the annual meeting if any, bonding, the audit, and miscellaneous small items.

to be recognized as important. Management of the capital account of the AAEA could emphasize current income or annual yield, growth of the equity base, emphasis on yield with some growth in the capital base, or emphasis on growth in capital with some minimum annual yield. The committee believes that in the past investment decisions have tended to encourage the holding of quality issues that allow both growth in equity and reasonably high dividends. Only a small number of changes in the portfolio have been made in the past decade. If the Board was to suggest that primary emphasis should be placed on current yield with some growth in the capital base, then some shift toward holding some bonds and out of some of the common stocks might be in order. We recommend that the Board provide the committee with a sense of its emphasis, either toward the third or fourth items above. We can then come to the Board at the winter meeting with more specific information about the costs and associated expectations if this small portfolio is managed by professionals (trust company) or by a committee of AAEA members.

Report of Tellers Committee

Ballots received from the AAEA secretary-treasurer were counted by the Tellers Committee in the manner prescribed by the bylaws to preserve the secrecy of the ballots. The following candidates received the largest number of votes in their respective categories: R. James Hildreth for president-elect, Sylvia Lane for director, and Richard T. Crowder for director.

A. Frank Bordeaux, Jr.
Harry H. Hall

Report of the Editor

The editor devotes considerable time to activities other than reviewing and selecting manuscripts for publication. For example, from 1 July 1975 to 30 June 1976, I wrote thirty letters granting permission to reprint *Journal* material. (It is nice to know that the *Journal* is used.) In addition, I responded to many inquiries and questionnaires about the *Journal* and the AAEA.

The selection of an outstanding article was especially time consuming this year. After four rounds of balloting, we had a tie vote, and Paul Kelley and I agreed, after consulting with the editorial council, to make a coaward to the two articles. Our intent is to continue to give one award per volume, but because of the tie, the award is being shared this year. This approach seemed preferable to using an arbitrary method of breaking the tie.

I continue to doubt the value of the awards program relative to the cost of administering it. However, this is my personal view and not necessarily the view of the editorial council. I will, of course, continue to carry out the wishes of the AAEA to the best of my ability.

Two administrative matters have required my special attention in the past year. One involves the page charge instituted with the August 1975 issue. The page charge is mandatory, but exemptions are granted under certain conditions. Over 75% of the pages in the August 1975 through May 1976 issues that were eligible to pay did honor the charge. The most difficult exemption to administer is the so-called "poverty oath," which permits authors to certify that funds do not exist to honor the charge. The intent of this exemption is to permit students, retired persons, and others without access to institutional or grant funds to publish in the *Journal*. It has been difficult to administer this exemption fairly and consistently, and I have asked the AAEA directors for guidance. On balance, however, I think the policy is working successfully.

A second administrative matter has been participation in the ad hoc committee on the renewal of the *Journal's* printing contract. This committee,

chaired by Wallace Barr, has made a separate report to the directors, but I want to mention the sharply rising costs of publishing the *Journal*. The 1,032 pages in the 1975 volume cost about $75,000 to print, and the 1976 volume will be at least 5% higher. The 1977 volume will probably cost more than the 1976 volume. Thus, the cost of printing a 1,000 to 1,100 page volume in 1977 may be about $85,000. We will likely reduce the quality of the cover, the paper, and the binding of the *Journal* to make some modest savings in costs. Little more can be done to reduce costs aside from major modifications such as reducing the pages published. The directors may well have to face some difficult decisions about the future nature of the *Journal* in the years ahead.

Two hundred sixty-three manuscripts were submitted from July 1975 through June 1976, a decrease of sixty-nine from last year (table 1). The current level of submissions is similar to the recent norm, and last year's experience must be viewed as an exceptionally large number of submissions. I am surprised, however, that an association of about 4,000 members cannot generate a larger volume of submissions. In addition, the breadth of subjects covered by submissions appear to be smaller than the breadth of interests of the AAEA members.

I think, however, that our publication record indicates an openness to manuscripts in all aspects of agricultural economics. Four papers this year deal directly with undergraduate teaching. These are papers that have gone through the review process and do not include invited proceedings papers. In addition, I would hope that other papers are useful to teachers as well as to researchers. The *Journal* contains articles on contemporary policy issues, such as buffer stocks, and also essays with no mathematics as well as methodological pieces.

Ninety-two articles and notes were published in 1976, 35% of the manuscripts submitted (table 1). This acceptance rate is within the range of experience of the past eight years. The *Journal* does not have a backlog of manuscripts awaiting publication,

Table 1. New Submissions, Manuscripts Accepted, and Acceptance Rate, 1966/67–1975/76

Year	Number of New Submissions[a]	Manuscripts Accepted for Publication	Acceptance Rate (%)
1966–67	195	96	49
1967–68	212	100	47
1968–69	268	105	39
1969–70	249	95	38
1970–71	250	96	38
1971–72	264	96	36
1972–73	263	90	34
1973–74	285	98	34
1974–75	332	91	27
1975–76	263	92	35

[a] Excludes proceedings papers and book reviews.

Table 2. Number of Articles, Notes, and Proceedings Papers Published, 1972–76

	1972	1973	1974	1975	1976
Articles	30	22	25	48	47
Notes	66[a]	68[a]	73[a]	43	45
Proceedings	60	51	58	56	43
Total	156	141	156	147	135

[a] Short articles and communications combined.

and once accepted, papers are promptly published. A typical lag from date of initial submission to date of publication is one year. Manuscript review usually requires about two months, and the publication process requires about four months. The remainder of the lag is related to the time spent by authors on revisions.

In addition to refereed manuscripts, the editor's office handled forty-three proceedings papers (table 2). Our main role is to prepare the manuscripts for the printer. Last year my associates and I read each paper with some care and undertook a more extensive editing of these papers than has been customary. Our intent was to have a somewhat more uniform product than in the past. We expect to continue this practice.

I have invited two papers that will appear in 1977. One will compare organic farms with traditional Corn Belt farms. The objective of this invitation is to stimulate research, thought, and comment on this controversial topic. A second invited paper will review the literature on sequential estimators in econometrics. Most of the empirical econometrics that we publish involve data dredging, and many authors do not appear to understand the statistical implications of their procedures. Thus, the objective of the second invitation is to survey the literature and to increase the understanding of our profession about the implications of modifying models in the light of a set of preliminary results.

The *Journal* can be published only with the assistance and cooperation of a number of persons. Carol Burns, the assistant editor in 1975, resigned to continue a graduate program in English literature. Carol made significant contributions to the current style of the *Journal*. As we wish Carol well in her graduate studies, we welcome Nancy Larrabee as the new assistant editor. The editorial council continues to assist with reviews, to comment on policy as well as to select an outstanding article. In addition to the council members, 388 individuals assisted with reviews; the number of persons reviewing manuscripts has grown even though the number of submissions has declined. I am pleased to recognize the important contribution of the reviewers by publishing their names in table 3.

Report of the *Handbook-Directory* Committee

Energies of the *Handbook-Directory* Committee have been devoted to implementing the publication of the *Handbook-Directory* in November 1976. All deadlines in the schedules have been met and we expect to meet the 1 November 1976 publication date.

The remaining decision to make is the price of the *Handbook-Directory*. Formerly, the price for nonmembers was the same as the annual membership dues; thus, the price of the last *Handbook-Directory* was $15. If we follow this same policy, the price of this issue would be $25 to nonmembers.

Only 100 copies of the last *Handbook-Directory* were sold at $15 to nonmembers. We cannot foresee any precipitous increase in the nonmember demand for this publication. The marginal cost of copies for this purpose would be minimal. We feel that a price of $25 per copy would be prohibitive and recommend the price of $15 to nonmembers. However, we would like to have the thinking of the Board on the two alternatives.

We appreciate the input of the Board and the membership in the development of this publication.

Respectively submitted,
Joseph Ackerman (deceased)
Emanuel Melichar
John Redman
Howard F. Robinson, *chairman*

Report of the *Postwar Literature Review* Committee

All seven of the surveys to be included in volume I are in the hands of the publisher, the University of Minnesota Press. As of 1 August copy editing on the first six surveys had been completed and typesetting was under way on the first three. The table of contents for volume I will look like this:

Survey

I. "Farm Management—Production Economics" by Harald R. Jensen, University of Minnesota (125 pp. of text, 36 pp. of references).

II. "The Analysis of Production Efficiency in Agricultural Marketing—Models, Methods, and Progress" by Ben C. French, University of California, Davis (109 pp. + 98 pp.).

III. "Policy for Commercial Agriculture: A Review of Literature" by G. E. Brandow, Pennsylvania State University (118 pp. + 23 pp.).

IV. "Postwar Policies Relating to Trade in Agricultural Products" by D. Gale Johnson, University of Chicago (35 pp. + 28 pp.).

V. "Agricultural Price Analysis and Outlook: A Review of Literature" by William G. Tomek and Kenneth L. Robinson, Cornell University (102 pp. + 41 pp.).

VI. "Agricultural Finance and Capital Markets—A Review of Literature since World War II" by John R. Brake, Michigan State University, and Emanuel Melichar, Board of Governors of the Federal Reserve System (102 pp. + 32 pp.).

VII. "Technical Change in Agriculture" by Willis Peterson, University of Minnesota, and Yujiro Hayami, Tokyo Metropolitan University (65 pp. + 27 pp.).

All of the surveys that will go into volume II have been received from the authors and have been placed in the hands of the publisher. The table of contents for volume II will look like this:

Introduction by George Judge, University of Illinois.

VIII. "On Estimating the Parameters of Economic Relations: A Review" by George G. Judge, University of Illinois (about 38 pp. + 12 pp.).

Commentary on VIII by Richard J. Foote, Texas Technological University (5 pp. + 2 pp.).

IXA. "On Economic Optimization: A Nontechnical Survey" by Richard H. Day, University of Wisconsin (40 pp. of text, 22 pp. of figures, notes, and references).

IXB. "Optimization Models in Agricultural and Resource Economics" by Richard H. Day and Edward Sparlin, University of Wisconsin (28 pp. + 36 pp.).

IXC. "Agricultural Production Functions from Experimental Data" by Roger C. Woodworth, Tennessee Valley Authority (26 pp. + 14 pp.).

X. "Systems Analysis and Simulations: A Survey of Applications in Agricultural Economics" by S. R. Johnson, University of Missouri, and Gordon C. Rausser, Iowa State University (124 pp. + 68 pp.).

XI. "Developments in Agricultural Economic Data" by M. L. Upchurch, University of Florida (136 pp. + 19 pp.).

The surveys for volume III are further from completion. The status of these surveys is approximately as follows.

XII. "Philosophic Foundations of Agricultural Economic Thought" by Glenn Johnson, Michigan State University (about 75 pp.); Johnson expects to have a first draft ready by 15 September 1976.

XIII. "Organization and Performance of Agricultural Markets" by Peter Helmberger, Gerald R. Campbell, and William D. Dobson, University of Wisconsin

(about 100 pp.); Helmberger and his colleagues expect to have a first draft by the end of summer 1976.

XIV. "Natural Resource Economics" by Emery N. Castle, Oregon State University and Resources for the Future; Maurice M. Kelso, University of Arizona; and Herbert H. Stoevener and Joe B. Stevens, Oregon State University (about 125 pp.); the authors are in the process of preparing the final draft, which is anticipated this fall.

XV. "Economics of Rural Poverty" by D. Lee Bawden, University of Wisconsin and Urban Institute, and W. Keith Bryant, Cornell University (about 100 pp.); a first draft has been promised by the end of 1976.

XVI. "Rural People, Communities, and Regions"; leadership for this set of surveys is being provided by George S. Tolley, University of Chicago.

Introduction by George S. Tolley, University of Chicago (about 12 pp.); will be prepared when three principal surveys are brought to final form.

XVIA. "Economic Bases for Growth" by Clark Edwards, Economic Research Service (about 81 pp. + 27 pp.); Edwards's draft is in the hands of committee reviewers, after which it will be prepared in final draft.

XVIB. "Rural Development: Problems and Prospects" by Dean Jansma, Hays Gamble, Patrick Madden, and Rex Warland, Pennsylvania State University (about 92 pp. + 26 pp.); a draft of this draft is also in the hands of committee reviewers, after which it will be prepared in final draft.

XVIC. "Population Distribution: Migration and Settlement Patterns" by Marion Clawson, Resources for the Future (about 18 pp. + 7 pp.); Clawson's draft is in the hands of committee reviewers, leading to a final draft.

XVII. "Agriculture in Economic Development"; leadership for this group of surveys is being provided by Carl Eicher, Michigan State University, John Mellor, Cornell University, and G. Edward Schuh, Purdue University.

XVIIA. "Africa" by Carl Eicher (about 75 pp.); first draft promised by the end of 1976.

XVIIB. "Asia" by John Mellor (about 75 pp.); first draft promised by the end of 1976.

XVIIC. "Latin America" by G. Edward Schuh (about 75 pp.); first draft promised by the end of 1976.

The title of survey XVI has not been finally decided upon.

The title of the three volume set is to be *A Survey of Agricultural Economics Literature*. The subtitle of volume I will be "Traditional Fields of Agricultural Economics, 1940s to 1970s," edited by Lee R. Martin; that of volume II will be "Quantitative Methods in Agricultural Economics, 1940s to 1970s," edited by George G. Judge, University of Illinois, Richard H. Day, University of Wisconsin, S. R. Johnson, University of Missouri, Gordon C. Rausser, Iowa State University, and Lee R. Martin, University of Minnesota; and that of volume III will be something like "Development, Welfare, and Natural Resources in Agriculture," edited by Lee R. Martin. The title pages will include the information that the set was published for the AAEA by the University of Minnesota Press.

Report of Committee on Publication of *Postwar Literature Review*

The committee considered two methods of publishing the first volume of the *Review*: use the services of a book publisher or have the AAEA act as its own publisher. Invitations to submit proposals were sent to forty-three publishers and ten proposals were received. Invitations to submit bids on printing were sent to twelve printers and ten proposals were received. A detailed analysis of these proposals was made, and the committee met 15 December 1975 to finalize recommendations to the Board. Recommendations about alternative methods of publication were presented to the Board at its December meeting. The Board instructed the committee to negotiate an agreement for publication of volume I with the University of Minnesota Press. An agreement was signed in April 1976, and volume I is scheduled for distribution in early 1977.

The University of Minnesota Press has accepted volume II of the *Review* for publication. The committee recommended that the Board enter into this agreement, which is almost identical to that for volume I.

Emerson M. Babb, *chairman*

Report of the Awards Committee

The central objective of the awards program of the AAEA is to encourage the achievement of excellence for a broad range of professional activities of agricultural economists. The process of selecting award winners might have limited purpose if it did not provide a means for communicating to the total membership standards of professional excellence of achievement by a large proportion of the AAEA. Furthermore, the awards activity provides a means of communicating to other professional groups our standards of achievement not only in terms of rigor and quality but their social relevance in today's world.

If these are among the more fundamental reasons for the existence of the AAEA awards activity, then it follows that (*a*) continuing effort needs to be directed toward goal definition and processes that result in wide acceptance of the purpose and worth of the awards activity; (*b*) there must be wide participation in terms of entries; (*c*) selection processes must be such that truly outstanding winners are selected (those who do not achieve final winner status must have some indication of their relative rank in the awards activity, i.e., to make it worthwhile to "run the race"); and (*d*) there must be a continuing high level of professional performance by the Awards Committee in carrying out the awards activity and feedback to the total membership.

The AAEA is a complex institution. Leadership needs to constantly search out methods that promote real incentives and mechanisms for participation by a broad base of the membership.

There appears to be a substantial belief among smaller departments in smaller universities that they do not have a chance of winning in national competition. Hence, they do not enter. My evidence is that our national leadership is deeply concerned about this type of problem and has made every possible effort to select the Awards Committee from as broad a representation as possible with regard to geographic area, size of department, and degree-granting institutions. If the awards program is to continue to move ahead as the committee thinks it should and is, membership must participate more fully. There are some encouraging signs in this direction.

The M.S. and Ph.D. programs appear to be the most popular in terms of number of entries. Only about one-third to one-half as many entries are submitted for teaching and extension activities as for the above degree program. For the program to offer something to all experience and interest levels in the association, greater participation emphasis in areas other than the M.S. and Ph.D. categories must be achieved.

The committee strongly supports the awards program and urges that it be continued subject to certain modifications. Committee chairmen have carefully evaluated the activities of their representative award area during the past year. Their recommendations have been forwarded to President Bonnen, President-elect Farrell, and the 1977 general chairman of the awards program, Gordon Ball.

I wish to personally express my thanks to each committee member for the dedication and effort they exerted in making the 1976 awards program a meaningful and successful activity for the AAEA.

The AAEA awards winners for 1976 follow.

Distinguished Extension Program

Less than ten years. **Harold D. Guither,** professor, University of Illinois, agricultural policy.

Ten or more years. **Edward Uvacek, Jr.,** associate professor, Texas A&M University, livestock marketing.

Distinguished Undergraduate Teaching

Less than ten years. **William D. Dobson,** associate professor, University of Wisconsin, agricultural marketing.

Ten or more years. **Neil E. Harl,** professor, Iowa State University, resource economics.

The winner will be announced at the annual meetings of the American Society of Agronomy, 28 Nov.–3 Dec. 1976, Houston, Texas.

Report of the Bibliographic-Retrospective Search Committee

A memorandum of understanding between the AAEA and the National Agricultural Library (NAL), Economic Research Service, and Statistical Reporting Service of the U.S. Department of Agriculture was signed in October 1975. The memorandum of understanding confirms the interest and support that each party will contribute in making operational a computerized retrieval system of relevant literature by agricultural economists, other researchers, and administrators.

Last year's recommendations of this committee and the Gardner committee and the subsequent actions by the Board in August 1975 changed the "charge" of the committee. Consequently, this committee met in early December 1975 to consider ways of fulfilling its new responsibilities and to prepare a preliminary report for the Board's consideration at the winter meetings. All members of the committee participated in the meeting, as did Isabel Jenkins, director, American Agricultural Economics Documentation Center (AAEDC).

The two major topics considered at the committee meeting were how to increase participation of the membership in submitting documents to the AAEDC and how to best promote the use of the retrospective search routine by members of the association.

A report of the committee was submitted to the Board at the winter meetings in Dallas. The report is summarized as follows. The committee discussed the Board's approval to publish an author-title list in the *Journal* to publicize documents received by the AAEDC. The annual cost was conservatively estimated to be $1,600. Although such a listing could be a most effective means of promoting the retrospective search system, the committee recommended that publication in the *Journal* be deferred. It was felt that other alternatives for promoting the retrospective search system would be more cost effective. Alternatives suggested included (*a*) a descriptive brochure, (*b*) a letter to the department heads, (*c*) an annual report by the AAEDC, (*d*) a one-page announcement in the *Journal* promoting the AAEDC and the retrospective search system, and (*e*) a demonstration of the system at the next annual meeting.

The report was well received by the Board. Alternatives (*a*) and (*b*) have been effected. In addition, a special newsletter was sent out with the president's newsletter in April, announcing that the "*American Bibliography of Agricultural Economics* Goes On-Line" in late April. Alternatives (*c*), (*d*), and (*e*) were also given strong support by the Board. A report from the AAEDC is to be prepared on an annual basis, the editor of the *Journal* gave support to a page announcement in the *Journal,* and arrangements are underway for a demonstration of the system at the annual meetings.

The information base of the AAEDC was added to the CAIN System maintained by the NAL. There are almost thirty departments of agricultural economics whose university libraries currently have CAIN on-line operations. Thus, members of these departments have direct access to the AAEDC file through terminals in their libraries. Other departments or firms will need to contact one of the two commercial vendors who offer access and training in the use of on-line terminals and search routines.

It will take some effort on the part of each department to assess the system. The committee should follow through on this and provide any information that will be helpful to individual departments and potential users of the system. Perhaps the experiences of some of the earlier users can be documented so that it will be helpful for other potential users.

The committee unanimously decided that it would be helpful to assign a committee member to be the primary contact in each of five geographic areas. The committee member would be responsible for maintaining liaison with the cooperators and department heads in the assigned areas. The geographic assignments were as follows: (*a*) Northeast (Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, Pennsylvania, West Virginia, Delaware, and Maryland)—Ray C. Smith; (*b*) Southeast (Virginia, North Carolina, South Carolina, Georgia, Florida, Kentucky, Tennessee, Arkansas, Alabama, Mississippi, and Louisiana)—J. Edwin Faris; (*c*) Great Plains (North Dakota, South Dakota, Wyoming, Colorado, Montana, Nebraska, Kansas, Oklahoma, Texas, and New Mexico)—Ivan W. Schmedemann; (*d*) Midwest (Ohio, Indiana, Illinois, Michigan, Wisconsin, Minnesota,

Missouri, and Iowa)—John T. Scott; (*e*) Far West (Washington, Oregon, California, Utah, Nevada, Idaho, Arizona, Alaska, and Hawaii)—Marvin G. Julius; (*f*) Canada and other countries—Isabel Jenkins; and (*g*) ERS and other government agencies—Allan S. Johnson and Richard C. McArdle.

The committee suggests that it would be appropriate to have a Canadian on the committee. Also, future appointments to the committee might be partly based on the above listed geographical areas.

The committee members have not been very active this year in terms of their geographical responsibilities. It was necessary to have the retrospective search routine fully operational before making individual contacts. Too often a computerized system has not lived up to its expectations in terms of the time it was operational. The committee members will follow up on the letter recently sent to all department heads and cooperators.

Another area that was given consideration by the committee during the year was possible cooperation with other organizations having literature-retrieval systems. A subcommittee investigated several systems: AGRIS, sponsored by the Food and Agricultural Organization; Smithsonian Science Information Exchange (SSIE), originally sponsored by the Smithsonian Institute; and the Psychological Abstract File, sponsored by the American Psychological Association. Basically, each is oriented toward other areas than agricultural economics. AGRIS has a cooperative agreement with NAL. However, NAL has been unable, as of this time, to get any information off the AGRIS tapes. SSIE obtains their information from NAL but is biologically oriented. The subcommittee feels that now is not the time to spend much effort in pushing cooperation with others concerning information-retrieval systems. The system being developed by our profession is far superior for the needs of agricultural economists than the other systems. It is more complete, and the cost of searching the files would undoubtedly be considerably less than using a combined file. Perhaps at a later date cooperation with AGRIS should be reconsidered. However, we would be giving much more than we would be receiving.

Several possibilities for having the AAEDC files published have presented themselves during the year. The Oryx Press, current publisher of the *Bibliography of Agriculture*, is one possibility. These possibilities should be further investigated next year as they may provide a means of obtaining a hard copy of documents submitted to the AAEDC at no cost to the AAEA.

The committee briefly discussed the possibility of microfiche as an alternative to publishing the *ABAE*. The Committee felt that it was not a very good alternative and would not really help promote the use of the retrospective-search system.

J. Edwin Faris

Report of Agricultural Statistics Committee of Federal Statistics Users Conference

The FSUC Agricultural Statistics Committee was reactivated in late 1975. A new committee was formed with a representation from many areas of agriculture that utilize federal statistics. A meeting of the newly formed committee was held in Washington, D.C., on 11 November 1975 for the primary purpose of establishing objectives and determining the general direction that the committee should follow.

The objectives of the Agricultural Statistics Committee are: (*a*) to aid in maintaining and improving quality and timeliness of federal statistics related to agriculture, (*b*) to improve communications between users and producers of federal statistics, (*c*) to increase awareness of both short- and long-term changes and additions to federal statistics necessary to meet requirements of a changing agriculture, (*d*) to convey to producers of agricultural statistics the requirements of statistical users and to prioritize those requirements, (*e*) to provide information and make appropriate recommendations to FSUC staff and Board of Trustees concerning matters of consequence related to agricultural statistics, (*f*) to assist FSUC staff in presenting a statement relative to federal budget requests for statistical programs to respective subcommittees on appropriations, and (*g*) to maintain liaison with other committees that have an interest in maintaining and improving the quality and timeliness of federal statistics related to agriculture.

The methods of operation were established. The meeting schedule is one meeting each year to coincide with the FSUC annual meeting, and special meetings may be called as required by the committee. The FSUC staff will assist and participate in coordinating the activities of the committee. Committee membership shall be limited to members of FSUC member organizations and to those interested and involved in agricultural statistics. Subcommittees may be appointed by the chairman, as required.

The intention of the committee is to provide a positive and progressive influence in the area of agricultural statistics. This intent was expressed at a February 1976 meeting in which the committee met in Washington, D.C., with key producers and users of federal statistics. The objectives of the committee were discussed, and the key producers of federal statistics outlined their programs and priorities.

The committee's offer to assist in the evaluation of federal data revisions, additions, and deletions was well received. This offer is being carried out with suggestions offered as the need arises.

There are a number of current activities in the federal government focusing attention upon agricultural statistics such as congressional hearings on the definition of "a farm" and House and Senate

bills on the transfer of the *Census of Agriculture* from the Department of Commerce to the Department of Agriculture. These are being monitored by FSUC and the committee, and appropriate action will be taken as indicated. Plans are being made for committee participation in the proposed Agricultural and Rural Data Workshop to be sponsored by ERS, SRS, AMS, and the AAEA Economics Statistics Committee.

Suggestions for furthering the objectives of this committee will be appreciated.

Norman M. Coats, *chairman*

Report of the Economic Statistics Committee

The most significant accomplishment of the committee was a review and evaluation of food price data by a joint task force of the AAEA Economic Statistics Committee and the Economic Research Service, U.S. Department of Agriculture.

The task force studied the statistical series published by the ERS on farm retail price spreads for food and the annual food marketing bill. A 40-page publication, "Review and Evaluation of Price-Spread Data for Foods," was published in January 1976 and distributed widely. The task force was chaired by George Brandow, Pennsylvania State University. Other members were D. W. Barrowman, Statistical Reporting Service, USDA; P. A. Baumgart, Safeway Stores; J. W. Hammond, University of Minnesota; G. L. Nelson, Purdue University; R. E. Ward, University of Florida; and G. E. Worden, ERS, USDA.

A member of the Economic Statistics Committee, Norman Coats of Ralston Purina, has been appointed chairman of the Federal Statistics Users Conference's Agricultural Statistics Committee. This committee is planning an active program. Thus, good coordination of the efforts of the two groups is provided.

The committee has received regular reports from Louis Upchurch, the AAEA's representative of the Census Advisory Committee. In addition, there has been informal coordination with the data activities of the Office of Technological Assessment. Without the cooperation of the USDA agencies that collect and publish data, the Statistical Reporting Service, the Agricultural Marketing Service, and the Economic Research Service, the task of the committee would have been more difficult and the results fewer.

At the 1975 meeting of the AAEA, an excellent series of papers was presented on rural, social, and economic statistics under the leadership of Keith Bryant. These papers, in addition to Jim Bonnen's excellent presidential address, have led to significant ferment in the thinking about data by AAEA members.

The major activity planned for the coming AAEA year is a two-and-a-half day workshop in Washington, D.C., in March or April 1977. The proposed title is "Agricultural and Rural Data Workshop: Improvement of Concept in Operation." The workshop will be sponsored and funded by the ERS, SRS, AMS, and the committee. The plans and procedures for the workshop have been reviewed with the Federal Statistics Users Conference and the Office of Technology Assessment. These organizations will be invited to send people to the workshop. Invitations will also be sent to a wide range of data users in industry, universities, and government agencies. The purpose of the workshop is to bring together data producers and users to develop suggestions and recommendations for use by the responsible agencies to improve data and data series. The workshop will focus on conceptual problems, but operational and data flow issues will also be covered.

The workshop will include concurrent half-day sessions on specific topics. At each session a paper will be presented by a team made up of data producers and users. The lead member of each team will be a member of the unit producing the data or series under discussion. Following is a listing of the topics for the half-day sessions and the lead member of each team: (*a*) price reporting—types and levels of transaction (lead member: James Bonnen, Michigan State University); (*b*) price reporting—coverage priorities, value to users, and alternative reports (lead member: James Bonnen, Michigan State University); (*c*) capacity of the food and fiber system (lead member: Earl Swanson, University of Illinois); (*d*) data for indicators of economic well-being of people engaged in farming (lead member: Luther Tweeten, Oklahoma State University); and (*e*) concepts and measures of nonmetropolitan employment, unemployment, and related manpower information (lead member to be selected).

Report of the AAEA Representative on the Advisory Committee for the *Census of Agriculture*

The Advisory Committee met in October 1975 and June 1976. On both occasions the main topic of discussion was the problems and progress of the 1974 *Census of Agriculture*. An early decision by the Bureau of Census to not take a 1974 census and a later mandate from Congress to do so caused delay and confusion in planning and carrying out the enumeration. This contributed to a low rate of response in some areas and to other inaccuracies. Reenumeration was necessary in some areas with unusual efforts for follow-up on nonrespondents. The result was further delay and some sharp resistance by respondents. Some of the more serious problems have been corrected or corrected for, and the computers are running again on a delayed schedule. We will in time get a 1974 *Census of Agriculture*.

Another factor adding to the confusion was the decision by the Bureau (concurred in by the Advisory Committee and U.S. Department of Agriculture) to change the definition of a farm to include only those places with $1,000 or more of sales. The Bureau did enumerate on both the old and the new definitions and will provide "bridge" data to make the 1974 data comparable with earlier censuses.

The ineptness with which the Bureau has handled the 1974 *Census of Agriculture* and the ire of respondents prompted bills being introduced in both the House and Senate that would transfer responsibility for all agricultural data from the Department of Commerce to the USDA (H.R.12397). Hearings were held by the Subcommittee on Census and Population, House Post Office, and Civil Service Committee on 22 and 23 June 1976. I am not aware of any action taken on the bill. An identical bill introduced in the Senate has had no action that I know of. Changing the agency responsible for the *Census of Agriculture* does not necessarily remove some of its more serious problems.

There has been an evident need for a long time to achieve better coordination between the *Census of Agriculture* and other economic censuses. As one step to fulfilling this need, Congress acted to change the dates of the *Census of Agriculture*, authorizing a *Census of Agriculture* in 1978, another in 1982, and subsequent ones in the "2" and "7" years of each decade. This would correspond to the dates of enumeration of other economic censuses. Much more must be done to achieve the coordination needed, but this is one step in the right direction.

M. L. Upchurch

Report of the National Professional Employment Registries Committee

In President Bonnen's letter of appointment of 16 December 1976 he asked the National Professional Employment Registries Committee "to take primary responsibility for (*a*) explaining and promoting the computerized employment registry to other professional groups and potential users and (*b*) to develop a stable financial and organizational basis for continuing the AAEA employment registry when the Labor Department financing ends September 29, 1976." He further wrote that "our overall objective is to establish a solid financial base under our own operation by developing a system of financing and by combining with some configuration of other professional groups" and also said, "I would hope that you would design a feasible run plan for stabilizing our employment registry for the next two years and a long-run road map of the possible and preferred options as we evolve into something of greater scale and/or a different nature."

In an April committee meeting, some aspects of the committee's task were identified and discussed, including the role of the employment registry; advantages of a university base of operation versus a nonuniversity location; budget—survival, short run, and long run; advantages of a national registry including all professionals as opposed to an employment registry including largely those seeking employment; the possibility of producing the *Directory-Handbook* from a national registry data bank; and advantages and disadvantages of combining with other agriculturally related professional associations versus nonagriculturally related groups.

Loys Mather, chairman, Employment Services Committee, was extremely helpful in providing information essential to the committee, including the contact by the U.S. Department of Labor (USDL) requesting an assessment of the possibility of adapting the AAEA system for use by the USDL in recruiting personnel for their Comprehensive Employment and Education Act (CETA) program.

A minimum base budget was estimated assuming no USDL funding and no collaboration with other professional organizations. Circumstances mandated consideration of a survival alternative. This minimum budget was viewed as the base against which to compare other alternatives. The minimum cost of continuing the employment registry is estimated to be about $20,000 per year, assuming location on a university campus with provision of space being the only expected subsidy from the host university. This budget would permit some promotional activity but probably no travel funds for explanation-demonstration by system personnel. In a short-run period of three years, we estimate the cost of a viable, continuing operation to be $20,000–$25,000 per year.

The most feasible possibility for generating $20,000 is user charges, at least in the short run. One possibility that should be explored is the following: (*a*) fifty agricultural economics departments at an average of $250—$12,500; (*b*) U.S. Department of Agriculture (Economic Research Service, Agricultural Marketing Service, Statistical Reporting Service, and Foreign Agriculture Service)—$2,000; (*c*) other organizations (U.S. Agency for International Development, Federal Reserve Banks, and industry)—$4,000; and (*d*) registration fees for each employee registrant on the system (500 employees at $5 each)—$2,500, a grand total of $21,000.

A rough estimate of the reduction in cost to the AAEA by operating the registry in conjunction with another association is, at the maximum, 25%. This means that even in a joint venture under the minimum cost budget configuration it would still cost the AAEA a minimum of $15,000 per year to operate the registry. On the basis of available information we see a very high proportion of variable costs.

There is great long-run potential from possible collaboration with agriculturally related profes-

sional associations. One consideration ties back to a belief that the system can be operated at lower cost on a university campus. We expect the willingness of deans of agriculture to support hosting of the system to be greater if it involves agriculturally related professions.

We recommend exploring the idea of a joint or cooperative registry (probably covering U.S. and Canadian professionals) that would include all individuals in the covered professions. A computerized data base for agriculturally related professions could serve many purposes—to analyze professional profiles, to project manpower needs in a discipline or subdiscipline, to estimate manpower availability, to advise prospective graduate students on manpower needs, and to do objective educational planning. Funds might be obtained to cover at least a portion of the cost of setting up and operating a registry for several professions in order to provide the data for educational planning studies. To the best of our knowledge this has not been done, and at least part of the funding might be forthcoming for a demonstration project.

The committee members agreed on the following. (*a*) The registry should include all professionals, not just those seeking employment, which is necessary if it is to be used for educational planning purposes and as a direct aid for producing *Directory-Handbooks*. (*b*) The AAEA registry should emphasize U.S. and Canadian professionals. Others would be welcome, and the computer should be programmed to maintain separate identity of other groups. (*c*) The name of the registry should be changed, perhaps to Registry for Agricultural Economists.

The following agriculturally related associations were selected for contact by a member of the committee to explore possible interest in collaborating with the AAEA on a computerized professional registry: American Society of Agricultural Engineers, American Forestry Association, American Society of Horticultural Science, Entomological Society of America, American Institute of Biological Sciences, American Society of Animal Science, American Society of Agronomy, and American Phytopathological Society.

Committee members felt it important to explore within the AAEA some of the ideas outlined above regarding the future of the registry. Discussions have already taken place or are planned with the Great Plains department chairmen, Southern Region department chairmen, North Central department chairmen, Northeast department chairmen, Canadian Agricultural Economics Association, U.S. Department of Agriculture, AAEA Industry-Advisory Committee, and the Farm Foundation.

In June the committee reviewed a proposal for a demonstration project to operate and assess a computer-based employment system for agricultural economists and extend operations to CETA prime sponsors. The draft proposal represented an amendment to the then current USDL/AAEA contract, proposing a side-by-side operation of the AAEA and CETA registries in Chicago and incorporating twelve-month funding for the CETA component beginning 1 July 1976 and a nine-month extension of support for the AAEA contract to continue operation through June 1977. The committee recommended to President Bonnen and the AAEA Board that the proposal be submitted to the USDL with minor modifications.

This report is intended to be an overview of progress to date along with "tentative conclusions" pertaining to related issues. We are still in the information gathering and idea testing stage. We plan to formulate recommendations for consideration by the Board and solicit suggestions from any AAEA member.

Report of the Professional Activities Committee

Following the winter meeting of the Board of Directors, President Bonnen reconstituted the Professional Activities Committee, charging it with the responsibility of recommending immediate rule changes, studying the balance between the AAEA's offering of collective and selective goods and examining alternative future configurations for the AAEA. The committee has some overlap with other committees, so it must perform a coordinating function while developing its own plan of work. In the single meeting held to date, several major topics emerged as important themes for future deliberation.

Among the most important is recognition of the large and growing number of subspecialties within the AAEA. Many of these have only tenuous connections with agricultural economics as it has been traditionally formulated. The AAEA faces a fundamental set of choices in developing strong relationships among professionals in the specialties. The information system sponsored by the AAEA may change as the roles of specialties and special interest groups change. A change may yield a set of information disseminating mechanisms quite different from the present *Journal*. Reconstructing the system may yield a number of kinds of publications as well as a central text file with an automated retrieval system that could be used on a fee-for-service basis.

The AAEA is only one of several associations of agricultural economists in the United States today. The relationship between the american association and the regional associations has varied in intensity during the past two decades. In this era of rapid communications and replication of research efforts, all associations will find it advantageous to coordinate professional programs to take advantage of economies of scale and reduce the burden of travel imposed by many associations having separate, uncoordinated meetings. The committee will explore

various possibilities for interassociation cooperation and membership.

The committee recognizes the responsibility of the professional association to aid in maintaining the skills of its members. At present, the AAEA does this only through the annual meeting and the *Journal.* In future meetings, the committee will discuss alternative modes of retraining, updating, and improving skills. These modes will vary in design to suit a wide variety of members working in any of a number of professional capacities.

The AAEA has grown in size and complexity. Both types of growth have required increased time commitments from elected officers and Board members alike. It is rapidly becoming unreasonable for the AAEA to expect universities, government agencies, and private firms to subsidize the official activities of the professional group. The AAEA, its committees, and its Board may wish to consider establishing permanent offices and employing a salaried staff.

In addition to these general themes, the committee makes the following specific recommendations to the Board for its immediate consideration. These recommendations are designed primarily to increase the number of selective goods offered to the AAEA members. (*a*) The AAEA should, in general, limit committee membership to AAEA members. (*b*) Higher registration fees should be charged nonmembers registering to attend the annual meeting. (*c*) The privilege of presenting contributed papers at the annual meeting should, in general, be limited to AAEA members. (*d*) The privilege of presenting and discussing invited papers at the annual meetings should be reserved for AAEA members except in special cases in which the condition is waived by the president. (*e*) Nonmembers should be assessed a page charge of $75 per page on articles accepted for publication in the *Journal.* (*f*) The AAEA president should establish a committee to investigate the possibility of developing a fee structure to be imposed on users of the national registry. (*g*) An appropriate reviewing fee should accompany all refereed papers submitted to the *Journal*'s editorial office.

Report of the Membership Committee

The activities of the Membership Committee during the past year have been divided into efforts directly related to recruiting members for 1976 and efforts related to substantially restructuring the Membership Committee and its approach to membership development in order to enhance future effectiveness.

With regards to direct recruiting activities for the present year, the approach taken was similar to that for the previous two years but somewhat more intensive. Letters were sent to chairmen of economics and agricultural economics departments and heads of agencies asking them to designate recruitment representatives for their institution. When these representatives were designated, they were sent follow-up mailings to assist them in their task and were asked to promote membership in AAEA and in the regional associations. Appropriate materials were provided to them for their task. Special mailings were sent to individual member prospects in the 1890 institutions and in industry. Mailings to these individuals were based on lists of prospective members prepared by David Chen, chairman of the task force for 1890 institutions, and Ed Williams, chairman of the industry task force. Regional task force chairmen for the land grant institutions were involved and provided suggestions, but we were not sufficiently prepared nor appropriately organized at the time for the regional chairmen to be most effective. A final follow-up letter went to all institutional membership representatives in March indicating a "last-chance" opportunity for payment of dues in time to vote and be listed in the new directory.

The activities of the committee were supported by substantial activity on the part of President Bonnen. He met with a number of regional groups to enlist their support and the support of department chairmen in the membership effort.

Bonnen and several members of the committee have been actively involved this year in restructuring the entire approach to membership recruitment and development. Present and prospective members of AAEA are a heterogenous group of applied economists having some common interests and needs but who also identify with subgroups having more specialized and unique interests and needs. There is a growing awareness of the need to approach these subgroups as different target groups for recruitment and for the design of selective goods and services by the AAEA. Accordingly, we now have in place and ready to function a committee whose members are, in effect, chairmen of task forces oriented toward reaching specific membership target groups. The target groups for whom task forces have been organized and chairmen identified are northeastern land grant institutions, southern land grant institutions, midwestern land grant institutions, western land grant institutions, 1890 land grant and related institutions, non-land grant colleges and universities, industries (including cooperatives), foundations and nonprofit institutions, and Canadian institutions. I propose that a task force chairman be added to cover the Economic Research Service and other federal agencies including the Congress.

A meeting of the entire committee is scheduled for 16 August 1976 at Penn State University. The lengthy agenda includes development of specific plans and operational procedure for the committee, specific strategies and plans for reaching the various target groups, the purpose and plan for the institutional membership program, joint payment of

dues to AAEA, CAEA, and the regional associations, improvement of membership statistics, and a number of miscellaneous items. I also hope that we can set some realistic yet challenging membership goals for next year.

I offer the following recommendations. (*a*) The function of the committee should be defined as having emphasis on membership development, that is, on the identification and recruitment of new members. The billing of existing individual members and of institutional members should be handled by the secretary-treasurer. Presently, there is some confusion about who has responsibility for billing institutional members. (*b*) We should work toward computerization of membership lists and accounting systems for the AAEA. (*c*) If the membership list can be computerized, we should publish the *Directory-Handbook* more frequently, possibly every two years with the printing cost borne by advertisers or by institutional members. The directory-type data for individuals that would be available on a computerized membership list would be valuable information for use by the committee in identifying present membership and target groups for further membership efforts. The same data would also be valuable for developing selected mailing lists for delivery of selective goods and services by the AAEA. Such a list and the associated information on individuals would also be useful to the president and the Board for the purpose of making committee appointments, etc.

The committee will likely have further recommendations to make to the Board following the 16 August meeting. These recommendations will be submitted to the Board prior to its fall meeting.

Again, the Committee would like to express its appreciation for the personal interest and support of President Bonnen and for the untiring efforts of our secretary-treasurer, John Redman.

John E. Lee, Jr., *chairman*

Report of the Extension Affairs Committee

The Extension Affairs Committee was appointed in December 1975. Since that date the chairman and members of the committee have conducted an active correspondence. Our first assignment from President Bonnen was to advise him regarding the desirability of a session on extension affairs at the annual meetings in August 1976. A caucus of the committee was conducted and recommendations forwarded to President Bonnen.

The major charge given to the committee was to identify, design, and implement new "selective goods" that would be of value to extension members. An active correspondence among committee members has sought to identify such goods.

Among the possible courses of action being debated currently is a survey of extension economists concerning their views of the AAEA as it relates to the needs of extension professionals. This survey would attempt to specifically identify the services currently offered by the AAEA through the organization, the *Journal*, and the annual meetings that are of value to extension members. Second, we would solicit positive suggestions for improvement in services offered to the extension economist.

Other ideas that have been suggested by members of the committee include a special issue or supplement to the *Journal* devoted to extension affairs, professional meeting sessions concurrent with the annual meetings or entirely separate, and a workshop or workshops on issues facing extension sponsored by the AAEA.

It is hoped that several members of the committee will be able to meet at the annual meetings in August to discuss courses of action for the coming year.

Robert L. Christensen, *chairman*

Report of the Industry Advisory Committee

The AAEA has the tremendous value of establishing an environment in which all groups of agricultural economists can provide their inputs to the profession. During the past year the Industry Advisory Committee has worked at providing this input via the annual meetings. We are sponsoring an industry banquet and an invited papers session at the 1976 annual meetings.

The committee would like to offer more ideas with the following recommendations to the Board of Directors. (*a*) An "open letter" should be sent to all AAEA members to express concern with the current employability of agricultural economists. (*b*) The committee should continue to sponsor a banquet and invited papers session at the annual meetings. (*c*) Industry agricultural economists should be encouraged to respond formally to articles in the *Journal*. Industry agricultural economists would be much more able to give short responses to published articles as opposed to being asked to write lengthy formal research articles for the *Journal*. (*d*) The industry representative on the Board of Directors should be a member of the Industry Advisory Committee. (*e*) A section of the agenda of each AAEA business meeting should be devoted to receiving input from the various "groups" within the AAEA. (*f*) The AAEA should work towards providing a forum through which the profession can respond to current topics in policy or market. (*g*) The Board should consider having fewer contributed papers sections at the annual meetings with a simultaneous attempt to improve the professionalism of these sessions. (*h*) The AAEA should develop and mail to all members a quarterly calendar of relevant workshops and seminars being offered by universities, associations, consulting groups, etc. (*i*) Sustaining membership dues should be kept at $100.00 per year, but all

sustaining members should be invited to take out an advertisement in the *Handbook-Directory*. The cost of such an advertisement could be $100.00 per year. Therefore, sustaining members taking an advertisement in the *Directory* would pay $200.00 per year to the AAEA.

Report of the International Committee

Work of the committee in 1975–76 was concentrated on the five recommendations from the 1973–74 *Review of International Training* on which the Executive Board had asked the committee to follow up. Some attention also has been given to an additional problem.

Action on 1973–74 Recommendations

Recommendation #1 is that a meeting of appropriate officials be convened to examine issues of training needs. Since an interagency committee was being formed by the USDA, AID, and NASULGC to consider arrangements for international training, we considered how we could relate ourselves to this committee. We therefore initiated an exchange of correspondence between President Bonnen and Don Paarlberg (cochairman with Elmer Kiekl of the International Science and Education Committee). We asked Peter Timmer to extend his liaison role if a follow-up opportunity presented itself. Don Paarlberg was provided with a copy of the committee's "1973/74 Report on International Training in Agricultural Economic Development." Our committee has had no further communication from the USDA/AID/NASULGC committee. The International Committee should give further consideration to recommendation #1 in the coming year.

Recommendation #2 is to evaluate benefits that have been derived from international travel grants. We did not see any way we could constructively assess this question at reasonable cost, so no action was taken.

Recommendation #3 is with respect to sessions at the 1976 annual meetings. Our committee organized an invited papers session on "Small Farmers Resources in Rural Development: Current Research and Application" and an international dinner.

Recommendation #4 relates to improvement of placement and admissions policies and practices. Our committee has communicated with the American Association of Collegiate Registrars and Admissions Offices, the National Association for Foreign Student Affairs, and the Economics Institute (University of Colorado) and has studied materials from these bodies pertaining to evaluations of foreign students and foreign institutions. We considered the desirability of asking the AAEA to name a liaison person with one or more of these agencies but do not think it advisable at this juncture. At a 17 August meeting, the committee will consider framing a note on the services available from these groups for insertion in the *Journal*.

Recommendation #5 related to a sample survey of foreign agricultural economists regarding their U.S. graduate training. James Houck has outlined a possible study for consideration at the 17 August meeting of the committee. Our recommendations will be submitted subsequently to the AAEA president or to the next International Committee chairman, as is appropriate.

Other Activities of the International Committee

Committee member Peter Timmer, the AAEA liaison with RTN/ADC, has summarized his activities in a letter of 17 June to President Bonnen.

The committee is concerned with the deteriorating support for international agricultural economics research at U.S. universities and research centers. This diminished support, and thereby diminished interest, has meant a cutback in the number of personnel engaged in international research, teaching, and training, and such a cutback most drastically affects the hiring and retention of young professionals just beginning their teaching and research careers.

The impact has been that many young, able, well-trained economists with strong interests and significant field experience in the problems of less developed countries are no longer able to find research and/or teaching positions in those universities that historically have maintained large enough international programs to attract a critical mass of experienced scholars committed to understanding and solving those problems. Consequently, many of these young economists are now teaching at universities, colleges, and junior colleges that have no active programs in international economics and no other professionals interested in the problems. In short, these young economists find themselves isolated outside the (now diminished) mainstream of research interaction that is characteristic of the larger and identifiable programs.

The problem is how to avoid losing these young and committed professionals to the field of international agriculture. The committee feels that some effort should be made to determine the overall seriousness of the problem and to recommend desirable steps to alleviate it. The problem will be further considered at the 17 August meeting.

Report of the Resident Instruction Committee

Much of the emphasis of the committee this past year pertained to developing a program for the resident instruction session and to assisting the undergraduate officers with their program for the annual meeting. The format of the resident instruction session for the summer meeting includes two invited papers, with discussants, and time for group interaction. The committee believes that these formal comments, focusing on instructional needs in a changing world, should provide a good "springboard" for continued group discussion.

The undergraduates are allowed to submit papers to either the "regular" contributed papers section or to a "special" undergraduate contributed papers section. The papers submitted to the regular section are being treated in the same manner as for professionals. However, the papers submitted to the "special" section are being screened and numerically evaluated by selected numbers of the committee. The oral presentations for the "special" group will also be evaluated at the annual meeting. This then allows for special recognition (a certificate prepared by the committee) to be given to undergraduates preparing and presenting outstanding papers.

Our committee believes that the student contributed paper session has a definite professional posture and one that will be attractive to undergraduates. Of course, the extent of interest and the degree of success is unknown but will be evaluated.

The committee has no recommendations for changes. It wants to first gain experience with this format.

Report of the Committee to Review the AAEA Constitution and Bylaws

The committee was appointed in October 1975 to review the governing documents of the AAEA. The committee made no recommendations for change in the articles of incorporation and constitution. Several recommendations were made in the final committee report to the executive Board at the August 1976 meetings for amendment to the bylaws. Amendments to that document require a majority vote of the Executive Board.

In addition to its own review of the AAEA documents and organizational structure, the committee also obtained suggestions from the Executive Board at the December 1975 meetings in Dallas, the editor of the *Journal,* the committee to review the fellows selection process, and the present and past chairmen of the awards committee.

The committee's final recommendations for amendment to the bylaws are of several types: (*a*) actions of the Executive Board, since its creation in 1968, that should by virtue of their policy nature be included in the bylaws; (*b*) policies and procedures of some standing committees that involve the membership to a substantial degree, and (*c*) suggestions from the committee and other interested individuals.

The specific recommendations include several editorial changes as well as the following substantive suggestions for amendment: elimination of the classification of "corresponding" members; redesignation of "sustaining" membership category to "institutional"; permission for a duly designated representative of a department to countersign applications for junior membership; reflection of the scale of dues approved by the membership in August 1975; nomination procedure for fellows modified including the addition of a requirement that a nominee be "a current member of the Association in good standing or have been a member thereof for at least ten years"; the maximum number of newly selected fellows increased from three to four annually; the fellows election committee procedures modified to include an annually revolving chairmanship selected from among members of the committee and a sixth committee member as the designated representative of the Executive Board; revision of procedures for the awards program based upon criteria and procedures in use; a provision that the AAEA president, in consultation with the Executive Board, is responsible for preparing the program for the annual meeting; revision of procedures for selection and evaluation of positions filled by appointment in the AAEA; codification of changes approved earlier on election procedures; increase in authority of the secretary-treasurer to borrow funds on behalf of the AAEA without further Executive Board authorization from $10,000 to $25,000; change in the list of standing committees to reflect current committee status as approved by the membership; change made to show the name "Resident Instruction Committee" rather than "Student Affairs Committee"; creation of a new article in the *Journal* with sections on the role of Executive Board, the role of the editor, and the role of the editorial council.

The committee also makes the following recommendations to the Executive Board. (*a*) The importance of precision in amending the bylaws be emphasized. In particular, problems may be created when the responsibility for amendment drafting is left to the secretary on an *ex post* basis. The committee suggested that, as a matter of practice, the minutes reflect the precise wording of any amendment of a governing document initiated or given final approval, as the case may be. (*b*) The governing documents, and particularly the bylaws, be

kept up to date with amendments added as enacted and that newly elected members to the Executive Board be given up-to-date copies of all three governing documents. (*c*) Whenever actions are taken relative to policy matters, the Executive Board consider whether such actions should be memorialized by inclusion in the governing documents. (*d*) Minutes of the AAEA, both with respect to meetings of the membership and of the Executive Board, be relatively complete and reflect fully the AAEA's actions and activities.

John E. Kadlec
John C. Redman
Neil E. Harl, *chairman*

Report of the Visiting Lecturer Committee

For a number of years the AAEA sponsored a Visiting Lecturer Program. The program has been successfully used by some schools, but it has not been as widely used as had been expected. This year, President Bonnen asked the Visiting Lecturer Committee to expand its function by considering other activities that might be feasible for the AAEA to undertake in order to improve services and communications to members outside the land grant system.

In accordance with this charge, the committee devised a questionnaire designed to elicit ideas about the kinds of assistance the AAEA might help provide faculty and students located in these institutions. Conclusions from this survey are as follows. (*a*) Respondents indicated a strong preference for assistance with instructional compared to either research or extension programs. (*b*) In providing assistance with instructional programs there was a stronger preference for workshops than for visiting lecturers or consultants. (*c*) Several ways were suggested for increasing communication between members of these institutions and other professionals. The alternative receiving the strongest preference was for special sessions at the annual meeting of the AAEA for discussing programs of these institutions.

Given the preferences of the responders to our questionnaire and assuming the AAEA desires to improve services and communications with members in these institutions, the committee requests permission from the Board to work with representatives of those institutions in planning a session, for next year's summer meetings, designed to meet their specific needs.

Minutes

Minutes of the Executive Board Meeting, Dallas

The meeting was called to order by President Bonnen at 8:00 a.m., 27 December 1975.

Present: Voting members:
Bonnen, Farrell, Nielson, Mangum, Stanton, Barr, Heitz, Raup, Robinson
Members ex officio:
Redman, Tomek
Guests:
Ackerman, Rasmussen, Holt, Lee, Harl

1. Bonnen reviewed the agenda for the meeting.
2. Stanton moved the approval of minutes of the summer meeting of the Executive Board at Columbus. Seconded. Passed.
3. Redman gave a preliminary report on the membership, financial condition, and investments of the AAEA, pointing out that all *ABAE* refund checks ($4,149) had been mailed, cash flow problem had been solved, *Handbook-Directory* forms were mailed, prepaid dues for 1976 were lagging, etc.
4. Tomek reported as editor of the *Journal,* discussing problems associated with size, scheduling, pricing of reprints, advertising, pricing of old issues, etc. It was the consensus of the Board that the editor and the secretary-treasurer develop the best alternative bid for *Journal* printing for consideration at the next Board meeting.
5. Stanton reported for the Finance Committee indicating that the committee will meet as soon as possible after the end-of-year data become available.
6. Barr moved that all single copy issues of the *Journal* be set at $10.00 each, effective with February 1976 issue. This applies also to all issues in inventory. Seconded. Passed.
7. Farrell reported for the Bibliographic-Retrospective Search Committee. After discussing the suggested ways to publicize the retrospective search system, Stanton moved that the committee's suggestion to defer the publication of author-title lists in the *Journal* be accepted and that all five alternative suggestions be implemented as soon as possible, namely, (*a*) develop a brochure describing the system and include a copy in bulk mailing to members; (*b*) send a letter to all department heads, discussing the system, the hardware, and financial aspects of its use; (*c*) arrange the annual report of the American Agricultural Economics Documentation Center to give data on use of the system, with entries by author and institution, and other operating information; (*d*) insert a one-page announcement in each issue of the *Journal;* and (*e*) give a live demonstration of the system at the meeting at Pennsylvania State University. Seconded. Passed.
8. Ackerman reported on the National Employment Registry for Agricultural Economists, indicating that the supplemental grant from the U.S. Department of Labor would expire 29 September 1976. President Bonnen announced the appointment of the Committee on National Professional Employment Registries to explain and promote the computerized employment registry to other professional groups and potential users and to develop a stable financial and organizational basis for continuation of the registry.
9. Rasmussen reported on possible approaches to a historical study of the agricultural economics profession and the AAEA. Bonnen and Farrell will further evaluate activities that might be appropriate for the AAEA.
10. Robinson reported that work on the *Handbook-Directory* was proceeding on schedule. The *Handbook-Directory* Committee will recommend a price for the issue at the August meeting of the Board.
11. Barr presented a summary of the final report on the 1975 meeting at Columbus, indicating that the budget was balanced but included a substantial subsidy by Ohio State University in the amount of at least $3,500. A copy of the detailed report was sent to the secretary-treasurer and to Pennsylvania State University. Nielson moved acceptance of the report with a special thanks to Ohio State University for hosting the meeting. Seconded. Passed.
12. Holt reported on preparations for the 1976 meeting at Pennsylvania State University. He indicated that meals can be had as a package or individually at the cafeteria. The administrative fee of $4,000 covers handling of registration, mailings, conference services, etc. Air commuter service would be provided from Pittsburgh to State College, etc. Stanton wanted to be recorded that he believed the differential in registration fee for single versus families is too small. After discussion, Stanton moved that the registration fee be $15 for single and $20 for a family. Seconded. Passed.
13. Barr moved that the 1976 meeting be held jointly with the Northeastern Agricultural Economics Council. Seconded. Passed.
14. Farrell discussed the program being planned for the Atlantic City meeting in September 1976, pointing out the need for greater coordination with the August 1976 meeting.
15. The Board discussed the need to shift the time of the Board meeting usually held in December at the same time as the Allied Social Science Associations meetings. Consensus was that, when the ASSA meets in early fall, the AAEA

Board meeting should be in the winter, preferably during the first week of January.

16. Farrell reported briefly on the plans for the 1977 meeting in San Diego.

17. Bonnen sought the Board's reaction to appointment of two ad hoc committees, an Alternative Publications Committee to look at objectives, format, and cost of publications other than the *Journal* and a committee to evaluate annual meeting programs. The consensus was one of support. Bonnen announced the discharge of several ad hoc committees, including the Committee to Review AAEA Affiliation with CAST and also the Bibliographic-Retrospective Search Review Committee. He announced also the appointment of a Committee to Review the Constitution and Bylaws and a Committee to Review the Fellows Selection Process, in addition to the Committee on National Professional Employment Registries.

18. Stanton moved the discharge of the "Publications Policy Review Committee." Seconded. Passed.

19. Bonnen discussed a strategy to strengthen the AAEA through improved services to members, recruitment of new members, and revival of the Professional Activities Committee. The Committee will deal with the impact on the AAEA of the growing diversity of specialization in the profession by designing new AAEA services and rules governing AAEA services.

20. Lee reported on plans for the membership committee.

21. Harl reported on the findings of the Bylaw Review Committee and sought Board guidance on specific categories of bylaw changes, namely, those changes having been adopted in general form previously, those appearing to be needed and noncontroversial in nature, and those having been suggested but needing further study. They were considered in reverse order and the following actions were taken. (*a*) Article II, Section 2, deleting classification of corresponding members, was approved. (*j*) Article VI, Section 1, stipulating that the cerning the rules governing the selection of fellows, was referred to an ad hoc committee for study and report by the August meeting. (*c*) Article VI, Section 2, requiring the announcement of committee appointments at the annual meeting or as soon thereafter as possible, was not approved. (*d*) Article VIII, Section 6, raising the limit the secretary-treasurer may borrow without further authorization to $25,000, was approved. (*e*) Article XII, Section 4, stating policy that AAEA does not assume responsibility for travel or other expenses associated with committee activities; was approved. (*f*) Article II, Section 2(b), permitting a designated representative of a department to attest to student membership status, was approved. (*g*) Article II, Section 2, allowing the institutional member one vote but to have up to three representatives, was approved. (*h*) Article XII, Section 1, listing the standing committees as awards, audit, editorial council, fellows election, finance, membership and institutional membership, professional activities, resident instruction, and tellers, was approved. (*i*) Article VII, permitting the secretary-treasurer with the approval of the Board to deviate from the U.S. balloting procedures for the foreign membership, was approved. (*j*) Article VI, Section 1, stipulating that the president in consultation with the Executive Board shall be responsible for preparing a program for the annual meetings, was approved. (*k*) Article VII, Section 1, implementing the current election procedures, was approved. (*l*) Article V, expanding the description of each award but not the criteria and the recommendation that the present and recent past chairmen of the Awards Committee be consulted on appropriate wording and format, was approved. Finally, (*m*) Article XIII, on student activities, was recognized to be developed.

Further, Harl, speaking for the committee, recommended that future bylaw changes be presented to the secretary in writing with precise wording so the minutes will reflect the exact approved change. Other recommendations included procedures to keep the bylaws up to date and available to Board members, maintaining important policy statements, and the degree of brevity of minutes. Farrell moved that these be accepted in principle and that the secretary-treasurer and the president reflect on how they be implemented and report by the August 1976 meeting. Seconded. Passed.

22. Babb reported on the alternative proposal for volume I of the *Postwar Literature Review*. The three proposals presented were (*a*) AAEA to act as its own publisher; (*b*) AAEA to enter into a joint venture with a major publisher; and (*c*) AAEA to make a grant-in-aid to a publisher. Nielson moved that the third proposal be adopted. Seconded. Passed.

Nielson moved that AAEA enter into a contract with the University of Minnesota Press under the option that involved a grant of $7,500 from AAEA. The option called for the book to sell at $25 per copy with a discount to members whose dues are paid by the time of the order, no discount to subscribers, and a 20% royalty to be received on nondiscounted sales. Seconded. Passed.

23. Nielson moved that AAEA impose a page charge on invited papers (not invited addresses such as fellow's address, presidential address, etc.) with the president having the perogative of granting specific exemptions when necessary.

24. Bonnen reviewed the program being planned for the August 1976 meeting.

25. After studying and discussing the supportive documentation on each person nominated for fellow, seven names were selected, and Barr moved that they be submitted to the Fellows Selection Committee. Seconded. Passed.

Adjourned at 5:30 p.m., 29 December 1975.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Minutes of the Executive Board Meeting, State College

The meeting was called to order by President James T. Bonnen at 8:40 a.m., 14 August 1976.

Present: Voting members:
Bonnen, Raup. Mangum, Nielson, Heitz, Farrell, Barr, Robinson, Stanton
Members ex officio:
Redman, Tomek, Martin, Sargent, King
Guests:
Hildreth, Holt, Malone

1. Holt and Malone reported on the local arrangements, indicating 1,037 had preregistered.

2. Bonnen reviewed the agenda, pointing out that most reports would be presented and received for later action at this meeting.

3. Mangum moved the approval of the minutes of the winter meeting of the Executive Board held in Dallas and as distributed. Seconded. Passed.

4. Bonnen presented the reports of the Tellers and Fellows Election Committees. R. J. Hildreth is the new president-elect and Sylvia Lane and Richard Crowder are the incoming directors. E. N. Castle, A. T. Mosher, and W. F. Mueller are the new fellows.

5. Redman distributed the secretary-treasurer's report and the AAEA investments report, which will be presented at the general business session.

6. Stanton, chairman of the Finance Committee, reviewed the financial needs of the AAEA in relation to income. The committee asked the Board to establish an investment policy. Heitz moved that the AAEA investment policy shall be to maintain the purchasing power of the fund and, within that constraint, the goal should be to maximize annual earnings. Seconded. Passed.

7. Redman distributed the audit report of the certified public accountant, and Bonnen read the report of the Auditing Committee, which will be presented at the general business meeting.

8. Tomek distributed and commented on the editor's report, which will be presented at the general business session. As instructed previously, Tomek and Redman presented a set of alternative prices for *Journal* reprints. After a discussion of increasing costs and the related issue of "free" reprints to those honoring the page charge, Nielson moved that a reprint price schedule be adopted that will reflect approximately a 50% increase on the first 100 copies, a 40% increase on additional 100 copies, and a 20% increase on regular *Journal* covers. Seconded. Passed.

Stanton moved that advertising rates be increased 40%, making the price of a full-page ad \$210, a one-half page ad, \$115, and a quarter-page ad, \$70 in one issue. Seconded. Passed.

Tomek further reviewed the policy on page charges, indicating a troublesome problem exists in determining the validity of requests for financial exemptions from the charge. The editor's experience to date has raised certain issues. The policy is that the page charge is mandatory and only the president and the editor have the power to grant specific exemptions on a case-by-case basis. Nielson suggested that an ad hoc committee be appointed to study the page charge procedures and provide a revised statement stating the policy more clearly. The consensus was that Farrell, the incoming president, will appoint the committee.

9. Mather reported for Employment Services Committee on the possibility of using the information in the registry for the *Handbook-Directory*. The basic decision at this point is whether further study and planning should be done into producing future *Handbook-Directory*'s from the registry. Mather reported also that 2,094 professionals are now registered.

Farrell will ask the Employment Committee to explore the feasibility of using the registry data for the *Handbook-Directory*.

Mather reported on the proposal to the U.S. Department of Labor to modify the demonstration project to incorporate the professionals employed by the Comprehensive Employment and Training Act (CETA) organizations and prime sponsors into a system to be developed and operated side by side with the AAEA registry for one year. After much discussion, Stanton moved to authorize the president to make the AAEA a party to the Illinois-CETA proposal and if arrangements with CETA fail then to explore with other associations. Seconded. Passed.

10. Boyne reported on the progress of National Employment Registries Committee, charged with exploring with other professional groups the use of the computerized employment registry and developing a stable financial and organizational basis for continuation of the AAEA registry. He estimated the minimum cost of a self-sustaining registry to be \$20,000. Boyne reported on possible approaches to generating the minimum \$20,000 support. He also indicated that other agricultural associations are being contacted about the possibility of a joint endeavor.

11. Barkley reported for the Professional Activities Committee with some recommendations governing current AAEA services designed primarily to increase the number of selective goods and services offered to the AAEA membership.

Farrell moved that in general that AAEA committee assignments be limited to active members. Seconded. Passed.

Mangum moved that higher registration fees be charged nonmembers registering to attend annual meetings. Seconded. Passed.

Nielson moved that the privilege of presenting and/or discussing contributed papers, invited papers, and invited addresses at the annual meetings be reserved for AAEA members, except in special cases in which the condition is waived by the president. Seconded. Passed.

Farrell moved that the recommendations (*a*) that nonmembers be assessed a page charge of $75 on articles accepted for publication in the *Journal* and (*b*) that a submission fee to accompany all refereed papers submitted to the *Journal* be referred to a Page Charge Committee to be appointed. Seconded. Passed.

The recommendation that AAEA awards be made to members only was referred by consensus to the Awards Committee.

The recommendation that at least one author of articles accepted for the *Journal* be an AAEA member was deferred by consensus for further study.

12. Barr, reporting on the study of alternative bids for renewal of the *Journal* printing contract, moved that a three-year printing contract for the *Journal* be negotiated with the lowest bidder, Edwards Bros., Ann Arbor, Michigan, with the following conditions: (*a*) the 9% discount offered for one year off the printing and binding costs quoted be finalized, (*b*) the maximum annual price escalation be limited to the annual increase of the U.S. Consumer Price Index, (*c*) additional savings be negotiated on the quality of the cover with the true green color being retained, type of binding, paper, etc., and (*d*) that acceptance of the Edwards Bros. bid shall be contingent upon successful negotiation of important miscellaneous items, such as reprint pricing, mailing costs, further verification of satisfactory performance, etc., which were inadequately specified in the bid. Seconded. Passed.

13. Gerke reported for the Industry Advisory Committee recommending (*a*) that the committee's "open letter" concerning the employability of agricultural economists be sent to all AAEA members and (*b*) that the committee continue to sponsor a banquet and invited papers session at the annual meetings. By consensus, the "open letter" will be included or coordinated with the mailing of one of the president's letters.

14. Lee reported for the membership committee recommending (*a*) that its emphasis be on identification and recruitment of new members, (*b*) that the billing of existing individual and institutional members be handled by the secretary-treasurer, (*c*) that work toward computerizing of the membership list be considered, (*d*) that the AAEA president and each regional association make joint appointments to the membership committee, (*e*) that the AAEA consider joint mailing of dues notices but that the associations not collect each other's dues, and (*f*) that an ad hoc task force be appointed to review current billing procedures.

The consensus of the Board was that there be an exchange of membership lists between regional associations and the AAEA and that action be taken on joint mailing of dues notices by the AAEA.

15. Robinson reported for the *Handbook-Directory* Committee and indicated that it was on schedule. After presenting two alternatives for the price of the *Handbook-Directory* to nonmembers, Robinson moved that the price be $15 each and that we print 9,000 copies. Seconded. Passed.

16. Farrell reported for the Bibliographic-Retrospective Search Committee.

17. Farrell reported on the travel grants to the IAEA meeting in Kenya, indicating that forty-one applied for the ten grants sponsored by AAEA. Recipients of the AAEA grants, totaling $4,900, were Malcolm Bale, Montana State University; Derek Byerlee, Michigan State University; Leroy Davis, Southern University; Brady Deaton, University of Tennessee; Charles Hanrahan, FDCD-ERS-USDA; Margo B. Rich, Food Research Institute; Kenneth Shapiro, University of Michigan; Robert Thompson, Purdue University; E. M. Wilson, Virginia Polytechnic Institute and State University; and Donald Larson, Ohio State University.

18. Hildreth reported for the Economic Statistics Committee and reported on plans for the Agricultural and Rural Data Workshop to be held in Washington, D.C., in March or April 1977 in cooperation with SRS-ERS and AMS of the USDA.

19. Harl, reporting for the Bylaws Revision Committee, presented the final version, incorporating the provisions previously approved by the Board and the provisions delegated to committees (e.g., fellows selection, awards, etc). Stanton moved that Article II, Section 2, be changed to allow any member in good standing to certify the eligibility for junior membership. Seconded. Passed.

Barr moved that the bylaws as prepared and distributed, with the change just made, be adopted. Seconded. Passed.

20. Bonnen and Redman presented suggestions for implementing four procedural recommendations made by the Bylaw Review Committee. (*a*) Upon request of the secretary-treasurer, all Board members who have introduced motions subsequently approved by the Board in any session should provide their motion in written form to the secretary before the meetings of the Board are adjourned. The Board is responsible for reviewing the written drafts of its approved motions for confirmation of original intent before it adjourns. (*b*) Members of the Executive Board should have their own copies of AAEA governing regulations at each meeting. The secretary shall provide all Board members with an updated version of the Constitution and bylaws in an appropriate form at the winter meeting of the Board. (*c*) All policy actions of the Board that are of more than a temporary nature shall be included in the bylaws. The president shall designate a member of the Board to prepare a draft of proposed bylaw changes or additions, memorializing the relevant policy actions arising out of the Board meetings held during the president's term of office. The proposed bylaw changes and additions shall be submitted for final approval of the Board before adjournment at its summer meeting or immediately thereafter. (*d*) The minutes of the Board shall in-

clude for the permanent record the following major items. Motions are to be made with a brief summary statement of intent underlying the motion if not obvious. Committee reports requesting specific action by the Board shall be in final form suitable for publication with copies to the editor and secretary so motions can be referenced to the report. Reports with no request for action or progress reports are to be noted only. Major problems or issues raised will be noted with no reference to views held by individual Board members.

Nielson moved the approval of the procedures. Seconded. Passed.

21. Farrell reviewed the many concerns that have been advanced regarding the contributed papers rules. Weeks, Coffey, and Boyne as chairman and former chairmen of contributed papers program offered comments. The general consensus was that this popular activity should be reevaluated because of some inherent problems, such as quality control.

22. Bonnen reported that the contract for the second volume of the *Postwar Literature Review* was ready for signing. It contained essentially the same provisions as the contract for volume I.

Stanton moved that the ad hoc committee on Publication of *Postwar Literature Review* be authorized to proceed with the contractual agreement with the University of Minnesota Press, subject to the stipulation that the University of Minnesota Press has only the "right of first refusal" for publication of volume III. Seconded. Passed.

23. An increasing number of requests to the AAEA president to endorse various symposia, conferences, etc., are occurring. Considerable discussion ensued concerning the limits and the role of AAEA in providing selective and specialized services, etc. The president assigned this to the Professional Activities Committee for development of policy statement and guidelines for Board consideration.

24. Richard King, as president of Southern Agricultural Economics Association, Fred Sargent, as president of Northeastern Agricultural Economics Council, and William Martin, as president of Western Agricultural Economics Association, each commented on relationships with the AAEA, emphasizing the need for closer cooperation with the regional groups. The Northeastern and Western Associations are now undertaking the publication of a journal.

25. Tomek asked for clarification of policy regarding the materials published in the proposed WAEA journal being eligible for consideration in the *Journal*. Previously, the material appearing in the WAEA's one issue, a proceedings issue, was considered eligible. Nielson moved that publication in the new WAEA journal be considered prior published material and hence not eligible for publication in *Journal*. Seconded. Passed.

26. Stanton reported for the Finance Committee and presented a budget of $191,200 for 1977, which is essentially a breakeven budget between income and expenses. After a discussion of high, medium, and low membership projections, Stanton moved that the medium level of 5,575 members and subscribers (3,300 regular members) be used for budgetary purposes and that the budget be approved. Seconded. Passed.

27. Farrell reported on the meetings scheduled with the Allied Social Science Associations in Atlantic City, 15–18 September 1976.

28. Redman presented three possible commercial sites for 1979, since no firm invitations had been received from universities. The consensus was that every university possibility should be explored first, particularly with those that have expressed some interest in the past.

29. Bonnen expressed his appreciation to the members of the Board for their assistance and especially to the retiring Board members, Glen Heitz and Howard Robinson, and to the past president, James Nielson, for their period of service.

30. Board recessed at 6:00 p.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Reconvened on 18 August at 11:40 a.m. with President Kenneth Farrell presiding.

Present: Voting members:
Farrell, Bonnen, Hildreth, Barr, Crowder, Lane, Mangum, Raup, Stanton.
Ex officio:
Tomek, Martin, King.

1. Farrell discussed the plans for the 1977 annual meeting to be held in San Diego on 31 July–3 August, outlining the nature and cost of facilities at the Town and Country Hotel. There will be no cost for the meeting rooms, and hotel rooms will range from $23 to $26 for single rooms, $28 to $31 for double rooms, and $4 for the third and/or fourth person occupying the same room and existing bedding. Certain other services such as registration assistance, name tags, etc., will be provided with no charge. The nature of the program, balance among invited papers, regular contributed papers, and self-invited sessions were principal topics of Board discussion.

2. Locations of future meetings were discussed. Lane moved that Washington State University for 1979 and the University of Illinois for 1980 be invited to host the AAEA meetings. Seconded. Passed. President Farrell will proceed with the invitations.

3. Hildreth moved that the president be authorized to issue an invitation to the Canadian Agricultural Economics Society to participate in a joint meeting with AAEA in 1978 at Virginia Polytechnic Institute and State University, Blacksburg, Virginia. Seconded. Passed.

4. Farrell discussed committee assignments for directors for 1976–77. Among the appointments

were Mangum on the Alternative Publications Committee, Crowder on the Industry Advisory Committee, and Lane on the Membership Committee.

5. President Farrell will be inviting nominations for editor. He appointed Hildreth, Lane, and Tomek with Farrell as chairman to serve as an ad hoc committee to review the nominees and to make a recommendation to the directors at the winter meeting.

6. The tenure of an AAEA liaison representative to various groups was discussed. Bonnen moved that such representatives be limited, in general, to two three-year terms. Seconded. Passed.

7. Farrell discussed some proposals that are an outgrowth of his presidential address. The directors concurred in (*a*) referring the public policy award idea to the awards committee for consideration, (*b*) referring the idea of AAEA sponsored symposium, seminars, etc., to the Professional Activities Committee and asking that committee for an interim report in January, (*c*) forming an ad hoc committee on the possibility of inviting public policy papers but without commitment to a specific form of publication, and (*d*) forming an ad hoc committee to explore the feasibility of a public policy institute.

8. The winter meeting of the Board will be held on 3–4 January 1977 in Washington, D.C.

9. After considering a request for AAEA to cosponsor a symposium on trade and trade policy, the Board decided not to sponsor any symposium until the Professional Activities Committee has made its report on establishing a policy and guidelines for such activities.

10. Barr reported some further details on the *Journal* printing contract.

11. Farrell discussed appointments to committee chairmanships.

12. Bonnen commented on the need for continued AAEA communication with regional associations and with departmental chairmen.

13. Board adjourned at 1:50 p.m.

Respectfully submitted,
William G. Tomek
Acting Secretary

Minutes of the Annual Business Meeting, State College

The 65th annual meeting was called to order by President James T. Bonnen at 8:45 a.m.

1. President Bonnen presented for approval the minutes of the annual business meeting held at Columbus, Ohio, 12 August 1975, as published in the proceedings issue of the *Journal*. Motion was duly made. Seconded. Passed.

2. Bonnen announced officially the results of the election. R. J. Hildreth was elected president-elect, and Sylvia Lane and Richard Crowder were elected directors.

3. Redman presented the secretary-treasurer's report for the fiscal year, 1 January 1975 through 31 December 1975. Redman also presented a report on AAEA investments for 1975.

4. Bonnen presented the Audit Committee Report for 1975, which incorporated the opinion of the certified public accountant employed by the AAEA.

5. Tomek reported as editor of *Journal*.

6. President Bonnen highlighted the activities of the Executive Board. (*a*) The AAEA reprint and advertising rates have been adjusted. (*b*) A policy was established to safeguard the purchasing power of AAEA investments and within that framework to maximize the income stream. (*c*) The *Handbook-Directory* will be published November 1976. (*d*) The Bibliographic-Retrospective Search is now on line. The National Agricultural Library and Pennsylvania State University are cooperating in providing a demonstration at the meetings. (*e*) The Resident Instruction Committee has developed a new format for student programs. (*f*) The Economic Statistics Committee continues to work on the data base for agricultural economics. (*g*) The bylaws have been revised with no change in the constitution. (*h*) A committee has begun a systematic evaluation of changes, if needed, in the annual meeting program. (*i*) In appointing committees this year, the president reviewed the geographical and functional distribution of members on committees. (*j*) The Board has a continuing concern for AAEA's financial situation. One possible solution lies in reducing services or increasing membership. For more than twenty years the dues were low, and individuals had few questions about being members. With increased dues, the question is now "what is there in it for me." The AAEA has been providing collective services, but now greater professional specialization leads to a need to provide specialized selective services. Not only will greater systematic effort be made in membership recruiting in cooperation with the regional associations but effort will be made to increase the attractiveness of AAEA membership, partially through limitation of AAEA services to active members. In implementing this policy, the Board has decided that assignments to committees will be limited to members, higher registration fees for annual meetings will be charged for nonmembers, the privilege of giving contributed papers will be limited to members, and the privilege of giving invited papers and addresses will be limited, in general, to members. In addition, committees are working on new services to enhance and/or maintain members professional capacity. Hopefully, within the next three to five years improved services will be available for members.

7. No old business was noted.

8. New business items were requested. (*a*) Hildreth reported as secretary-treasurer of the International Agricultural Economics Association that over 600 attended the meetings in Kenya, with 80 from the United States. The next meeting will be in

Baniff, Canada, in September 1979. (*b*) Hildreth presented a resolution thanking Pennsylvania State University and its staff for being an excellent host, with a request that it be printed in the *Journal* and copies be sent to appropriate personnel of the university. (*c*) Bonnen announced the dates and sites of future meetings: 31 July–3 August 1977 at Town and Country Hotel, San Diego, California, and 6–9 August 1978 at Virginia Polytechnic Institute and State University, Blacksburg, Virginia. (*d*) Bonnen thanked Redman for his assistance as secretary-treasurer, Tomek as editor, Howard Robinson and Glenn Heitz as retiring directors, James Nielson as past president, and all who assisted in various ways. He then turned the chair over to Kenneth R. Farrell, who became president. (*e*) Farrell congratulated Bonnen on developing a systematic approach to committee structure and assignments and expressed his personal appreciation to Bonnen for his contributions to the AAEA. (*f*) In the form of announcements, Farrell indicated that the affairs of the AAEA will be as open as possible, does not plan to appoint a large number of committees and will indicate most chairmen in his presidential letter scheduled for October, announced the appointment of the nominating committee of which James T. Bonnen will be chairman (all suggestions should be sent to Bonnen or any committee member by 10 December) announced that all nominations for fellows should be sent to the secretary-treasurer by 1 December, announced that a new editor will be named and asked for suggestions, described San Diego as being a good meeting place and asked for suggestions for topics and speakers, and announced that the next Board meeting will be in late December or early January 1977.

8. Meeting adjourned at 10:05 a.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal,* changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.
